It will be seen that the ratio for a gain of a given number of *T U,* is the reciprocal of the ratio for a loss of the same number of units. Also for an increase of 3 in the number of units, the loss ratio is approximately halved and the gain ratio doubled. If the approximate loss ratios corresponding to 1, 2 and 3 units are remembered, the others can be easily obtained.

From this consideration of the properties of the transmission unit, it is evident that there is much to commend its use in telephone transmission work. Furthermore, since its advantages are not peculiar to this work, such a unit may find applications in other fields. It is now being used in some of the work on sound.

New Telephone Transmission Reference System

With the standardization of the distortionless unit of transmission it is desirable also to adopt for a transmission reference system a telephone circuit which will be distortionless from sound input to the transmitter to sound output from the receiver. This system will consist of three elements, a transmitter, a line and a receiver. Each will be designed to be practically distortionless and the operation of each will be capable of being defined in definite physical units so that it can be reproduced from these physical values. Thus, the transmitter element will be specified in terms of the ratio, over the frequency range, of the electrical power output to the sound power input, this ratio being expressed in transmission units. The receiver element

1. Size Standardization by Preferred Numbers, C. F. Hirshfeld and C. H. Berry, Mechanical Engineering. December, 1922.

will be specified likewise in terms of the ratio of sound power output to electrical power input. The output impedance of the transmitter and the input impedance of the receiver elements will be 600 ohms resistance. The line will be distortionless with adjustments calibrated in transmission units and will have a characteristic impedance of 600 ohms resistance.

Such a reference system is now being constructed. The transmitter element consists of a condenser type transmitter and multi-stage vacuum tube amplifier. The receiver element consists of an amplifier and specially damped receiver. Each element is adjusted to give only negligible distortion over the frequency range.

It is proposed when this system is completed and adjusted that it will be adopted as the Transmission Reference System for telephone transmission work. Other secondary reference systems, employing commercial-type apparatus will be calibrated in terms of the primary system and used for field or laboratory tests when such commercial type systems are needed.

Discussion

A. M. Wilson: Of course, the application of preferred numbers offers a very reasonable solution for a number of problems that are arising more and more with different sizes of equipment and materials; but the use of the distortionless circuit should be of service in connection with problems in inductive interference.

I should like to know if there is any possibility of using this type of circuit in investigations of inductive interference, instead of, or in conjunction with, the telephone-interference-factor meter.

The type of meter is connected to a power circuit, for the purpose of indicating what may be going on in a neighboring telephone circuit. It would seem more logical, and very desirable, to have an instrument connected directly in the telephone circuit to indicate the effects produced in the telephone circuit.

W. H. Martin: Referring to Mr. Wilson's question, a distortionless circuit of the type referred to has been used in a fundamental investigation in the laboratory of the effects of loudness, distortion and the presence of noise on the intelligibility of reproduced speech sounds. For this purpose, the circuit was arranged so that all three of these factors could be varied, either separately or in combination. In this way, the circuit is of service in connection with the consideration of the noise produced in telephone circuits by induction from electrical power systems.

The telephone-interference-factor meter was designed to provide a ready and portable means for rating the wave shapes of power systems and apparatus from the standpoint of producing interference to telephone circuits. As described in the paper by H. S. Osborne in the 1919 TRANSACTIONS of the A. I. E. E., it is based on the interfering effects of extraneous single-frequency currents in a commercial telephone receiver on the intelligibility of speech sounds given out by the receiver and also on the general relation that the current induced in telephone circuits by a given voltage or current in a power circuit is approximately proportional to the frequency. It, therefore, takes into account both the inductive effect between the power and telephone circuits and the interfering effect of the currents in the telephone circuit. The distortionless circuit which has been described in the paper on the transmission unit does not provide a means for measuring interference which can be used instead of, or in conjunction with, the telephone-interference-factor meter.

Sensitive Radio-Frequency Relay

BY GEORGE LEWIS
Non-Member
Crosley Manufacturing Company, Cincinnati, Ohio

Review of the Subject.—*The present paper has been prepared with a view of describing the theoretical properties, mechanical construction, and possible application of a new electron relay, invented and developed by Samuel Ruben, a physicist of New York. This relay has been developed to control currents as great as 5 amperes by means of extremely small operating currents of any frequency, and its use is suggested, therefore, in radio and carrier-current systems, and where similar requirements are to be met.*

* * * * *

PRINCIPLES OF OPERATION

THE operation of this relay is primarily based upon the employment of the kinetic energy of the thermionic discharges brought about by a suitable emission element, such as a filament, when directed upon a sensitively responsive anode. The impact of the electron stream upon the anode results in the expenditure of the kinetic energy of the bombarding stream, which is translated as;

1. A slight and negligible mechanical effect,
2. A negligible radiation of low-wave length and
3. A temperature rise of the anode.

Various tubes have been constructed by Mr. Ruben, in which he has employed different anodes for the utilization of the thermionic bombardment principle. As the temperature rise of the anode is the major effect in this type of tube, amounting to practically the entire translation of the kinetic energy of the electron stream, the anode adopted as the most serviceable is the thermo-sensitive type. (Figs. 1 and 2).

In the type of tube described in this paper, the translated energy is employed as a means for operating the contacts of a relay located within the tube.

The rapidity of the action of this device is dependent on the rate of heating and the rate of cooling of the anode, which, in turn, are dependent upon factors as follows:

Rate of heating—dependent on:

(a) Power of bombarding electrons—this should be as great as possible.

(b) Heat capacity of anode—this should be as small as possible.

Rate of cooling—dependent on:

(a) Ability of anode to radiate power.

(b) Heat capacity of anode—this should be as small as possible.

In the device as now developed, the anode is composed of a blackened strip of nichrome which is initially maintained at a high temperature, in the neighborhood of 600 deg. cent. The strip form gives a large radiating surface with a small mass and therefore small heat capacity. The high initial temperature gives the anode increased ability to radiate power, since this depends on the fourth power of the temperature.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chiacgo, Ill., June 23-27, 1924.

This relay comprises four main elements:

1. A source of electron emission—a cathode.
2. A means for controlling the electron emission flow,
3. A sensitively responsive anode, and
4. A movable contact arm and a stationary contact for the control of a high-density external circuit.

The cathode element employed in this relay is a platinum-iridium strip having a newly-developed oxide coating which gives the cathode a high thermionic

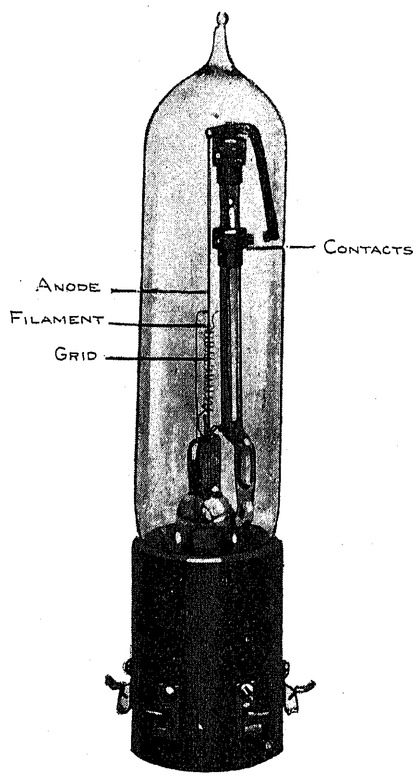

FIG. 1

efficiency and a long life. The strip is suspended parallel to the sensitively responsive anode, which is composed of nichrome, attached at one end to the movable contact arm of the make-and-break device, controlled by the movement of the anode responding to the impact of the electron stream upon it. The electron discharge from the filament is electrostatically controlled by a grid element interposed between the filament and anode, so that in operation the grid

controls the anode movement by virtue of its control of the electron stream.

The anode is maintained by a local circuit at a temperature at which the movable contact is normally at a point very minutely spaced from the stationary contact. Such close contact spacing, without any tendency to arc or spark, even when the external circuit carries a current of considerable potential, is made possible by the degree of evacuation to which the tube is subjected before the sealing-off process is completed.

As the necessary slight movement of the contact arm ot the make-and-break device is controlled by the thermo-expansive anode of the described characteris-

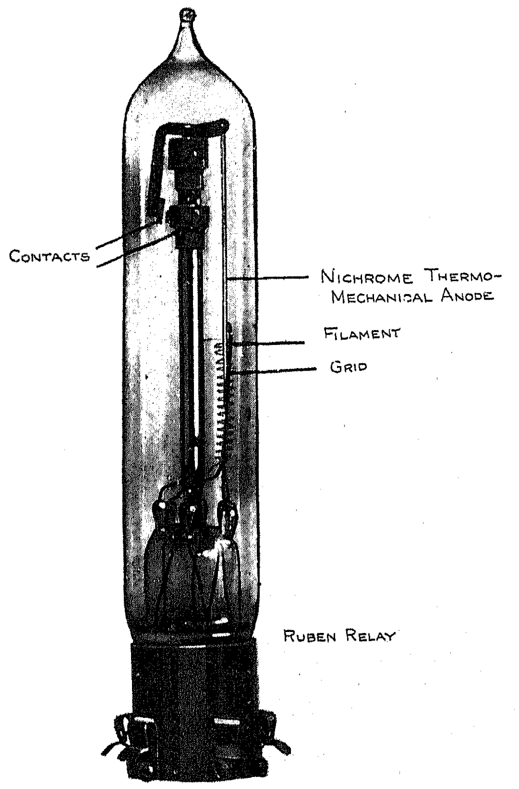

Fig. 2

tics, the operating speed of the device is high compared with usual thermal devices.

To avoid any deformation of the elements of this device from the repeated application of high temperatures, especially in the process of evacuation, great care has been taken in their composition and design. The result is a notable stability of adjustment under operating conditions.

Nichrome was selected for the anode as it was found to possess the following desirable electrical and physical characteristics:

a. Operating constancy over long and interrupted periods of use,

b. High and constant values of electrical resistance at various operating temperatures,

c. Suitable coefficient of expansion and

d. Adequate mechanical strength at operating temperatures.

The contacts of the circuit control device are composed of tungsten, one being affixed to a lever supported for the proper ratio of its arms. The lever and stationary contact support are composed of nickel-manganese, an alloy found suitable for vacuous devices. One end of the lever carries the tungsten contact, and the other is attached to the thermo-expansive anode. As the anode expands and contracts in response to the action of the controlling electron stream, the movable

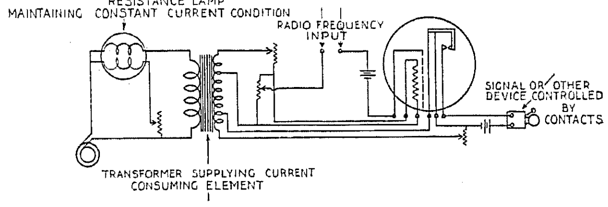

Fig. 3

contact moves towards and away from the stationary contact, thus serving to close and open the external circuit.

The normal position of the lever can be made practically independent of the position of the apparatus itself, which can be mounted in a horizontal or vertical plane.

The actual energy necessary to control the external circuit of high density is of very small magnitude, being only that necessary to electrostatically charge the grid element sufficiently to modulate the impacting electron stream, as in the present thermionic devices. The

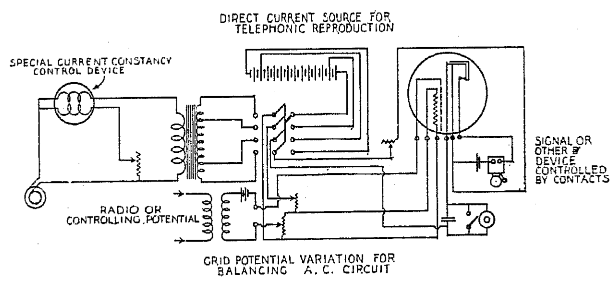

Fig. 4

time required for the actuation of the lever is controlled by the heating current normally discharged through the anode.

Connection of Relay in Circuits

Fig. 3 shows a typical connection of such a relay into a circuit. In the circuit as shown the relay is operated by incoming radio signals, and controls a signaling device indicated as a call bell. The anode is so connected that its energizing circuit is partially short-circuited when the contact of the relay circuit is

closed, thus causing the anode to cool by radiation, and causing the circuit to open. By this rapid heating and cooling of the anode element the relay contact opens and closes the external circuit at a rate of about 20 times per second.

The relay can be employed in this manner as a call device for radio or carrier-wave circuits for either telegraphy or telephony. When used in this manner, all of its circuits can be supplied with energy from a single transformer as indicated.

To keep the adjustment constant and independent of line variations, a ballast lamp specially developed for this relay has been supplied. The lamp comprises two resistance elements in a hydrogen filled tube, one element being iron, which controls a current flowing to the primary of the transformer, and operated at about 500 deg. cent. at which temperature iron has an exceedingly large resistance temperature coefficient. The other element is nichrome wire which is directly connected across the line; its temperature is adjusted by means of an external resistance to bring the controlling iron resistance element to a proper temperature. When adjusted, large variations in the line potential are compensated and the relay adjustment is stable.

Fig. 4 shows the same circuit with a change-over switch to allow the use of telephone receivers in the plate circuit, by which a call-signal relay and an audio-frequency relay in one tube are obtained.

This relay can be connected in a circuit as a reflex, a regeneration or an amplification tube, or in any connection in which the usual three-element tube is applicable, with the added advantage of the local circuit control of current of high density or high potential.

In conclusion, it may be stated that the Ruben relay has been designed to obtain a relay which could be controlled by minute energies in the form of currents of any frequency, either radio or otherwise, could be operated at adequate speeds for certain telegraph applications, and could control circuits of considerable current and potential. Its application is suggested for any conditions where these requirements are to be fulfilled, such as radio and carrier calling and recording systems, as a telegraph recorder and repeater, either line or cable, and for similar purposes.

Discussion

J. Slepian: The device described by Mr. Lewis has several distinct elementary parts performing rather distinct functions; there are the filament and grid, giving the usual detector action, there is a thermally responsive element and there is a contact which opens and closes.

A pertinent question seems to me to be whether anything gained beyond compactness in this rather ingenious combination of all these elements, and whether it is necessary to sacrifice the best performance of some of the individual elements for the sake of getting this compactness.

Now it does seem as if the detector action of the tube has to be modified. A standard plate surrounding the filament in the usual way cannot be used because that would give too large a volume for the thermally responsive part. Instead a very small plate must be used and thus a detector element of higher impedance than the standard tube results. There appears then to be some disadvantage here. On the other hand, if one tries to separate the two functions, and use a standard thermionic tube to deliver electrical power into a thermally responsive element, great difficulty will be encountered in constructing a thermally responsive element with sufficiently high resistance to work with an ordinary tube.

By having the michrome ribbon heated directly by electron bombardment, a thermal element results which has a high impedance. There is, therefore, considerable advantage in the combination.

I would like to call attention to some points with respect to the operation of contacts in high vacuum. At first sight it would seem that a very great advantage is to be obtained by working contacts in a vacuum. In a high vacuum an arc is impossible, and since the principal trouble with contacts which handle any considerable power is the destructive arcing by putting the contacts into a vacuum, one would expect to eliminate the arc and to be able to handle tremendous power for an indefinite time.

This argument seemed so plausible to me that a number of years ago I actually carried on a considerable number of tests on contacts opened and closed in vacuum. These contacts were opened and closed by magnetic means, not by the method shown here. The results I obtained were very disappointing. After working on it quite a bit I arrived at the following understanding as to why better results were not to be expected.

As a contact is opened, the area of contact reduces very rapidly from a finite area down to a very small value. Just at the last moment of break, the resistance of the contact goes up enormously, and the voltage of the circuit begins to concentrate on it, so that whatever the voltage of the circuit is it will all act on this last contact.

It is not very difficult to calculate the temperature rise at a point of contact between two materials when a voltage is applied to it. As I remember the figures, the formula comes out $\frac{E^2}{33\,K\,\rho}$, where E is the voltage, K the heat conductivity and ρ the electrical resistivity. Taking the heat conductivity of the metal as unity, and 10^{-6} as the resistivity, for 1 volt, we get 3000 degrees. That is, the last point of contact, for one volt in a circuit, will be necessarily raised to 3000 degrees. Hence, there must be melting of the very last point of contact, and for the heavier currents that I dealt with in my own experiments I found that the contact soon roughed and became useless after a few operations, since it was impracticable to apply heavy mechanical pressure in the vacuum. Furthermore, the volatilization of metal spoiled the vacuum and permitted arcs to flow.

The Transient Visualizer

BY H. M. TURNER
Member, A. I. E. E.
Assistant Professor of Electrical Engineering, Yale University, New Haven, Conn.

THE "transient visualizer" which is described in this paper was developed to make possible a more satisfactory study of transients by means of the oscillograph. It is, of course, well known that the oscillograph has been an effective instrument for many years for studying a-c. phenomena where the successive cycles are identical and are repeated synchronously, but in the case of transient phenomena which are not recurrent, there have been limitations to its usefulness.

It has not been possible to make visual observations of transients, because the trace produced by a single sweep of the light spot across the viewing screen is insufficient to make an impression on the eye. As a consequence, only photographic records were obtainable and satisfactory results were difficult to obtain for two reasons. In the first place, the amplitude of the curves could not be determined beforehand, and in the second place it was difficult to place the curves properly on the film.

In order to overcome some of these limitations the transient visualizer was developed. The function of the device is to repeat the transient phenomena periodically so that they may be studied in the same way as the a-c. phenomena have always been studied. As a result of periodic repetition, stationary curves of the transients may be obtained on the oscillograph screen. Furthermore, as the amplitude and position of these curves may be controlled, coordinated photographic records may be secured.

The transient visualizer consists essentially of a synchronous switch in the form of a contact-making drum or commutator, driven through helical gears by a synchronous motor. By means of interchangeable gears this drum may be driven at various desired speeds. The speed of the drum bears a definite relation to the speed of the rotating mirror in the oscillograph. As this commutator opens or closes the test circuit at definite periods, the transient is repeated. The curve of the transient is similarly repeated in the oscillograph and, due to the fixed relative speeds of drum and mirror, the light spot follows the same path at each repetition and the result is a visible stationary curve.

While observing the curve, adjustments may be made to regulate the amplitude of the curve as well as its exact position on the screen. Thus, the effect of changed conditions may be studied and, furthermore, accurately located photographic records may be taken. If photographic records of several different curves are to be taken on the same film, their positions relative to each other may be adjusted. This is possible whether (1) the curves are to be taken at the same time by different elements of the oscillograph or (2) they are to be taken at different times on the same film. Several different circuits may be connected so that their respective phenomena may be studied (or recorded) in succession.

The main part of the visualizer drum consists of six circular sections mounted on a common shaft, as shown in Fig. 1. This shaft is driven through gears by a self-starting synchronous motor. The circumference of five of the drum sections is divided into two segments, one a conductor and the other an insulator. The conducting segments are of various lengths, for use with transients of different duration, and their relative angular spacing around the circumference of the drum is such as to give maximum flexibility in its use. The sixth section is one continuous conductor and is electrically connected to the five others.

Brushes mounted on a common arm make contact

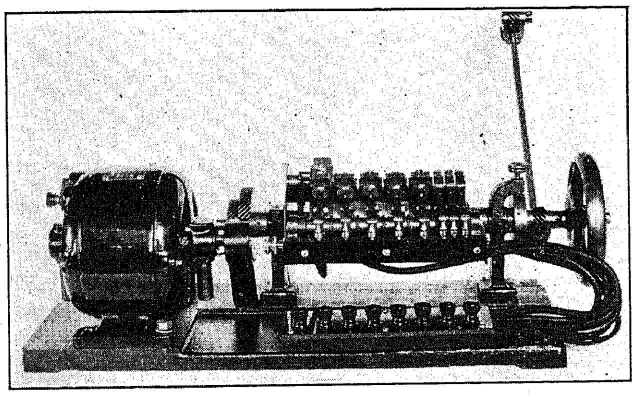

FIG. 1

with these sections. This brush arm is rotatable through a large angle and may be locked in any desired position by a setscrew. Connections are made to the brushes through flexible leads terminating in binding posts to which the circuits under test and the oscillograph are connected. At the extreme left is an additional brush carried by a disk which may be rotated independently of the main arm, or locked so as to turn with it. This brush rests on the same section as one of the other brushes which is more clearly visible in the illustration. It is used for making special adjustments which will be mentioned later. Each brush is provided with a convenient means for lifting when idle. The small geared shaft at the right is for the purpose of driving the photographic film drum of the oscillograph.

When the transient visualizer is used for visual study of curves, either with the projection oscillograph or the usual laboratory type, it may be mounted at any convenient place. Fig. 2 shows it being used with

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

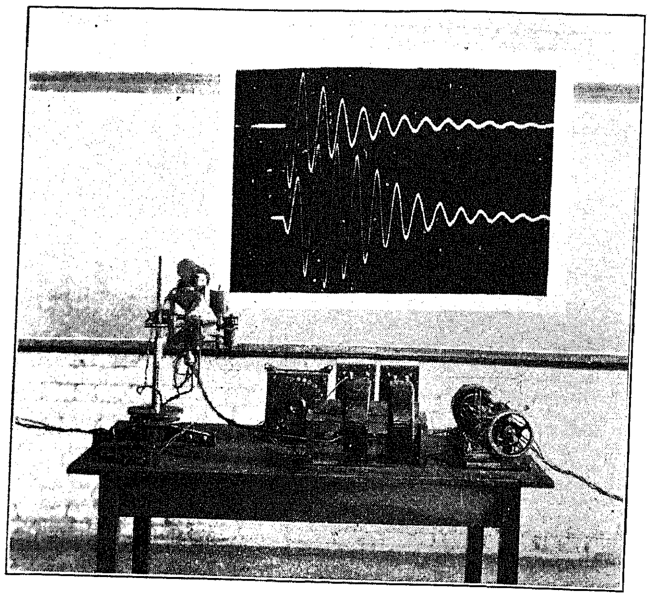

Fig. 2

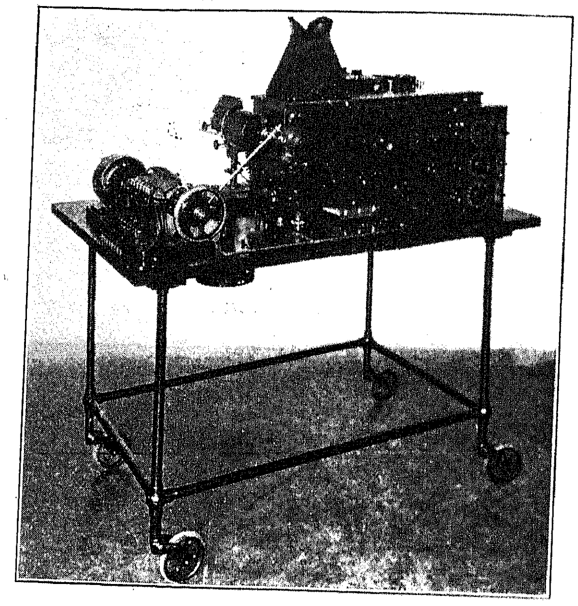

Fig. 3

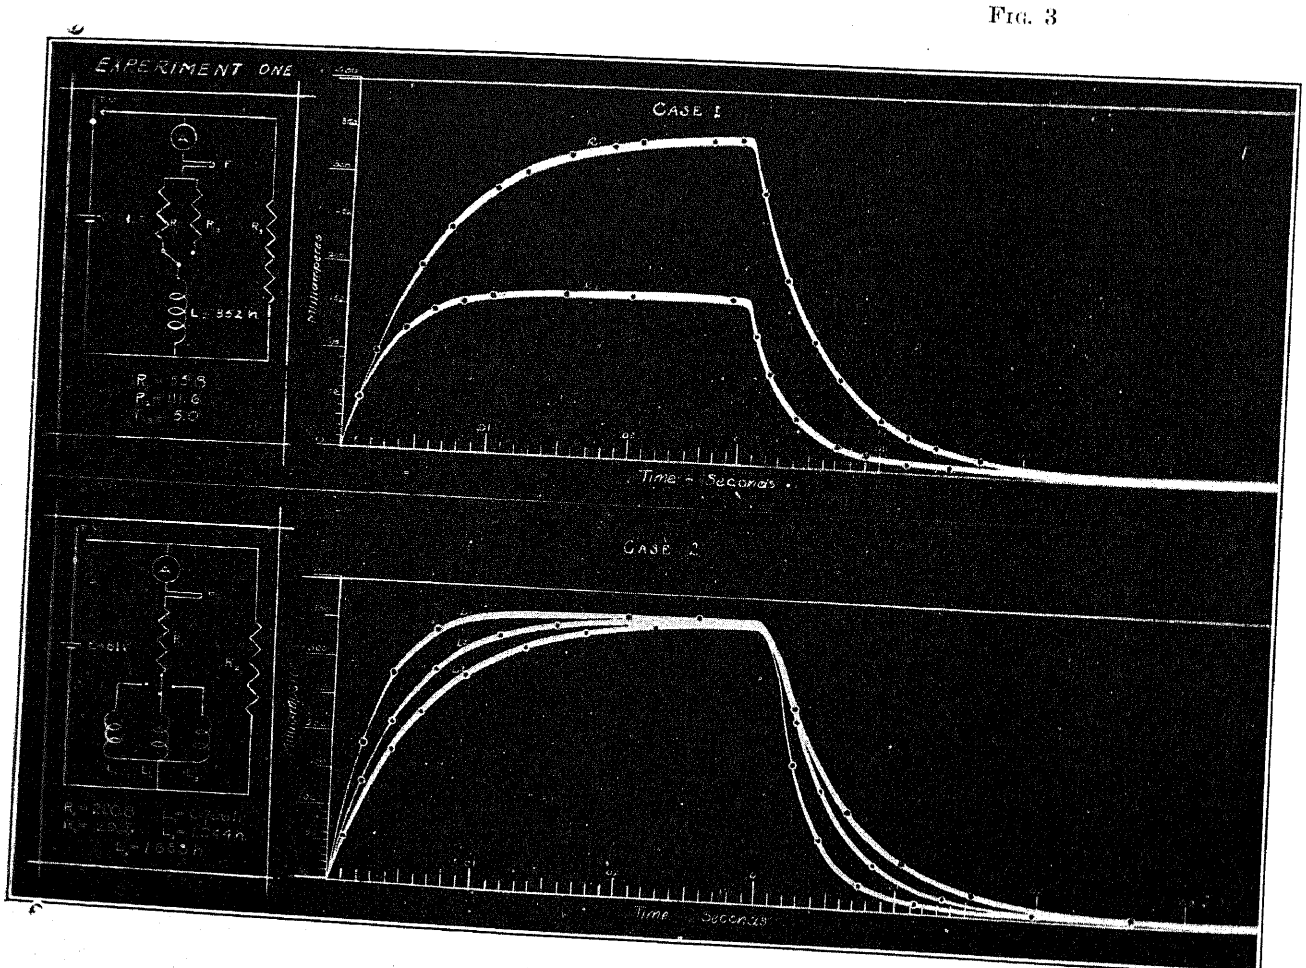

Fig. 4

the Crane projection oscillograph for studying coupled circuits. When the spacing between the coils is varied, the curves give immediate evidence of the change in coupling. Or with the secondary open, the effect of a change in the primary resistance, inductance or capacity upon the amplitude, frequency and decrement may be instantly observed. A study of this kind has a fascination for the observer that stimulates interest in the mathematical analysis. With a few known values of inductance and capacity the relation $f = 1/2\,\pi\,\sqrt{L\,C}$ may be experimentally verified by counting the number of cycles on a convenient length

of the screen and plotting the results on logarithmic paper.

In the case of d-c. transients the position of the curves on the screen may be changed either by restart-

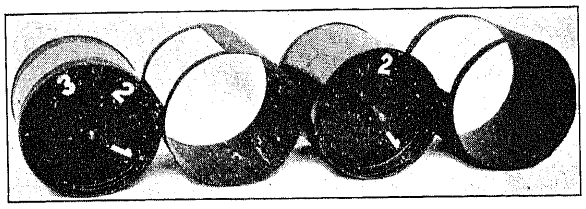

Fig. 5

simple matter to start the curve at any desired point of the film. First, with the transient visualizer motor running, rotate the brush arm until the curve appears on the screen so as to make sure of the correct amplitude; second, stop the transient visualizer motor and rotate the commutator by means of the handwheel until the brushes are at the point of closing the circuit, then loosen the setscrew that holds the gear to the film drum shaft and then rotate the drum to the desired angular position.

Since an oscillogram can be made to start at a definite point on the film it is possible to make multiple exposures. In Fig. 4, the upper film was exposed twice

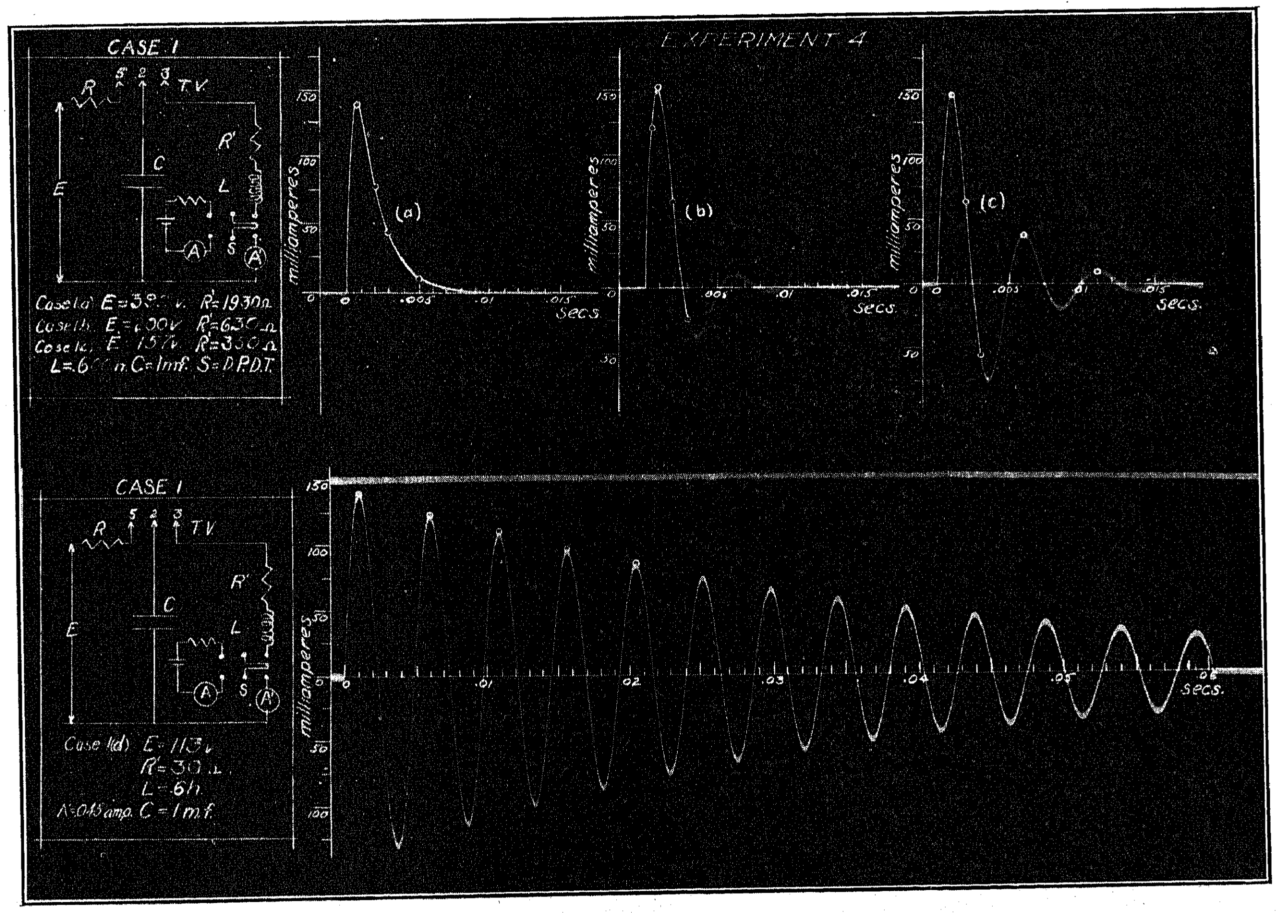

Fig. 6

ing the transient visualizer motor until the correct position is obtained, or by rotating the brush arm.

For photographic purposes, the transient visualizer should be mounted in front of the oscillograph cabinet at a distance of about 8 or 9 in. and connected directly to the film drum by means of two sets of helical gears, as shown in Fig. 3. Since the mechanical relation between these parts can be adjusted, it is possible to start the oscillogram at any predetermined point of the film and by the selection of suitable gear ratios to control the spread of the curves, thus saving time and films and improving the appearance of the oscillograms. When investigating d-c. transients, it is a

and shows the effect of a change of resistance upon the building-up of the current in a circuit of constant inductance. The lower film was exposed three times and shows the effect of inductance upon the building-up of current in a circuit of constant resistance. The same oscillograph element and field strength were used for the curves of a given set, therefore the comparison is direct and shows most advantageously the effect of a change in circuit conditions. The small circles indicate calculated values.

Frequently, it is desirable to take a number of exposures on a film where each set of curves occupies but a portion of the length of the film. This is an

advantage when the phenomena being studied normally occupy but a small part of the film and where it is desirable to bring several curves together for the purpose of comparison. Two points are involved; first, the ability to select the point on the film at which each exposure is to be started; second, to shield all of the film except the portion on which the exposure is to be made. Special shields have been devised for this purpose which are shown in Fig. 5. If reasonable care is used in slipping these shields over the drum, there is little likelihood of scratching the film. In shifting the shield to expose different portions of the film, it is simply rotated on the end rims of the drum, instead of removing, to further reduce the possibility of scratching. The value of the transient visualizer in work involving multiple exposure is clearly illustrated by Fig. 6 which shows the effect of resistance upon the discharge of a condenser through an inductance.

In the study of a-c. phenomena (transient and periodic) an important feature is the constant cycle length. By this is meant that the length of a cycle on the film is independent of frequency changes of the power source, since any change in angular velocity of the film is exactly balanced by the change in the period of the cycle. This constant cycle length is extremely useful in comparing wave forms. It is not even necessary that the curves to be compared be taken the same day or on the same machine. Fig. 7, film 1, which was taken recently, shows the impressed voltage (110) and the exciting current for: (a) 144 turns giving a low value of saturation for the first exposure and (b) 84 turns giving a high saturation for the second exposure. Film 2, taken two years ago, shows the impressed electromotive force, the secondary induced e. m. f. and the e. m. f. induced in the tertiary winding around the magnetic shunt. The shunt path has two air gaps, and therefore its reluctance will be practically constant and the induced e. m. f. in tertiary winding will vary approximately as the rate of change of the exciting current. Since the cycle length is the same for the two films, they may be lined up in the proper phase, and the relation between the current and the induced e. m. f. made clear.

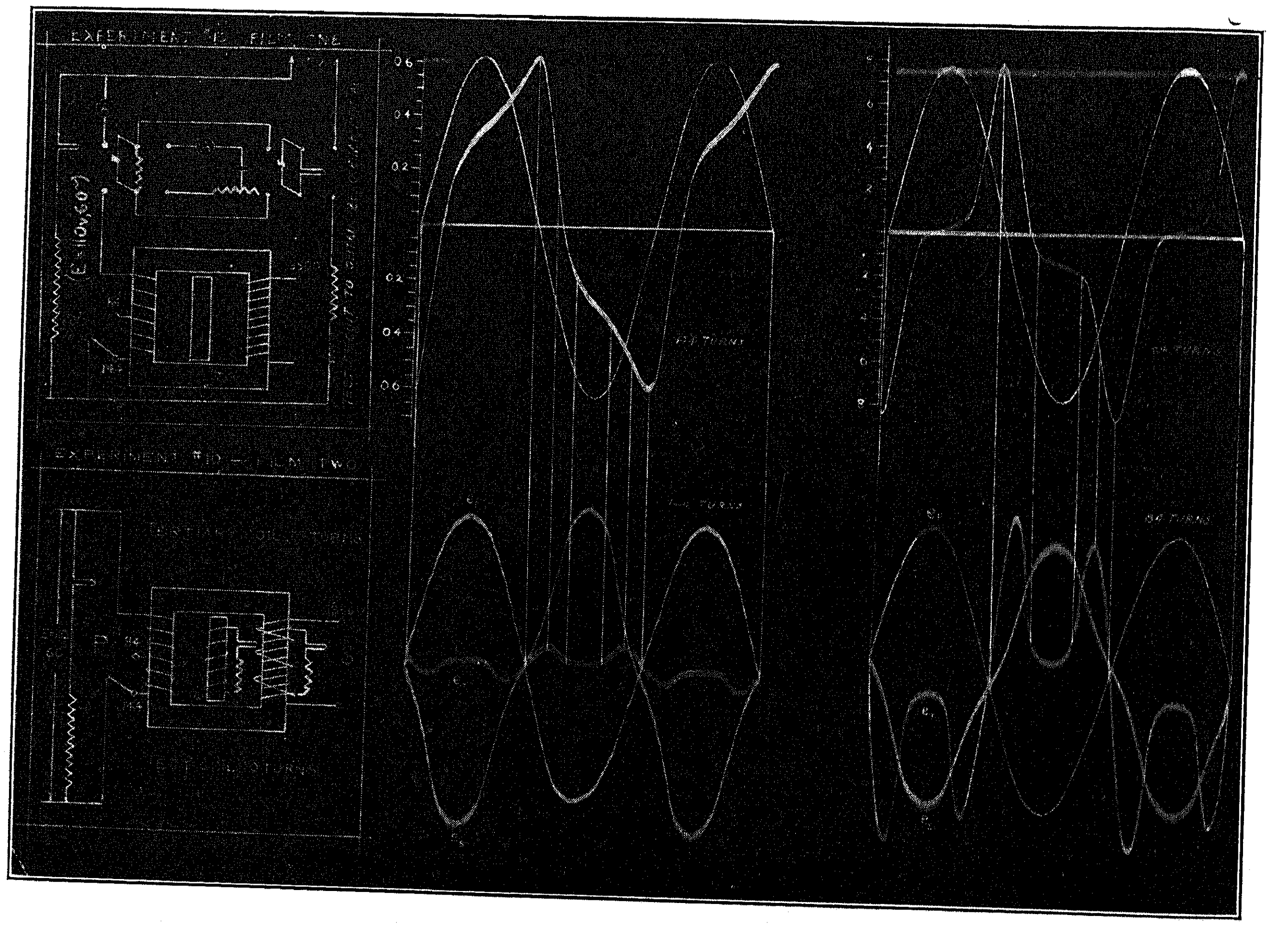

Fig. 7

Occasionally it is desirable to show the components of a mathematical solution in order to better understand the physical significance of the problem. If an alternating e. m. f. is impressed upon a circuit of resistance and inductance in series the solution is

$$i = I \sin (w\,t - \phi) - I'\,\epsilon^{-Rt_0/L}$$

transient current = permanent component − logarithmic component. I is the maximum of the permanent current, ϕ is the angle of lag, I' is the value the current

would normally have for the e. m. f. at the point of the wave where the circuit was closed and t_0 is the time counted from the instant of closing the switch. The use of the transient visualizer for showing the various components will be made clear by referring to Case 1, Fig. 8. At the first exposure the e. m. f. and the transient current were taken, at the second exposure (on the upper film) the sinusoidal component or permanent alternating current and on the third exposure the transient component. All of the current curves are to the same scale and in their proper phase relation.

Since a-c. transients depend upon the point of the e. m. f. wave at which the circuit is closed, it is desirable to be able to close the circuit at any predetermined point. This may be accomplished by rotating the brush arm while making observations on the screen. Fig. 8, Case 1, shows the circuit closed when the e. m. f. was passing through zero, and Case 2 shows the effect produced by closing the circuit at different points of the e. m. f. wave.

A convenient test circuit for determining the zero point of the wave is an air-cored inductance whose power factor is near zero. With a suitable d-c. ammeter in series with the a-c. line, adjust the transient visualizer brush arm until the ammeter gives a maximum deflection. This feature is especially valuable where two or more oscillograms of alternating currents are to be taken on different parts of the same film, as shown in Fig. 7. This is a matter that needs going into more in detail, otherwise the synchronous motors pulling in at different phase relations will cause the inexperienced operator considerable trouble. Assume that the two periodic curves shown in Fig. 7 are to be taken and that for the sake of appearance of the oscillogram the exposures are to be started at zero e. m. f. Use a shield with an opening one and a half cycles in length and arrange the shield stops so that the second exposure begins exactly two cycles from the first. First, with the switch shown in the diagram thrown to the test circuit on the right, start the transient visualizer motor and adjust the brush arm until the circuit is closed at the zero e. m. f. and the transient curve is seen on the screen (this will be called the reference condition). Second, with the oscillograph motor still running, stop the transient visualizer motor and slowly rotate the commutator by means of the handwheel until the test circuit is just closed, as indicated by the current curve appearing on the screen, when the film arm may be adjusted to start the first exposure at the correct point. Third, restart the transient visualizer motor two or three times, if necessary, or until the reference condition is re-established. Fourth, stop the oscillograph motor and throw both switches to the left so the element will be in series with the primary of

the transformer and make the exposure. Fifth, with the test circuit again connected, restart the oscillograph motor and until the reference condition is restored, stop the transient visualizer motor and change the film shield to position 2. Sixth, replace the film drum and restart the transient visualizer motor until the reference condition is restored, stop the oscillograph motor and make the exposure. After a little experience it is surprising how easy it is to perform these operations and how quickly it can be done. Where successive exposures are to be taken on a film it is necessary to keep one motor running in order to re-establish the reference condition. It should be pointed out that after the brush arm and film arm have once been adjusted, any number of oscillograms may be taken without further attention.

When studying the starting current in transformers, the requirements are rather severe. It is necessary to be able to start the oscillogram at any desired point of the film, to close the circuit at any desired point on the e. m. f. wave, to control at will the amount and direction of the residual magnetism, and in some cases to introduce a series resistance for limiting the initial starting current and later to short-circuit it after the disturbance is somewhat reduced. The control of the residual magnetism is accomplished by the use of a micrometer adjustment of the auxiliary brush, previously referred to, by means of which the point of opening the circuit is under the control of the operator. It is interesting to note that where a maximum residual is to be left in the transformer, the circuit may be opened without sparking at the brushes by adjusting the auxiliary brush so the circuit is opened just as the current reaches zero, decreasing from a maximum value. If the current is decreasing from a positive maximum, a positive residual is left in the transformer ready for the next cycle of events. By referring to the curves of Figs. 9 and 10, it will be seen that there is absolutely no sign of sparking at the brushes. In Fig. 9, Case 1, the circuit was closed where the e. m. f. was passing through zero increasing in a positive direction and with a positive residual. Case 2 is the same except that the circuit was closed when the e. m. f. was a positive maximum. Fig. 10, Case 2, is the same as Fig. 9, Case 1, except that the impressed e. m. f. was increased 40 per cent and due to the higher saturation the current increased 225 per cent. Case 4, is the same as Case 3 except that a series resistance equal to about four times the primary copper resistance was introduced to limit the initial current. The current was decreased to approximately one-third that of Case 3. This resistance was short-circuited after about one and a half cycles, and as a result, the third peak is slightly higher than the second. On account of the fact that the initial current may be many times full-load value, these experiments were performed upon small transformers in order to avoid serious line disturbances.

By means of the transient visualizer all of the transient curves reproduced in this paper may be studied on the screen of an oscillograph in exactly the same way as a-c. curves.

Two oscillatory circuits, tuned to the same frequency when coupled, no longer oscillate at their natural frequency. The change in frequency is shown by Fig. 11 where Curve a is the primary current when the two circuits are coupled, and Curve b shows the free period of the primary.

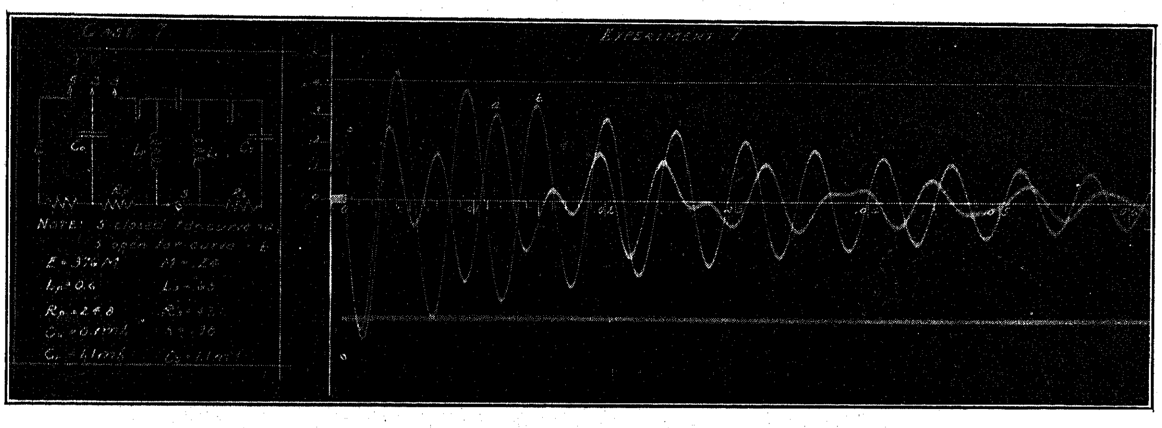

Fig. 11

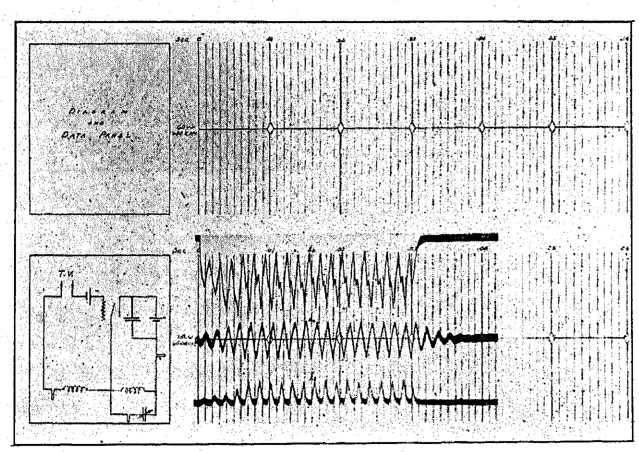

Fig. 12

By means of an opaque paper shield an unexposed space on the film may be conveniently reserved for a diagram of connections and essential data. This is an important feature, for it makes the record complete in itself and eliminates the possibility of losing the data. The curves mean much more when studied in connection with the circuit diagram.

Usually one element of the oscillograph is required for a timing curve. With the transient visualizer, a more satisfactory and convenient way is as follows: The synchronous motor, and therefore the film drum, runs at a speed that is determined by the frequency of the power source, which is quite constant over considerable periods of time, so if the speed is measured by a precision tachometer either before or after the oscillogram is taken, an accurate time scale is possible. Knowing the diameter of the film drum and the speed range to be covered, a series of charts for different speeds may be made up and the time marked off in thousandths of a second as indicated in Fig. 12. Then all that is necessary is to place the film upon the proper chart and mark off with a pen the desired units of time and trace the panel as shown in the lower half of Fig. 12 which shows a negative of the starting currents in a vacuum tube oscillator when the grid circuit is completed by the transient visualizer.

The use of the transient visualizer in making a progressive study of periodic phenomena is well illustrated by Fig. 13 which shows curves of kenotron and S-tube rectifiers for half-wave and full-wave rectification without filters and also with four different kinds of filters. For the convenience of comparison all current curves were taken with one oscillograph element. Including ground lines, each film was exposed a total of 13 times. All of these curves are brought together in order that they may be studied to the best advantage.

In a short article there is time for only a few hints as to the possibilities of the transient visualizer, but experience will suggest many other applications. Many uses are found for it in connection with the study of transmission line problems and three-phase transients. Practically the whole field of transient phenomena is brought within the understanding of students and engineers. It helps the mathematically inclined to visualize the physical relations, and it enables a person with limited technical training to obtain an understanding of complex phenomena. It largely eliminates the element of chance from the experimental study of transients and puts it on a scientific basis.

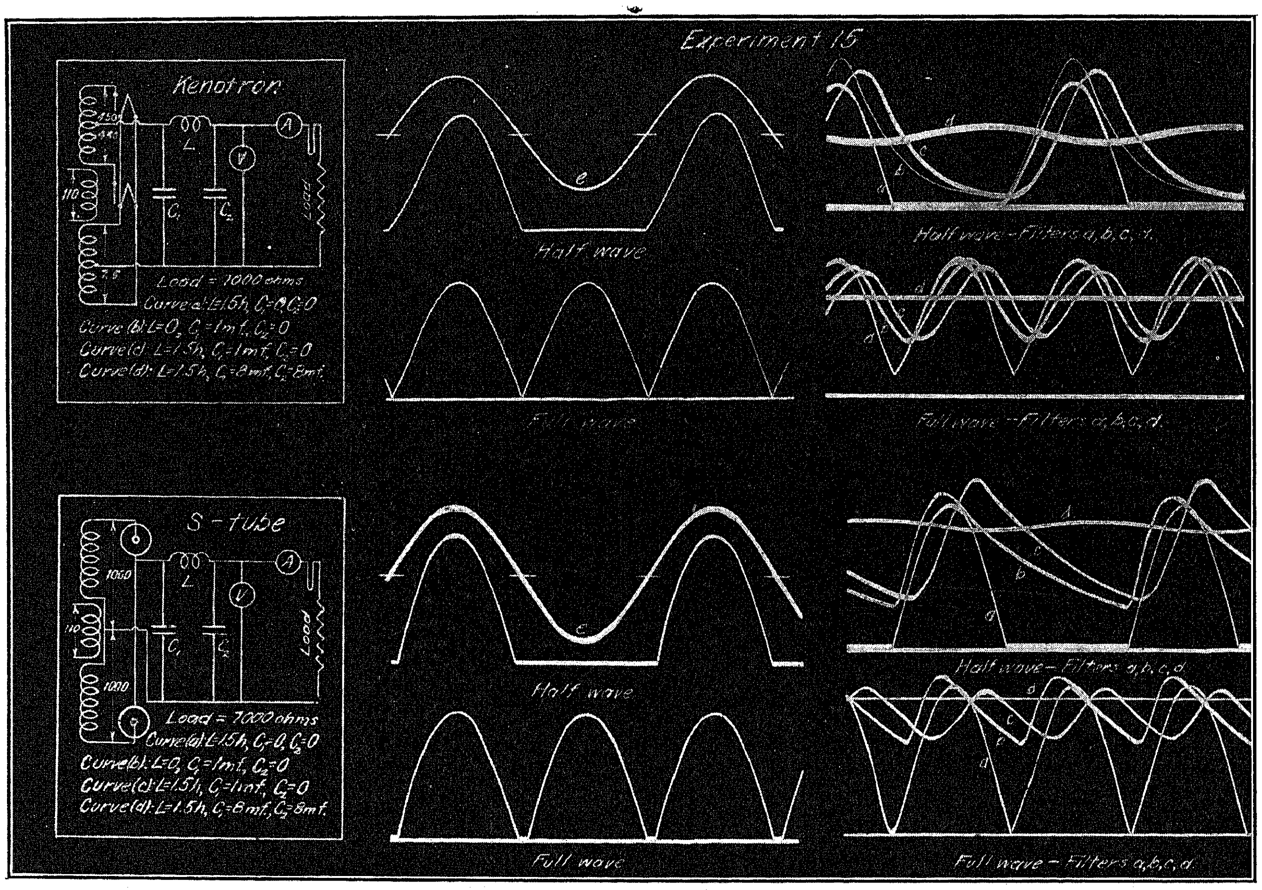

Fig. 13

The oscillograms reproduced in this paper were taken by graduate students in their regular laboratory work in Communication Engineering. The author is greatly indebted to A. J. Ralph, expert technician of the Department of Electrical Engineering, Yale University

for his excellent suggestions regarding mechanical details and for his painstaking care and expert workmanship in the construction of the five machines used in our laboratory.

Discussion

J. R. Craighead: This device serves the purpose of repeating a transient so that it can be properly studied by the eye or where there is any question of suitable illumination can be better photographed because of repetition. This should lend itself to the use of higher velocities and consequently larger and more easily readible records on the oscillograph than have been obtained. The possible limit of speed on the oscillograph in the direction of the motion of the film is chiefly the photographic effect. This device should enable the photographic effect to be much improved, provided the nature of the switch is such that duplication can be assured in the transient at excessively high speeds. Can Mr. Palmer furnish any statement regarding the practicable limits?

Another point which enters into the successful duplication of a transient is the effect of varying contact in a switch. In attempting to get single transients at definite points in the e. m. f. wave, I have had occasion to work with somewhat larger currents and the results have not been successful. That is, it is possible to construct a switch for small currents or for potentials which carry practically no current at which duplication can be made quite accurately.

When we get to apparatus the size of ordinary oil switches and large circuits, this kind of duplication is not practicable because although the actual duplicating relay can be made to operate accurately, the oil switch itself has a sufficient variation in time so that it is not practicable to secure a duplication of the particular point on the wave that is desired.

In regard to the separation of components of wave forms, as mentioned on page 5, the method of separation is not very clearly stated. I understand it to be the use of the transient visualizer to maintain a constant zero, and alteration of the circuit connections is necessary to obtain the oscillogram in each particular case. I should like to ask Mr. Palmer whether this solution is that which is intended.

H. M. Turner: Mr. Craighead raised the question regarding duplication at high film speed. I can say that we have experienced no difficulty with retracing when operating at a film speed of 1200 ft. per min. Usually, however, we are operating at 600 ft. per min. and the retracing is practically perfect. It should be pointed out that a small constant friction load on the photographic drum shaft is necessary to prevent oscillations.

So far as current-carrying capacity is concerned there is no reason why it cannot be greatly increased by using wider brushes. In demonstrating fundamental principles there is no particular advantage in using large currents. In general it is convenient to use currents of 15 amperes or less. However, when studying the performance of particular pieces of equipment where several hundred amperes, or in extreme cases, probably several thousand are involved a special design would be required. In the case of alternating current, advantage may be taken of the fact that the circuit may be opened when the current is at or near the zero value.

With reference to the method of separating the components, the transient visualizer makes it possible to start all components from the same point on the film. First, the transient current is taken by closing the circuit at the desired point at the electromotive force wave. Second, the transient visualizer is short-circuited and the permanent component is taken. Third, with the permanent component flowing through the oscillograph element in the reversed direction the line is short circuited by means of the transient visualizer and the transient component is taken in proper relation. In order to avoid tripping the circuit breaker, two identical circuits are connected in series and the short circuit is applied to one of them.

Temperature Rise of Stationary Electrical Apparatus as Influenced by Radiation, Convection and Altitude

BY V. M. MONTSINGER and W. H. COONEY
Member, A. I. E. E. Associate, A. I. E. E.
Both of General Electric Co., Pittsfield, Mass.

Review of the Subject.—Part I of the paper takes up first the division of losses by radiation and convection from tall vertical planes. It is shown that the loss by convection from tall planes can be expressed by the formula

$$W_c = 0.0014\, A\, \theta^{5/4}$$

in which W_c is the watts, A the square inches of surface and θ the temperature rise in degrees centigrade.

It is then shown that the division of losses from a black plane is, for temperature rises up to 100 deg. cent., approximately 45 per cent convection and 55 per cent radiation. Based upon this division, a simple formula is given for determining the ratio of losses for an irregular surface where the greater part of the loss is by convection.

The effect of various colors on the temperature rise of transformers having both plain and corrugated tanks is discussed.

In Part II it is shown that altitude does not affect radiation. The general average of the results obtained by various investigators shows that convection varies as the square root of the air density. Based on this, it is shown that for a constant loss by convection the temperature rise increases about 4.6 per cent for each 1000 meters increase in altitude. For transformers where a part of the loss is by radiation (unaffected by air density) the effect is reduced by the ratio of the convection loss to the total loss. Also the effect on the winding rise over the ambient is further reduced by the fact that the winding rise over the oil is not affected by altitude. The effect of the copper loss, however, is to increase the effect of altitude because the resistance is increased by temperature.

Based upon the above facts it is shown that the temperature rise and rating of the two main classes of oil-immersed self-cooled transformers are affected by altitude as follows:

	Per cent increase in Copper Rise per 1000 Meters Increase in Altitude	*Per cent decrease in Kv-a. per 1000 Meters Increase in Altitude*
Self-cooled transformers.........		
(a) with plain tanks..........	*1.75*	*1.35*
(b) with corrugated, tubular and radiator tanks............	*3.0*	*2.3*

INTRODUCTION

WHILE the main purpose of this paper (which is a companion paper of the one by Doherty and Carter[1]) is to give the effect of altitude on the heating of stationary apparatus cooled by radiation and free convection, it is very essential to first determine how the cooling is effected. For instance, we must know the relative parts radiation and convection play in cooling the different shapes of surfaces used, especially for self-cooled oil-immersed transformers, because (1) the ratio of losses by these two modes of cooling varies, depending on the shape and color of the surface, etc., and (2) these two modes of cooling are not affected alike by altitude. The paper, therefore, falls into two logical divisions, namely:—

1. The temperature rise of various shaped surfaces as influenced by radiation and free convection for a given altitude and
2. Effect of altitude on temperature rise of apparatus having various shapes of surfaces.

One of the writers gave a paper[2] before the Institute in June 1916 in which was shown by tests how the heating of three transformer tanks, each having different shapes of surfaces, were affected by altitude.

Since that time considerable experimental work has been carried on to establish, first, the correct formula for free convection; and second, a method for calculating the cooling capacity of various shapes of surfaces under a constant air pressure where both radiation and convection enter into the cooling, especially where convection plays such an important part as it does for tank surfaces having different widths and depths of corrugations. So far as literature shows, no method has ever been given by which to predetermine with any degree of accuracy the thermal efficiency of corrugations.

Part I gives the results of tests made on a large plate to determine the formula for free convection. Also the results of tests and a discussion are given on the effect of different colored cases on the temperature rise of transformers in the shade and sunshine.

Part II deals with the effect of altitude on the temperature rise of transformers having different shapes of tank surfaces, of rheostats, bus bars, reactors, etc.

Part I

TEMPERATURE RISE OF VARIOUS SHAPED SURFACES AS INFLUENCED BY RADIATION AND CONVECTION FOR A GIVEN ALTITUDE

A. Radiation. The accepted law of radiation, known as the Stefan-Boltzman law, is of the form:

$$W_r/A = K\, e\, (T_2^4 - T_1^4) \qquad (1)$$

where W_r/A is the watts dissipated per unit surface, K is a constant, e is the emissivity factor depending on color, being 1.0 for a lamp black surface, and T_2 and T_1 are the hot body and ambient temperatures in absolute degrees centigrade respectively. If expressed

1. Effect of Altitude on Temperature Rise by R. E. Doherty and E. S. Carter.

2. Effect of Barometric Pressure on Temperature Rise of Self-Cooled Stationary Induction Apparatus" by V. M. Montsinger.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27 1924.

in watts per square inch, according to the latest accepted value, $K = 3.68 \times 10^{-11}$.

Fig. 1 shows the radiation of heat in watts per square inch plotted against temperature rises over various ambient temperatures.

B. Convection. Several years ago, Dr. Irving Langmuir developed and published[3] the film theory which assumes that heat loss by convection is dissipated by first passing through an adhering film of gas, where most of the temperature drop occurs, and then is carried away by convection air currents.

While the film theory formula checked tests made at high temperatures, it did not check tests made on tall planes at low temperatures. According to the formula, the loss was approximately proportional to the temperature rise up to 100 deg. cent., whereas numerous tests made on various kinds of tank surfaces showed that convection loss varied as the temperature rise raised to the 5/4 power. This was pointed out in the paper presented in 1916.

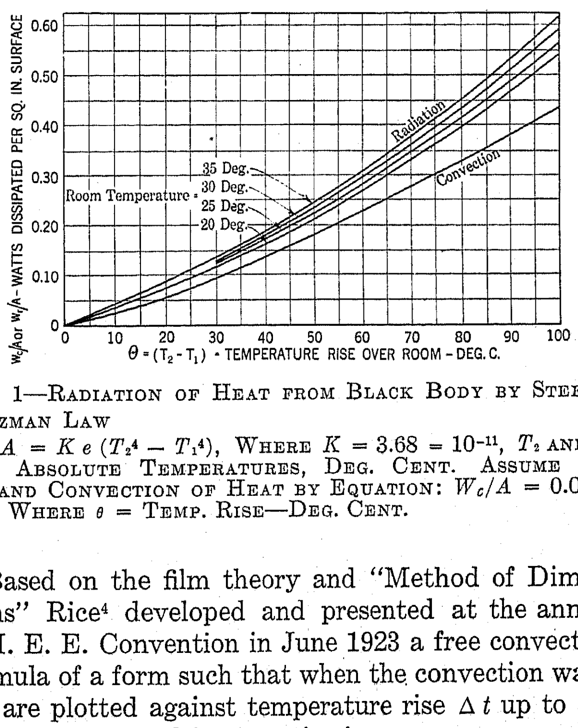

FIG. 1—RADIATION OF HEAT FROM BLACK BODY BY STEFAN-BOLZMAN LAW

$W_r/A = K\,e\,(T_2^4 - T_1^4)$, WHERE $K = 3.68 = 10^{-11}$, T_2 AND T_1 ARE ABSOLUTE TEMPERATURES, DEG. CENT. ASSUME $e = 0.9$ AND CONVECTION OF HEAT BY EQUATION: $W_c/A = 0.0014\ \theta^{1.25}$, WHERE θ = TEMP. RISE—DEG. CENT.

Based on the film theory and "Method of Dimensions" Rice[4] developed and presented at the annual A. I. E. E. Convention in June 1923 a free convection formula of a form such that when the convection watts W_c are plotted against temperature rise Δt up to 100 deg. cent. the resulting equation is:

$$W_c = K\,A\,\Delta\,t^{1.06} \tag{2}$$

in which K is a constant, A is the area.

But from 100 to 500 deg. cent. rise, the exponent in Rice's formula is approximately 1.25.

Since the temperature rises of most electrical apparatus do not exceed 100 deg. cent. it appeared to be of sufficient importance to make accurate laboratory tests to determine (1) the correct value of the exponent and (2) the constant for vertical surfaces representing tall tanks. As Rice's formula was known by the writers well in advance of its publication, there was sufficient time to complete these tests and give, in a condensed form, the results in a discussion of his paper. In this discussion it was shown that free convection from tall planes can be expressed for temperature rises up to 300 deg. cent. by the formula:

$$W_c = K\,A\,\theta^{5/4} \tag{3}$$

in which W_c = convection watts,
K = 0.0014 for a plane 31.5″ tall
A = area in sq. in.
θ = temperature rise in degrees centigrade

Fig. 1, also shows values of W_c/A plotted against θ.

Further details as to how the formula was derived are given later under "Experimental Observations on Vertical Plate."

Recently Rice[5] has, by introducing the temperature coefficient of density of the air in his previous formula, developed one for large vertical plane surfaces in air which agrees in substance with equation (3). It is of the form:

$$W_c = 0.0078\,A\,(1/H)^{1/4}\,P^{1/2}\,(1/T_{avg})^{.123}\,\Delta\,t^{5/4} \tag{4}$$

in which W_c = Loss in watts
A = Area of surface
H = Height of plane
P = Absolute air pressure in atmospheres
T_{avg} = Average of hot body and ambient absolute temperatures degree K.
Δt = Temperature rise of hot body in deg. cent.

For a rise of approximately 50 deg. cent. in a 25 deg. cent. room and for a plane 31.5 in. (80 cm.) tall, equation (4) reduces to

$$W_c = 0.001285\,A\,P^{1/2}\,\Delta\,t^{5/4} \tag{5}$$

Rice has, therefore, cleared up the disagreement between the *rate* of *loss* with *temperature rise* which has existed between the film theory formula and results of tests made at low temperature differences. We now have for the first time a true conception of the physics of convection for both high and low temperatures differences.

C—Radiation and Convection from Various Shaped Surfaces

(*a*) *Large Vertical Planes.* Table I shows the calculated division of losses from a plain black surface, using the convection formula $W_c = 0.0014\,A\,\theta^{1.25}$ and the radiation formula $W_r = 3.68 \times 10^{-11}\,A\,e\,(T_2^4 - T_1^4)$, in which $e = 0.9$ and $T_1 = 298$ deg. K (25 deg. cent.)

For practical purposes we can say that for vertical planes the losses from, say, 20 to 100 deg. cent. rise, are 55 per cent radiation and 45 per cent convection.

(*b*) *Large Vertical Corrugated Surfaces.* One of the most universal methods of increasing the area of a trans-

TABLE I
DIVISION OF LOSSES FROM LARGE PLAIN, BLACK VERTICAL SURFACE IN 25 DEG. CENT. ROOM AT SEA LEVEL

Temperature Rise Deg. Cent.	Watts per sq. in. by:		Per cent of Total Loss by:	
	Radiation	Convection	Radiation	Convection
10	0.039	0.025	61	39
20	0.0765	0.057	57.5	42.5
30	0.121	0.095	56	44
40	0.171	0.137	55.5	44.5
50	0.224	0.182	55	45
60	0.28	0.230	55	45
70	0.344	0.279	55	45
80	0.415	0.329	56	44
90	0.492	0.382	56	44
100	0.57	0.439	56.5	43.5

former tank without increasing its floor space is to corrugate the surface. Since there are so many possible variations in the pitch depth and height of corrugations, it is very essential to be able to predetermine the cooling capacity, *i. e.* the loss per unit of area of the developed surface for various temperature rises.

(*c*) *Surface of Corrugations Effective for Radiation and Convection Radiation:* Referring to Fig. 2 the surface A represents the envelope of a single corrugation

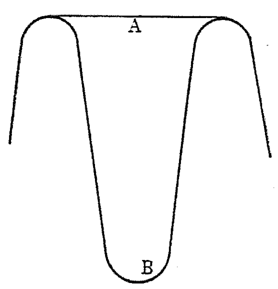

FIG. 2—SHOWING SURFACES OF A CORRUGATION EFFECTIVE FOR RADIATION AND CONVECTION

B. It is obvious that both sides of A will radiate equal amounts of heat. Now B will radiate the same amount of heat to A as A radiates to B; otherwise one body would gain heat at the expense of the other. Since A is the envelope area of B and, furthermore, since A and B have equal radiating capacities, the true radiating surface of a corrugation (or any irregular surface) is its outer envelope. (A mathematical proof of this which is rather long, is given by Rud. Kuchler in *Electrotechnische Zeitschrift,* Jan. 1923, Vol. 44).

Convection. The surface effective for convections is of course the total developed area, providing the air currents are allowed to circulate freely over the entire surface.

(*d*) *Total Cooling Capacity of Plain and Corrugated Surfaces*

(*1*) *Actual Losses:* The actual losses for any given maximum oil rise of either a plain or corrugated tank are difficult of accurate predetermination for the following reasons: (1) There are certain losses from the bottom and cover whose temperature rises are seldom accurately known; (2) the vertical tank gradient must be known; and (3) there exists a certain temperature drop from the oil to the tank, which drop must be known. However, in practise it is just as important and very convenient to be able to make comparisons of the heating of tanks having different shapes of surface with other tanks having similar vertical gradients. For instance, if we know what a plain tank will do for any given oil rise, it is convenient to know what some other tank with a corrugated, surface will do for the same oil rise.

(*2*) *Relative Losses:* For any given top oil rise (providing the vertical gradients of the tank are similar) the ratio of the loss from the average shape of corrugation used in practise to the loss from a plain tank can therefore be expressed by the following equation:

$$L = \frac{55\, E\, e \times 45\, D}{100\, D} \tag{6}$$

in which L = ratio of total loss per unit of developed area to loss per unit of plain area, having the same temperature rise of the oil.

E = Outside envelope area.

e = Emissivity factor = 1.00 for ordinary black paint in this case.[6]

D = Developed area of surface.

There are, of course, limitations as to depth and width of the air space in the corrugation for which equation (**6**) holds. Experience has shown that it holds for a ratio of depth divided by width of approximately 4. However, as this ratio increases, it would be expected that the air circulation would become more and more restricted until the loss by convection was materially reduced. For instance, if the width of air space in a corrugation, 6 in. depth was only 1/4 in., there is no question but that the air would be so restricted that the convection loss would be reduced enormously.

If the entire surface of a tank consists of similar corrugations we can let E equal the pitch, and D the developed length of a single corrugation and by substituting these values in equation (**6**) determine L. For instance if the pitch is 2 in. and the developed length is 6.6 in., the value of

$$L = \frac{55 \times 2 \times 1 + 45 \times 6.6}{100 \times 6.6} = 0.62$$

In other words one sq. in. of the corrugated area will dissipate 0.62 as much loss as one sq. in. of a plain area.

Now, since this tank has 6.6 in. of surface to each 2 in. of envelope, it has 3.3 times the total area of a plain tank of the same outside diameter. Therefore, the total loss dissipated by this corrugated tank will be $3.3 \times 0.62 = 2.04$ times that of the plain tank.

If equation (**6**) is expressed in terms of total loss L_1 per unit of envelope area instead of loss per unit of developed area (L), the equation reduces to

$$L_1 = L\, D/E$$

$$= \frac{55\, E\, e + 45\, D}{100\, E} \tag{7}$$

6. See Table II for values of e for Various Colors.

Effect of Height. Carefully made tests have shown that the effect of height is very small, the loss being only about 3 per cent more for a corrugated surface 36 in. in height than one 72 in. in height. In fact, experience has shown that the effect of height is so small that for practical purposes it can be neglected for all heights greater than about 2 or 3 ft.

D. Effect of Color on Temperature Rise. Table II gives the emissivity factors for various colors of paints often used on transformer tanks. These values were obtained from tests made on a plate 20 in. by 20 in. in a vertical position.

TABLE II
EFFECT OF COLOR ON EMISSIVITY

Color of Paint	Emissivity Compared with Black Surface (e = 0.9)
Black	1.00
Dark Green	0.97
Dull Red	0.91
" Grey	0.81
White	0.76
Copper (busbars)	0.65
Aluminum	0.62

The effect of color on radiation raises the question of how the temperature rise of a transformer is affected by various colors of paint when in the shade, or how it is affected by absorption of heat when exposed to the rays of the sun.

Since the division of losses from a plain black tank is approximately 55 per cent radiation and 45 per cent convection, the effect of other colors on the temperature rise may be easily calculated for any shape of surface in the shade. Table III shows this for a plain surface.

TABLE III
EFFECT OF COLOR ON TEMPERATURE RISE OF PLAIN TANKS

Color of Paint	Surface Rise in per cent of that for Black Surface
Black	100
Dark Green	101
Dull Red	104
" Grey	110
White	117
Aluminum	120

TABLE IV
EFFECT OF COLOR ON TEMPERATURE RISE OF TANKS HAVING APPROXIMATELY 75 PER CENT OF LOSS BY CONVECTION AND 25 PER CENT BY RADIATION

Color of Paint	Percentage Rise
Black	100
Dark Green	100.8
Dull Red	101.5
" Gray	104
White	105.8
Aluminum	109

It is thus apparent that a tank with an irregular surface is not appreciably affected by color.

IN SUNSHINE

(*a*) *Plain Tank.* A plain tank will probably be affected the most. The results of tests made by Messrs. Moore and Moulton[7] of the San Joaquin Light and Power Corporation to determine the effect on the temperature rise of both black and gray plain tanks in the sunshine, are summarized by them as follows:

"The number of successive days during which tests were made and the consistency of the results leave little doubt as to the accuracy of the full load tests. The fact that a gray paint will not reduce the oil temperature more than 3 or 4 deg. fahr. or 1 or 2 deg. cent. during the extremely hot weather encountered in the San Joaquin Valley seems established. This was a disappointment in view of the seemingly prevalent belief that a much larger reduction for gray paint would be found."

It is apparent that the increased temperature, due to the lighter color (and reduced radiation) is approximately counteracted by the reduced absorption of heat from the rays of the sun.

(*b*) *Tanks with Irregular Surfaces.* Since heat absorbed by radiation is a function of the envelope surface only, there is every reason to believe that a tank of irregular shape will not be affected as much by the sun's rays, for a given color, as a plain tank.

It should be understood, of course, that the temperature rise will be greater in the sunshine than in the shade, regardless of color of tanks, the difference depending on several factors, such as direction of the sun's rays, the area of the tank exposed to the sun, and the intensity of the rays. Unfortunately, no reliable data appears to be available on this point.

E. Experimental Observations on Vertical Plate. The plate was of cast iron, (Figs. 3 and 4) 31.5 in. (80 cm.) high, 13.1 in. (33.3 cm.) wide, by 1 1/16 in. (2.7 cm.) in thickness, and had imbedded in it sheath wire units of equal resistance about 2 in. apart. This produced a uniform temperature over the whole area, including both sides, and eliminated the necessity of making appreciable stray losses corrections which would have been necessary if one side of the plate had been blanketed, as is sometimes done in investigations of this kind. In some of the tests the terminals and

edges of the plate were blanketed. This accounts for the slight variation in the areas given in Tables V, VI, and VII.

The plate was suspended in a vertical position in the air in an open room having a constant temperature. Fifteen thermocouples were soldered in holes in the surface on one side and five on the other side of the plate, the five being used merely as a check to see if both sides were at the same temperature. The plate temperature was taken as the average of all thermo-couples. Direct current was used to supply the loss. All readings of volts and amperes and thermc-couples were taken with a potentiometer. For convection, the air was used as the ambient. For radiation, the temperature of the walls of the room about 10 ft. distant was used for the ambient, although the air and wall temperatures were usually the same.

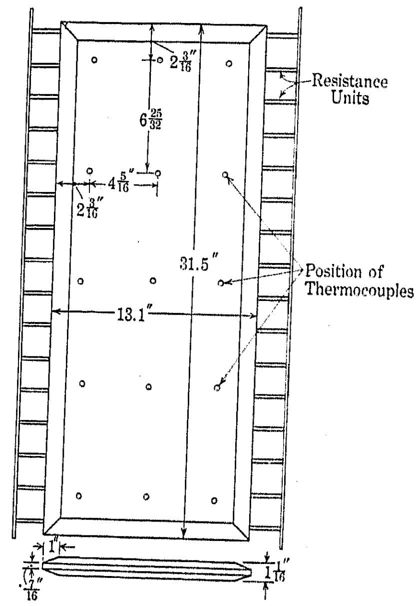

Fig. 3—Dimensions of Vertical Plate Used to Determine Convection Formula

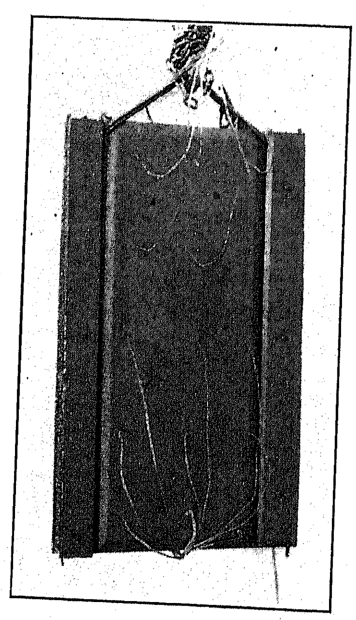

Fig. 4—Front View of Plate Used to Determine Convection Formula Blanketing on Terminals

Three series of runs were made with both sides of the hot plate under the same conditions, namely:

(1) painted a lamp black.
(2) nickel-plated and polished, and
(3) with the surfaces partly oxidized, before starting the tests.

For the first condition, the paint began to scale off when the temperature reached approximately 100 deg. cent. or about 72 deg. rise, and the test had to be discontinued. Up to this point, the loss by convection was taken as the difference between the total loss and the loss calculated by the standard radiation law, assuming that the emissivity factor was 0.9 of that for a perfect black body, as shown in Fig. 1.

The convection loss points fell practically on a straight line on double-log paper, the equation of the line being $W_c/A = 0.0014\ \theta^{1.25}$ where W_c/A is the watts per square inch of surface and θ is the temperature rise in degrees centigrade. Watts per square inch are plotted against θ in Fig. 5. The test data are given in Table V.

For the other two conditions of the plate surface, the emissivity factor for radiation was found by plotting the total loss in watts per square inch against temperature rise. The difference between this and the convection loss curve found from the black plate divided by the theoretical radiation loss where $e = 1.0$ gives the new emissivity factor. For instance, with the nickel plated surface, the total watts per square inch, when plotted in curve form, are 0.200 for a 50 deg. cent. rise over a 30 deg. cent ambient. Subtracting

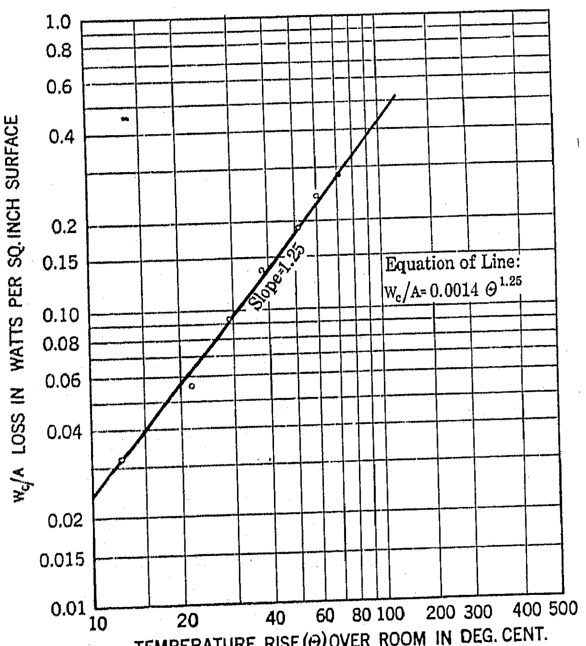

Fig. 5—Heat Loss by Free Convection from a Vertical Plane 31.5 in. in Height and 13.1 in. in Width, Painted Lamp Black

the convection value of 0.182, as shown on Fig. 1, gives a radiation loss of 0.018. But W_r/A, (for $e = 1$) is 0.261, so the emissivity factor $e = 0.018/0.261 = 0.069$ or approximately 0.07 This value of emissivity checks fairly well with that obtained by other investigators. The results obtained with the nickel-plated surface are shown in Table VI.

Up to about 150 deg. cent rise, the convection loss points fell in a straight line on double-log paper, Fig. 6, the slope of the line being about 1.25. From 150 to 200 deg. rise the points gradually drew away from the straight line and at 300 deg. rise the loss was about 25 per cent higher than the straight line.

At first it was thought that this departure from a straight line might be due to a change in the law, but as will be seen later where tests made with the surfaces

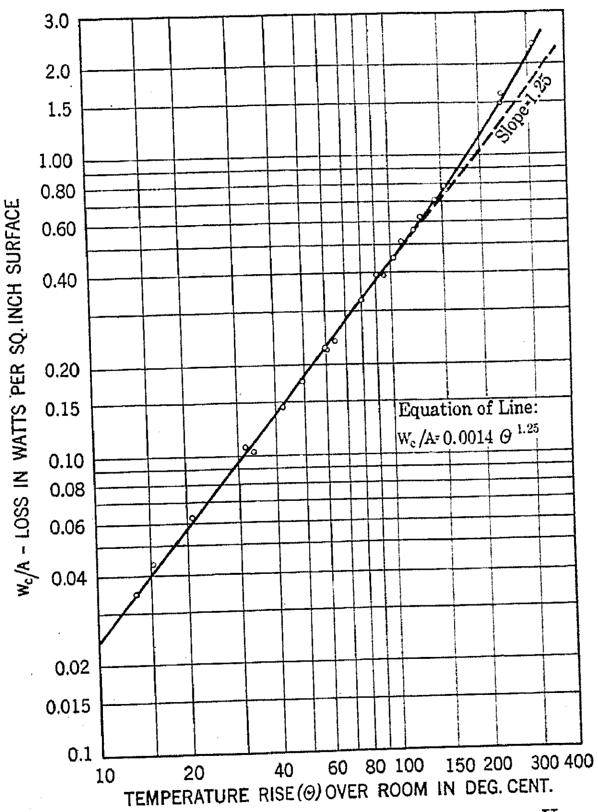

Fig. 6—Heat Loss by Free Convection from a Vertical Plane 31.5 In. in Height and 13.1 In. in Width, Surfaces Nickel-Plated and Polished

partly oxidized did not show this departure, it was apparently due to a gradual oxidation of the surface which at first was not discernible to the eye but which gradually increased the emissivity factor. At 280 deg. cent. rise, the surface became so tarnished that the tests were discontinued.

For the last set of tests the surfaces were painted black and then subjected to a temperature of 325 deg. cent. for about a day to let it get "set" before starting the tests. Some of the paint came off. What remained turned a brownish color.

Tests were taken first with the temperature decreasing and second with increasing temperatures. The emissivity factor, determined as described before, was 0.52. A tabulation of the data obtained with the partly oxidized surface is given in Table VII.

The convection loss plotted vs. temperature rise (Fig. 7) on double-log paper fell practically on a straight line up to 280 deg. cent. rise— as far as the temperature was taken—with a slope of the line of 1.25.

The point to be emphasized is that for a large vertical surface and for the temperature rises used in most electrical apparatus, the loss by convection can be expressed by an exponential equation in which the loss varies as the 5/4 power of the temperature rise. This

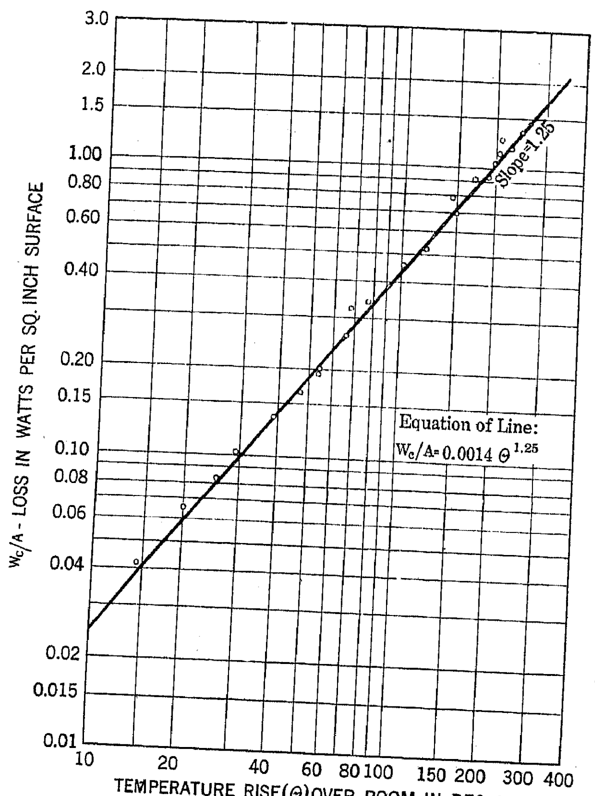

Fig. 7—Heat Loss by Free Convection from Vertical Plane 31.5 In. in Height and 13.1 In. in Width, Surfaces Partly Oxidized before Tests

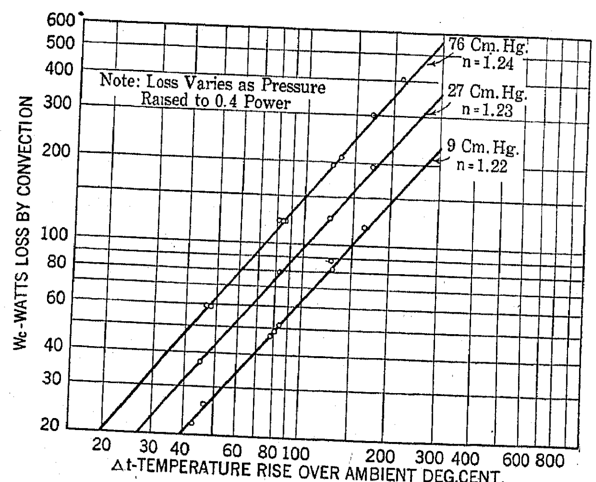

Fig. 8—Effect of Pressure on Loss by Convection, from Data Obtained by C. W. Rice on a Cylinder 1.68 In. in Diameter and 48 In. long

agrees approximately with tests made by Messrs. Ezer Griffiths and A. H. Davis, conducted under the auspices of the Department of Scientific and Industrial Research of England and shown in their Special Report No. 9 issued in 1922 on "The Transmission of Heat by Radiation and Convection." They tested vertical planes of various heights for rises up to 100 deg. cent. For heights of 69 in. and 104 in. they found the value of the exponent to be 1.3 and 1.34 respectively, while for heights less than 69 in. the exponent was 5/4. The constant in their formula was the same for all heights above approximately 12 in. (30 cm.). This checks the writers' experience with various heights of tank surfaces, excepting that the value of the constant found from the tests on the vertical plate was 1.4×10^{-3} when expressed in watts per square inch of surface, or about 9.5 per cent higher than Griffith's and Davis' value (1.28×10^{-3}) for the corresponding height. However, they found that the constant increased quite rapidly for heights less than about 12 in. (30 cm.) as will be seen from the following table.

Height in inches	Constant
11.8 (30 cm.)	0.00128
7.87 (20 ")	0.00175
5.9 (15 ")	0.002
3.94 (10 ")	0.0023
1.97 (5 ")	0.0035

Part II

Effect of Altitude on Temperature Rise of Self-Cooled Transformers and Other Apparatus Having Various Shapes of Surfaces

Self-Cooled Transformers

(*1*) *Radiation.* Altitude, of course, does not affect radiation of heat.

It was shown in Part I that the maximum part radiations plays in practise is approximately 55 per cent at or near sea level for a plain black surface, and that for certain types of complicated tank surfaces, the loss by radiation may be as low as 15 per cent of the total.

(*2*) *Convection.* The general results obtained by various investigators indicate that the loss by convection varies approximately as the square root of the air density. While Doherty and Carter's tests show that the exponent is 0.542, Rice's data[8] obtained on horizontal cylinders tested with the same apparatus show that the exponent lies below 0.5. For example, the data from Rice's Table III have been plotted on double-log paper and are shown in Fig. 8. (Before plotting these results the losses were all corrected for the three nearest pressures, namely, 9, 27, and 76 cm. of mercury.) These results are quite consistent and show that for the cylinder 1.68 in. (4.28 cm.) in diameter and 48 in. (122 cm.) long, the loss varies as the pressure raised to the 0.4 power. The data shown in his Table II for the largest cylinder 4.5 in. (11.42 cm.) diameter by 60 in. (152.5 cm.) long, while not so complete and not replotted, show that the loss varies as the pressure raised to the 0.45 power.

No single test or set of tests in an investigation of

8. Free Convection of Heat in Gases and Liquids, II A. I. E. E. Journal, February, 1924, by C. W. Rice.

this nature is conclusive and the best thing to do in drawing a conclusion is to take a general average of all the available data. In reviewing the results of various investigators, it has been found that the value of the exponent ranges anywhere from 0.4 to about 2/3. Rice's[9] final formula, *i. e.* equation (4), shows that for tall vertical planes, the loss is proportional to the square root of the pressure. The writer has found, as will be shown later, that the square root law agrees best with his experimental observations made in 1915 at three different altitudes on various shapes of tank surfaces.

Based on the square root law, the formula for free convection is:

$$W_c = K\,A\,\theta^{5/4}\,P^{1/2} \qquad (8)$$

in which W_c = Convection loss in watts
A = Area in square inches.
K = Constant = 0.0014 at or near sea level.
θ = Temperature rise in deg. cent.
P = Air pressure in atmospheres.

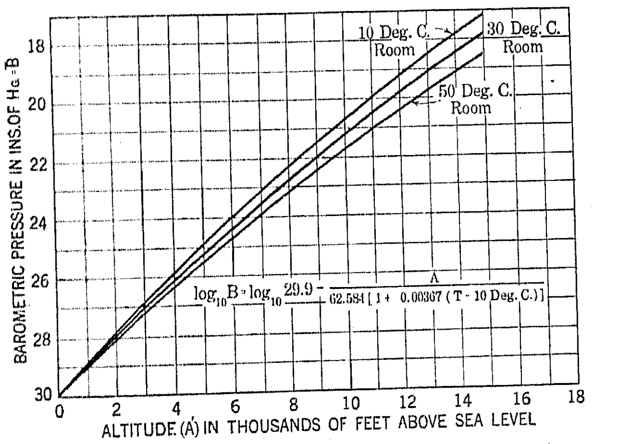

FIG. 9—VARIATION OF BAROMETRIC PRESSURE WITH ALTITUDE

Expressed in the reverse order, equation (8) becomes:

$$\theta = \frac{1}{P^{.4}}\left(\frac{W_c}{A\,K}\right)^{.8} \qquad (9)$$

For a constant loss dissipated by free convection the temperature rise therefore varies inversely as the air pressure raised to the 0.4 power.

Fig. 9 gives curves of barometric pressure in inches of mercury vs. altitude in thousands of feet above sea level for three different room temperatures. These curves were calculated by the Smithsonian Institute's formula:

$$\mathrm{Log}_{10} P = \log_{10} 29.9 - \left[\frac{A'}{62.58\,(1 + 0.00367\,(T - 10°\,C)}\right] \qquad (10)$$

in which P = Pressure in inches of mercury.
T = Temperature in deg. cent.
A' = Altitude in 1000's of feet above sea level.

9. Free Convection of Heat in Gases and Liquids, II A. I. E. E. JOURNAL, February, 1924, by C. W. Rice.

Substituting the values of P for various values of altitude (taken from 30 deg. cent. room temperature curve in Fig. 9) in equation (9), we find the following relation between altitude and temperature rise where all loss is by convection:

Altitude in thousands of feet	2	4	6	8	10	12	14
Per cent increase in temperature rise...........	2.9	5.8	8.5	11.8	14.5	17.9	21.2

It will be noted that the rate of increase in temperature is about 1.5 per cent per 1000 ft. increase in altitude.

Since air density does not affect radiation, the correction is smaller than the above for tanks where part of the loss is dissipated by radiation. For example, for a constant loss the following equation holds approximately for any shape of surface:

$$\theta_1 = \theta + \frac{1.5\,A'\,\theta}{100}\left[\frac{W_c}{W_c + W_r}\right] \qquad (11)$$

in which θ_1 = temperature rise in deg. cent. at higher altitude.
θ = temperature rise at lower altitude.
A' = altitude in thousands of feet above sea level.
W_c = loss by convection at the average altitude considered.
W_r = loss by radiation at the average altitude considered.

Table VIII gives the comparison between calculated

and tested values of maximum oil and tank rises for three styles of tanks, each of which was heated with a constant loss at Pittsfield, Mass., Boulder and Leadville, Colorado.[10] In fact, all conditions excepting altitude were as nearly the same as it was possible to make them, by using the same temporary housing, meters, thermometers, etc. The tank thermometers, after being

10. See paper by V. M. Montsinger, Effect of Barometric Pressure on Temperature Rise of Self-Cooled Stationary Induction Apparatus. A. I. E. E. JOURNAL, June, 1916.

placed on the surface in Pittsfield, were not disturbed until after the tests were completed at Leadville.

It will be noted that with the exception of the test on the plain tank at Boulder, the tests and calculated values (based on square root law) agree as well as could be expected. The other heat runs with lower rises given in the June 1916 A. I. E. E. paper show approximately the same agreement with the calculated values.

So far, we have discussed only conditions where the loss is constant; *i. e.*, the loss is unaffected by the increased temperature. In transformers where a part (copper loss) of the total loss is increased with temperature, the effect is to increase the percentage somewhat greater than 1.5 per cent for each 1000 ft. increase in altitude. For instance, according to equation (**15**) given in the paper by V. M. Montsinger of June, 1916: to which we previously referred:

$$\frac{\theta}{\theta_s} = (1 + \phi_2/100)\left(1 + \frac{\dfrac{\phi_2\, n\, a\, \theta_s}{100}}{234 + \theta_0 + a\,\theta_s\,(1 - n)}\right) \tag{12}$$

in which

θ = Temperature rise at higher altitude

θ_s = Temperature rise at lower altitude

ϕ_2 = Per cent increase in temperature rise per 1000 ft. in going from lower to higher altitude with a constant loss.

n = 0.8 = reciprocal of exponent in convection formula

a = Ratio of copper loss to total (iron plus copper) loss.

θ_0 = Room temperature in deg. cent.

The following shows the effect of the increased copper loss, due to increased temperature in increasing the rise for various ratios of copper to iron losses as calculated by equation (**12**)

—a— Ratio of Copper Loss to total loss	Increase in Temperature Rise in Per cent.	
	Per 1000 ft.	Per 1000 meters
0	1.5	4.58
0.50	1.62	4.94
0.67	1.65	5.03
1.00	1.75	5.24

The effect of temperature is to decrease the iron loss, but its effect is so small, being in the order of 1 or 2 per cent for a change of 40 to 50 deg. cent., that it can be neglected. Also it is standard practise to express the temperature increase or decrease in per cent of the guaranteed winding rise over the ambient. Since the winding rise over the tank surface is not affected by air density, the 1.5 per cent per 1000 ft. should be reduced by the ratio of the winding rise to the tank surface rise for all self-cooled oil-immersed transformers. Expressed in meters, the general equation for any type of self-cooled transformer or other type of self-cooled stationary apparatus may be expressed, close enough for practical purposes, by:

$$\phi = A''\, N\, S\, (4.6 + a) \tag{13}$$

in which ϕ = per cent increase in temperature rise

A'' = Increase in altitude in thousands of meters

N = Ratio of tank surface rise to winding rise over ambient temperature.

$S = \dfrac{W_c}{W_c + W_r}$ = ratio of convection to total loss

a = ratio of copper to total loss.

In case it is more convenient to express S in terms of the ratio of surfaces effective for convection and radiation *i. e.* the developed and envelope surfaces, we may put

$$S = \frac{45\,D}{45\,D + 55\,Ee}$$

$$= \frac{D}{D + 1.22\,Ee}$$

in which S = shape factor

D = total developed area

E = outside envelope area

e = emissivity factor

If the difference in altitude considered is large, the ratio of 45 to 55 no longer exactly holds because for a given rise the loss by convection decreases as the altitude increases, whereas the loss by radiation remains the same. For example, in going from sea level to 5000 ft. above sea level, the convection loss for a given temperature rise over a 30 deg. cent. ambient is decreased by the factor $\left(\dfrac{25.2}{29.9}\right)^{0.5} = 0.915$. This means that the 45 per cent factor has been reduced to 41.2 per cent. During this time, the temperature rise has slightly increased but the ratio of 42.2 to 55 still holds. For altitude differences of, say, 10,000 ft. (3000 m.) and over, it should be satisfactory for practical purposes to use the ratio corresponding to an average altitude of 5000 ft. and write

$$S = \frac{D}{D + 1.33\,Ee}$$

Summary of Parts I and II

1. The loss by free convection is proportional to the temperature rise raised to the 5/4 power.

2. For a vertical tall plane at sea level (and where the emissivity = 0.9) the ratio of losses by free convection and radiation are approximately 45 to 55 respectively.

3. For a given temperature rise, the loss by convection is proportional to the square root of the barometric pressure.

TABLE IX
EFFECT OF ALTITUDE ON TEMPERATURE RISE

Type of apparatus	N	S	a	ϕ
(a) Oil Immersed self-cooled transformers	—	—	—	Per cent in copper rise per 1000 m. (approx.)
(1) with plain tanks	40/55	0.45	2/3	1.75
(2) with corrugated, tubular and radiator tanks	40/55	0.80	2/3	3.0
(b) Air-cooled Transformers of Dry Type				
(1) Core wound coils	40/55	0.60	2/3	2.3
(2) Form wound coils	1.0	1.0	1.0	5.25
(c) Air Cooled Reactors	1.0	1.0	1.0	5.25
(d) Rheostats, Relays, etc.	1.0	0.80	1.0	4.5
(e) Bus bars	1.0	0.6	1.0	3.5
(f) Water-cooled transformers				0.0

4. For a given loss, the temperature rise (when the loss is by free convection) is inversely proportional to the barometric pressure raised to the 0.4 power.

5. For a constant loss dissipated by free convection, the surface temperature rise increases about 4.6 per cent for each 1000 m. increase in altitude.

6. By assigning practical values to the factors in the formula: $\phi = A'' N S (4.6 + a)$ Table IX gives the effect of altitude on the temperature rise of different types of stationary apparatus.

7. Considered from the standpoint of effect of altitude on change in kv-a. for a given temperature rise, Table X shows the per cent variation for representative cases of the two classes of transformers given under 6 (a) in which it is assumed (1) that the oil rise varies as the total loss raised to the 0.8 power, (2) that the winding rise over the oil is proportional to the square of the load, (3) that the ratio of copper to iron loss at sea level is 2:1 respectively, and (4) that the ratio of the copper to the oil rise is 55 to 40 respectively.

and

E. S. CARTER
Non-Member

Review of the Subject.—*The problem is to determine the effect of altitude in increasing the temperature rise of electrical apparatus.*

Stated in detail, heat is dissipated from the various surfaces of apparatus principally by convection and radiation. The former is a function both of temperature rise and of air density, that is, of altitude; the latter, of temperature rise only. The energy loss in the apparatus, that is, the heat to be dissipated, is not changed significantly by altitude. Thus, lower air density at higher altitude means decreased convection. Hence, higher temperature, which increases both convection and radiation, is required to carry off the same heat. Specifically, then, the problem is to relate these several factors so that quantitative calculations can be made for various types of apparatus.

An investigation was made in 1921 to determine how dissipation by convection varies with temperature, air density, and also with respect to the air movement—i. e., whether it is a blast or merely the natural movement created by temperature difference: in other words, whether it is "forced" or "free" convection. The results check reasonably with those obtained by Montsinger[1], Rice[2] and others.

The law of radiation, of course, has long since been well known.

The tested apparatus, consisting of electrically heated plates, was enclosed in a large wooden tank or drum, in which the air pressure could be controlled.

The constants from these tests were used in setting up the general equation (26), *and equations,* (30) *and* (32), *which give the increase in temperature rise occasioned by lower air pressure, for free and forced convection respectively. These are plotted in Figs. 16 and 17. Reasonable assumptions simplify these equations for practical calculations for various kinds of apparatus.*

To study altitude effect on actual rotating apparatus, a 7½ kv-a. synchronous motor was tested in the drum at various air pressures. The actual increase in temperature rise agrees well with the values calculated by the above equations. Also tests were made on a 2550-h. p. high-speed synchronous motor, first at Lynn, Mass. (sea level), *and later at Cerro De Pasco, South America, at an altitude of 3700 m. These tests afforded an opportunity to check calculations against actual data on rotating apparatus.*

Table I gives the increase in temperature rise which, on the above bases, would be expected in various types of electrical apparatus.

Introduction

THE effect of altitude on temperature rise has been a live engineering question ever since temperature guarantees have been made on electrical apparatus for operation at high altitudes. The answer has been evolved piecemeal. While a number of investigations[3] bearing on the subject preceded Montsinger's[1] paper in 1916, yet the latter appears to have been the first real attempt to make a rational calculation of altitude effect for a specific type of apparatus, *i. e.*, transformers. Later investigations by Rice[2] and also by Davis[4] afforded valuable, additional data regarding the dissipation of heat from surfaces. In none of these, however, has any attempt been made to calculate the effect of altitude for apparatus involving "forced convection,"[5] such as rotating apparatus and air-blast transformers. It is the purpose of the present paper to cover this ground, as well as to confirm Montsinger's results on stationary apparatus.

Plan of the Paper

Before the effect of altitude could be calculated, it was necessary to establish how dissipation by convection is related to temperature, air density, and air movement. This was determined by tests made in 1921. Dissipation by radiation is well known.[6] Thus, the paper is divided as follows:

(A) Tests on heated plates, to determine the variation of convection with temperature, air density and air movement.

(B) Comparison of results with those of other investigators.

(C) Final equations, which are applicable to various types of electrical apparatus, and the premises from which they were derived.

(D) Comparison of calculations with test results.
- a. Plates tested in the drum.
- b. 7½ kv-a. synchronous motor tested in the drum.
- c. 2250-h. p. synchronous motor tested at Lynn, Mass. and then at Cerro De Pasco, S. A., altitude 12,000 ft.

(E) Calculation and tabulation of temperature corrections for various types of apparatus.

(F) Acknowledgments.

(G) Notation.

A. Tests on Heated Plates

In order to determine the effect of atmospheric pressure on temperature rise, electrically heated plates, Figs. 3 and 4, were tested in a large drum, Fig. 1, in which the pressure was controlled by a vacuum pump, and the temperature by water pipes, Fig. 2. In spite of the pipes, practically uniform wall temperatures were secured by surrounding the plates by a cylindrical card-board lining, Fig. 2.

5. High velocity of cooling air relative to the velocity in "free convection," that is, air movement produced by temperature difference alone.

6. Stefan-Boltzman Law: $W_r = 5.7\, e\, (T_2^4 - T_1^4) \times 10^{-12}$ watt sper sq. cm. where T_2 and T_1 are respectively the absolute temperatures of the surface radiating, and of the surface receiving, the heat, and e is the constant of emissivitv.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

Temperatures were measured by thermo-couples:

(a) Partially embedded at a number of points at the surface of the card-board;

(b) Suspended in ambient air;

(c) Soldered on the surface of the plate.

Tests were made with and without fan to determine the effect of air movement—that is, to determine the relative effects of "free" and "forced" convection. The tests are thus divided into groups: (1) Free Convection; (2) Forced Convection.

1. *Free Convection.* A number of preliminary tests were made on the "single plate," shown in Fig. 3. However, slight uncertainties regarding dissipation from the sides and bottom,[7] precluded these particular data from influencing final conclusions regarding free convection. It is worth noting, however, that the results checked well with subsequent, more accurate data.

To avoid such uncertainties a "double plate," Fig. 4, was used. It was two steel plates with a heating element, between them, thus affording practically uniform surface and temperature. The plate surfaces were vertical.

Tests were made at four different pressures, namely 30, 22, 15 and 7 in. (absolute) of mercury. At each pressure a number of points was taken, giving curves of temperature rise vs. watts input, Fig. 5.

7. Although these were heavily insulated from the heated surface.

The computed zero pressure curve, Fig. 5, gives the watts dissipated by radiation. It is important to establish this curve accurately, since conclusions regarding convection rest upon it. It was arrived at in two different ways: analytically, from the Stefan-Boltzman Law,[8] and graphically, by extrapolating the watts-pressure curves, Fig. 7, to zero pressure. The curves in Fig. 7 were derived from Fig. 5.

The following method was used in analyzing the test curves given in Fig. 5. Since convection is a function of pressure, whereas radiation is not, it follows that the difference between any two curves as measured at constant temperature rise, must be the difference in convection produced by the two different pressures. Therefore, for any curve, Fig. 5, the abscissas, as reckoned from the radiation curve, instead of from zero watts, give the dissipation by convection. In this way, the curves in Fig. 8 were derived showing the variation of dissipation by pure convection, with temperatue rise and pressure.

Next, the plate was given a coat of aluminum paint, and tests under otherwise similar conditions were repeated. The amount of convection, as found by subtracting the radiation loss from the total watts input, should be practically unchanged by the change in paint; and it was so found. The radiation curve with aluminum paint was obtained by using the

8. Assuming $e = 0.9$ for the blackened surface.

TABLE I

CALCULATED PER CENT CORRECTION IN TEMPERATURE RISE FOR EACH 1000 METERS ALTITUDE, CALCULATED IN SECTION E

NOTE: These values are not proposed for A. I. E. E. rules. They might form the basis for rules; but, in this table, they merely represent the final results of the paper, as calculated under the assumptions in Section E.

Apparatus	Element	Per cent Temp. Corr.* per 1000 Meters x_m as applied to surface temperature rise	as applied to copper temperature rise

emissivity e for aluminum given by Langmuir.[9] The close agreement thus found, was an additional check on the radiation curve. See Fig. 12.

It is assumed that the rate of dissipation by convection, W_c, is the following function of temperature rise θ and pressure p:

$$W_c = k\,\theta^l\,p^m \tag{1}$$

Plotting the data given in Fig. 8 on log-log paper, Figs, 9 and 10, the following values were found: $l = 1.3$. $m = 0.54$.

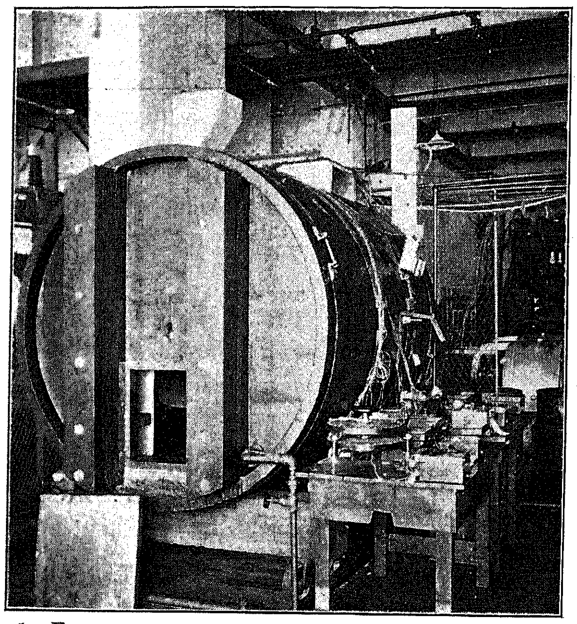

FIG. 1—EXTERNAL VIEW OF DRUM USED IN ALTITUDE TESTS

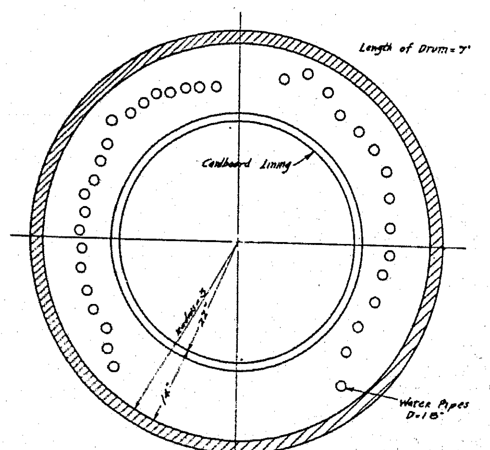

FIG. 2—CROSS SECTION OF DRUM SHOWING WATER PIPES AND CARDBOARD LINING

The data in Figs. 5 and 8 were plotted in another form, Fig. 11, convenient for the present study, showing the increase in temperature rise $\dfrac{\Delta\,\theta}{\theta_s}$ vs. the pressure p, for the same watts dissipated. One of these curves gives this increase for 47 per cent[10] convection and the other for 100 per cent convection. Since the present investigation is only concerned with the range[11] 20 in. to 30 in., the curves have been approximated by straight lines, Fig. 11, cutting the curves at 23 in.

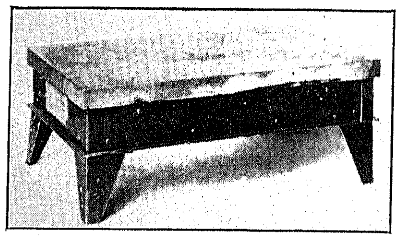

FIG. 3—SINGLE PLATE USED IN ALTITUDE TESTS

2. *Forced Convection.* Tests were made on the single plate[12] using a 16 in. fan for ventilation. First, the fan blast was directed across the plate, parallel with the surface; then, at an angle of 45 deg. The plate surface was horizontal. The fan speed was

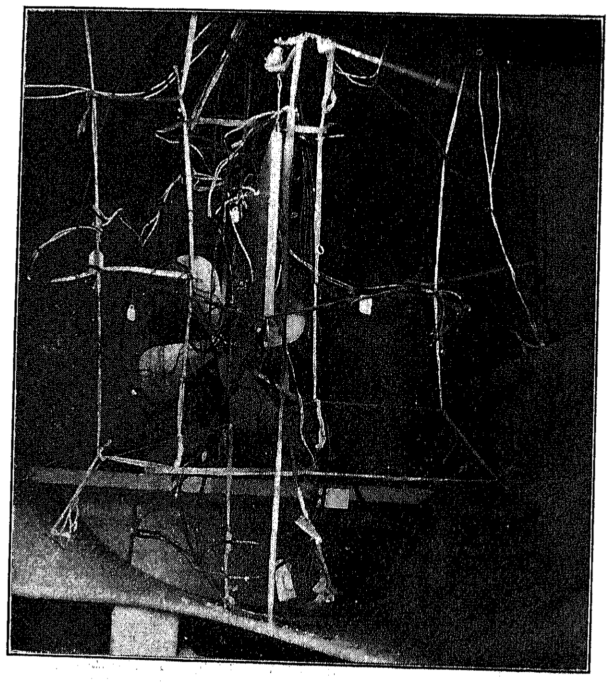

FIG. 4—DOUBLE PLATE MOUNTED IN DRUM, AS USED IN ALTITUDE TESTS

9. *Trans. Am. Chem. Soc.*, Vol. XXIII, p. 229, 1891, e = 0.67 at 325 deg. K, e = 0.60 at 350 deg. K, e = 0.53 at 365 deg. K, e = 0.45 at 400 deg. K.

10. 47 per cent convection, 53 per cent radiation, as found by comparing the radiation curve with total watts curve at 30 in. in Fig. 5.

11. This corresponds to altitudes up to about 12,000 ft. = 3700 meters.

12. Although these tests were subject to slight uncertainties, as discussed under "Free Convection," yet the errors, which were small in the latter case, are negligible in this case, where the blast across the heated surface carried off practically all of the heat. Moreover, this investigation is concerned with comparative, not absolute results. Forced convection was tried on the double plate, but the edge of the plates split the stream of air, caused eddies and therefore non-uniform temperatures over the surfaces.

kept constant under all conditions, giving a maximum air velocity of 1000 ft. per min.

The results are shown in Figs. 13 and 14. These were analyzed, in the same manner as the "free convec-

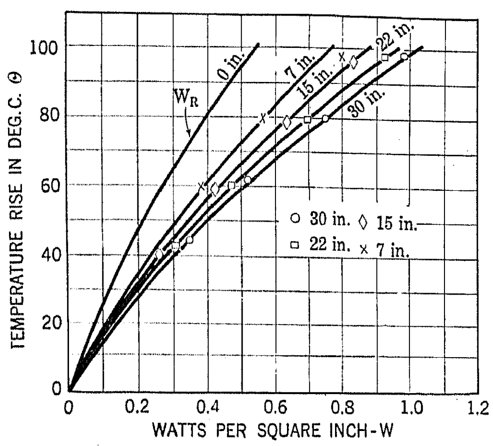

FIG. 5—TEST CURVES ON DOUBLE PLATE—FREE CONVECTION

tion" tests and the average results given for forced convection,

$$W_c \sim \theta^{1.00}\, p^{0.73}$$

3. *Summary of Results, Plate Tests.*

Free Convection, $W_c \sim \theta^{1.3}\, p^{0.5}$

Forced Convection, $W_c \sim \theta^{1.0}\, p^{0.73}$

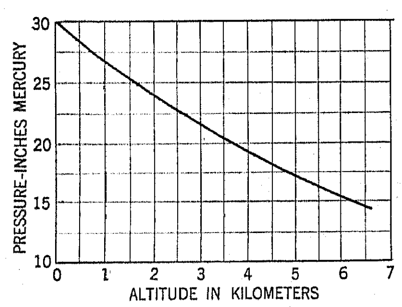

FIG. 6—ATMOSPHERIC PRESSURE—ALTITUDE CURVE

The per cent increase in temperature rise y_m per 1000 m. altitude as determined by the straight line approximation, Fig. 11 is given in Table II.

TABLE II

Convection W_c	Free or Forced Convection	y_n
47 per cent	Free	2.20 per cent
100 per cent	Free	4.80 per cent
74 per cent	Forced	5.50 per cent
100 per cent	Forced	8.5 per cent

B. COMPARISON OF RESULTS WITH THOSE OF OTHER INVESTIGATORS

1. *Free Convection.* The results of previous investigations can be put in the form,

$$W_c \sim \theta^l\, p^m$$

They are:

	l	m
Dulong & Pitt (1817)	1.23	n (n varies from 0.38 to 0.517 with nature of gas.)
Lorenz[13]	1.25	0.5
Kennelly & Sanborn[14]	0.5	—
Compan[15]	1.23	0.45
Montsinger[1]	1.25	—
Davis[4]	1.23	0.466
Griffiths & Davis[16]	1.25	—
Rice[17]	$1.0 + \frac{n}{2}$	n

The results found by the authors for free convection are: $l = 1.3$, $m = 0.54$.

The agreement is good with the values listed above, there being only a slight difference in the exponent l.

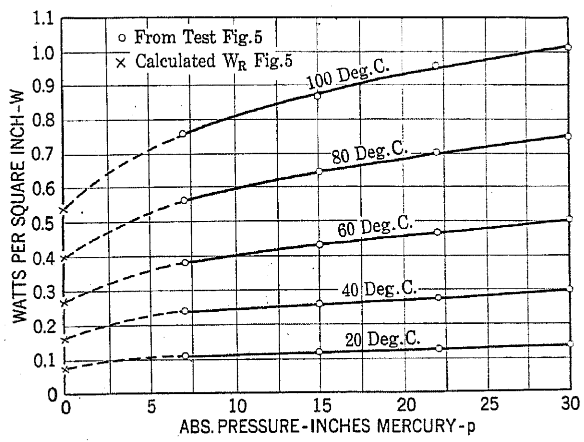

FIG. 7—DOUBLE PLATE TESTS—FREE CONVECTION: WATTS DISSIPATED VS. ABSOLUTE PRESSURE

The following average results will be used in equations for free convection:

$$W_c \sim \theta^{1.25}\, p^{0.5}$$

2. *Forced Convection.* Results of other investigations are:

Rice[18] $l = 1.0$ $m =$ (see footnote)

Davis[4] $l = 1.0$

The authors found for forced convection,

$$W_c \sim \theta^{1.0}\, p^{0.73}$$

Data regarding W_c as function of p for forced convection are not available to as satisfactory extent as

13. L. Lorenz, *Ann d'Phys.*, Vol. XIII, p. 582, 1881.

14. A. E. Kennelly & H. S. Sanborn, *Proc. Am. Phil. Soc.*, Vol. LM, p. 55, 1914.

15. Paul Compan, *Ann d'Phys.*, Vol. 26, p. 488, 1902.

16. Dept. of Scientific & Industrial Research, Food Investigation Board, Sp. Report 9—H. M. Stationary Office London, 1922.

17. C. W. Rice, Mid-Winter Meeting A. I. E. E., Feb. 1924. Rice finds that n varies with type of surface from ½ to 2/3, but that for most surfaces, $n \simeq$ ½. This gives $n = 1.25$, $m = 0.5$.

18. C. W. Rice, A. I. E. E. JOURNAL, Dec. 1923, p. 1288. Rice found that m varies from ½ to 1 depending on the shape and nature of surface, and on the degree of turbulence.

for free convection; but, Rice's results check reasonably with those found by the authors.

Thus, the following relation will be used in equations for forced convection in various apparatus.

$$W_c \sim \theta^{1.0} p^{0.75}$$

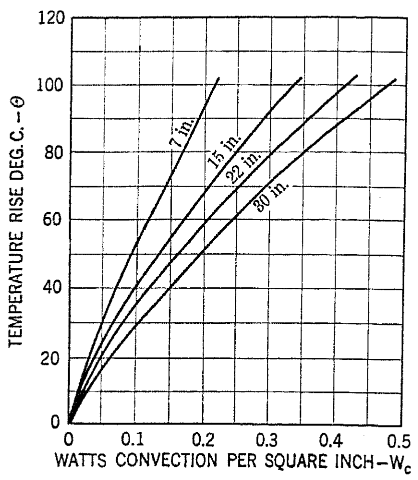

FIG. 8—DOUBLE PLATE TESTS—FREE CONVECTION—100% W_c CURVES. DERIVED FROM FIG. 5

In this, one may have confidence in the exponent of θ. There may be slight question as to the possible variation of the exponent of p with character of surface, air velocity, etc.; but, it is the authors' opinion that the value $m = 0.75$ is a reasonable average for the various conditions in electrical apparatus, to which the results have been applied in this paper.

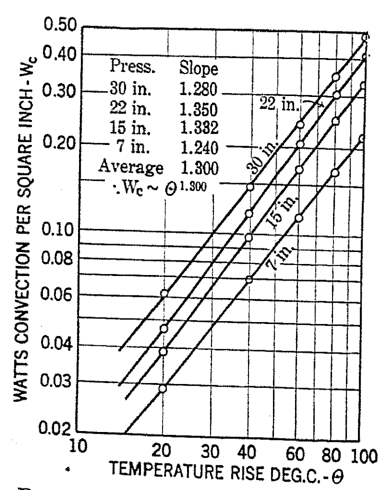

FIG. 9—DOUBLE PLATE TESTS—FREE CONVECTION LOG W_c VS. LOG θ

C. FINAL EQUATIONS AND PREMISES FROM WHICH THEY WERE DERIVED

1. *Premises.* (a) From (B), the dissipation by convection is:

$$W_c \sim \theta^l p^m \quad \text{(general)}$$
$$W_c \sim \theta^{1.25} p^{0.5} \quad \text{(free convection)}$$
$$W_c \sim \theta^{1.0} p^{0.75} \quad \text{(forced convection)}$$

(b) Dissipation by radiation,[10]

$$W_r = 5.7\, e\, (T_2^4 - T_1^4) \cong k\, (T_2 - T_1)^{1.25} = k\, \theta^{1.25} = k\, \theta^n$$

(c) Relation between altitude and pressure, as shown in Fig. 6.

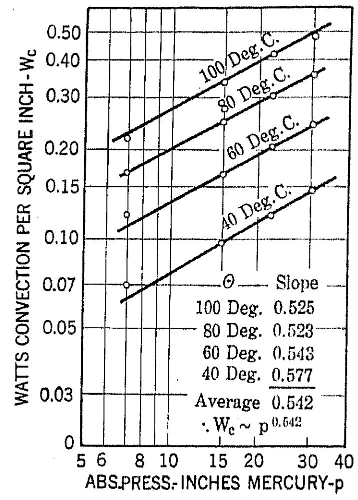

FIG. 10—DOUBLE PLATE TESTS—FREE CONVECTION LOG W_c VS. LOG p

(d) At constant speed of rotation the velocity of cooling air is the same at all pressures.

(e) Temperature rise of a given volume of air, for a given increment of heat, is inversely as the pressure.

(f) The total losses of electrical apparatus are

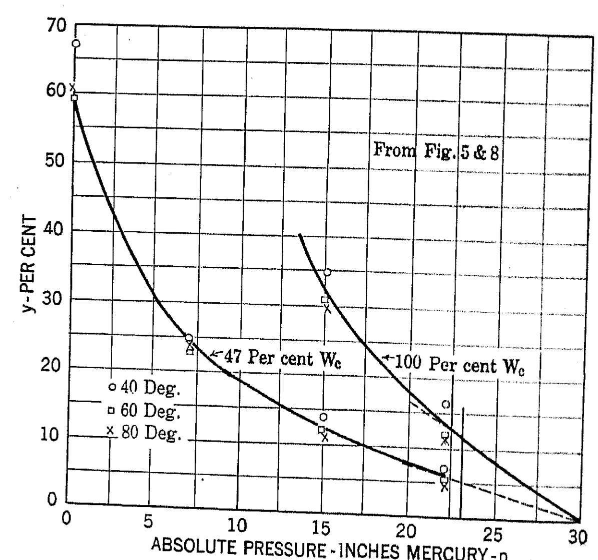

FIG. 11—DOUBLE PLATE TESTS—FREE CONVECTION

Test curves showing the general character of the increase in temperature rise above rise at 30 in. vs. absolute pressure inches mercury.

dissipated in two ways: convection and radiation. Thus, the total dissipation is,

$$W = W_c + W_r \qquad (1)$$

19. In the range up to a temperature rise of 100 deg. cent. this approximate relation holds. This is shown in Fig. 15, by plotting the following relations on log paper:

$$(T_2^4 - T_1^4) \text{ vs. } (T_2 - T_1)$$

It is assumed that T_1 (which, strictly, is the temperature of the surface receiving the radiation) is equal to the temperature of the cooling air.

(g) In electrical apparatus, the total heat dissipated from a surface comes from three possible sources:

1. Copper losses ($I^2 R$) which increase with altitude, due to the higher temperature and, therefore, higher resistance.

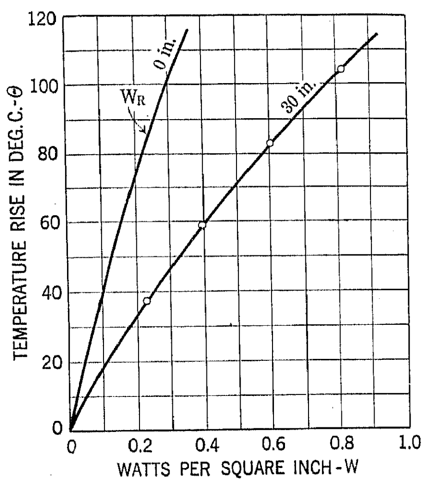

FIG. 12—TEST CURVE ON DOUBLE PLATE, COATED WITH ALUMINUM PAINT—FREE CONVECTION

2. Windage losses, which decrease with altitude, being inversely as the density of the air.
3. Core loss and other losses which are not affected by altitude.

(h) The total temperature difference between the copper and ambient air, comprises the drop through insulation, which drop is not affected by altitude; drop from the exposed surface to the cooling air; and the temperature difference due to the rise of the cooling air as it passes through the machine. The latter two are each affected by altitude.

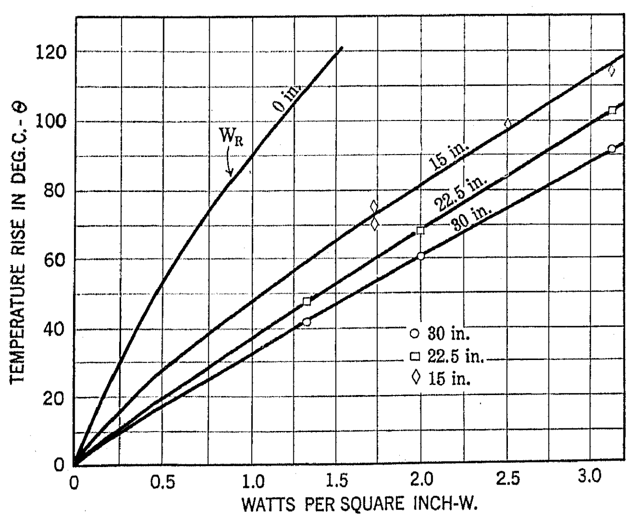

FIG. 13—TEST CURVES ON SINGLE PLATE, FORCED CONVECTION PLATE HORIZONTAL AND FAN DIRECTED HORIZONTALLY

(i) Free convection applies to stationary apparatus; forced convection, to all rotating apparatus.

(j) Sea-level pressure taken as 30 in. of mercury.

2. *Final Equations.* From the above premises, the following equations[20] are derived in Appendix A:

(*a*) *General.*

$$y = \frac{\Delta\theta}{\theta_s} = \frac{w_c D - k_1 \dfrac{\Delta p}{p_s} + k_2 \dfrac{\Delta p}{p\,a}}{w_c\,[1\,(1-D) - n] + n - k_3} \qquad (18)$$

where:

$$D = 1 - \left(\frac{p_a}{p_s}\right)^m ; \quad k_1 = b\,\frac{234 + T_s}{T_c}$$

$$k_2 = \frac{a\,\theta_s'}{T_c} ; \qquad k_3 = \frac{a\,\theta_s}{T_c}$$

$$T_c = 234 + T_s + a\,\theta_c^s$$

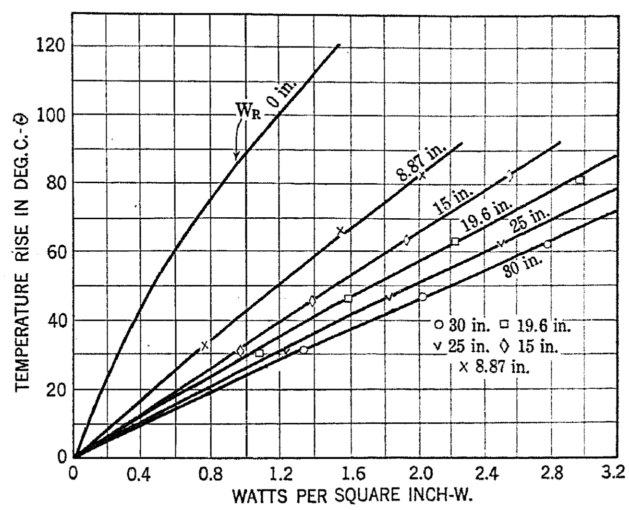

FIG. 14—TEST CURVES ON SINGLE PLATE, FORCED CONVECTION PLATE HORIZONTAL AND FAN POINTING DOWNWARD AT 50 DEG.

and where ($\Delta\,\theta$) is the increase (due to altitude) in *surface* temperature rise above the rise (θ_s) at sea level.

$$z = \frac{\Delta\,\theta'}{\theta_s} = \frac{\Delta\,p}{p_a} \qquad (20)$$

where ($\Delta\,\theta'$) is the increase, due to altitude, in temperature rise of the cooling air above its rise (θ_s') at sea level.

also

$$x = \frac{\Delta\,\theta + \Delta\,\theta'}{\theta_s + \theta_s'} = y\,\frac{\theta_s'}{\theta_s + \theta_s'}\,(z - y) \qquad (24)$$

(*b*) *Special Cases and Approximations.*[21]

1. *Stationary Apparatus—Free Convection.*

$$y_m = y/A = \frac{w_c\,D}{A\left[\,1.25\,(1 - w_c\,D) - \dfrac{a\,\theta_s}{T_c}\,\right]}$$

(as fraction) (26)

20. See "NOTATION" for definitions of symbols.
21. See Appendix A.

or, for altitude less than 3500 m., and assuming $\theta_s' = \theta_s$

$$y_m \cong y/A = w_c\left(4.8 + \frac{a\,\theta_s}{60}\right) \text{ in per cent} \qquad (28)$$

Eqs. (26) and (28) are plotted in Fig. 16.

(2) *Stationary Apparatus—Forced Convection.*

$$y_m = y/A = \frac{w_c D + \dfrac{a\,\theta_s'}{T_c}\,\dfrac{\Delta p}{P_a} - k_1 \dfrac{\Delta p}{P_s}}{A\left[1 - w_c D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}\right]}$$

(as fraction) **(30)**

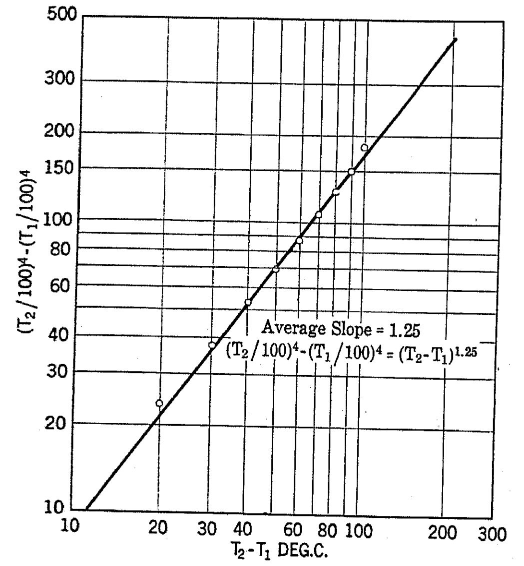

Fig. 15—Log $(T_2/100)^4 - (T_1/100)^4$ vs. Log $(T_2 - T_1)$

or, for altitude less than 3500 meters,

$$y_m \cong 14\, w_c + \frac{a\,\theta_s}{16} - 4.7 \text{ in per cent} \qquad (31)$$

Equations (29) and (31) are plotted in Fig. 17.

The above corrections y apply to *surface* temperature rise with respect to the cooling air. With respect to the ingoing air temperature, the correction is,

$$x_m \cong 11.6\, w_c \qquad (34)$$

(3) *Rotating Apparatus—Forced Convection.*

$$y_m \cong y/A = \frac{w_c D - 0.09\,\dfrac{\Delta p}{p_s} + \dfrac{a\,\theta_s'}{T_c}\,\dfrac{\Delta p}{p_a}}{A\left[1 - w_c D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}\right]}$$

(as fraction) (35)

or, for altitudes less than 3500 m.,

$$y_m \cong 14\, w_c - 4 \quad \text{in per cent} \qquad (36)$$

Also

$$x_m \cong 10.7\, w_c \quad \text{in per cent} \qquad (37)$$

D. Comparison of Calculations with Test Results

1. *Plate Tests.* To properly appraise the value of this comparison, remember that in the analysis of the test data, convection and radiation were segregated into separate and different functional relations with respect to pressure and temperature rise. These relations were incorporated with other premises, Section C, into the general equations (**18**) and (**24**), applicable to conditions in various classes of apparatus.

Applying equation (**18**) to the conditions of the plate test, equations[22] (**38**) and (**39**) are obtained for free and forced convection respectively. These relations are represented in Figs. 16 and 17 by the curves $a\,\theta_s = 0$; they are also plotted in Fig. 20 with test points shown for comparison.

The test data referred to these curves comprise only four points:

Single plate:

$w_c = 1.0$ for forced convection
$w_c = 0.74$ " " "

Double plate:

$w_c = 1.0$ for free convection
$w_c = 0.47$ " " "

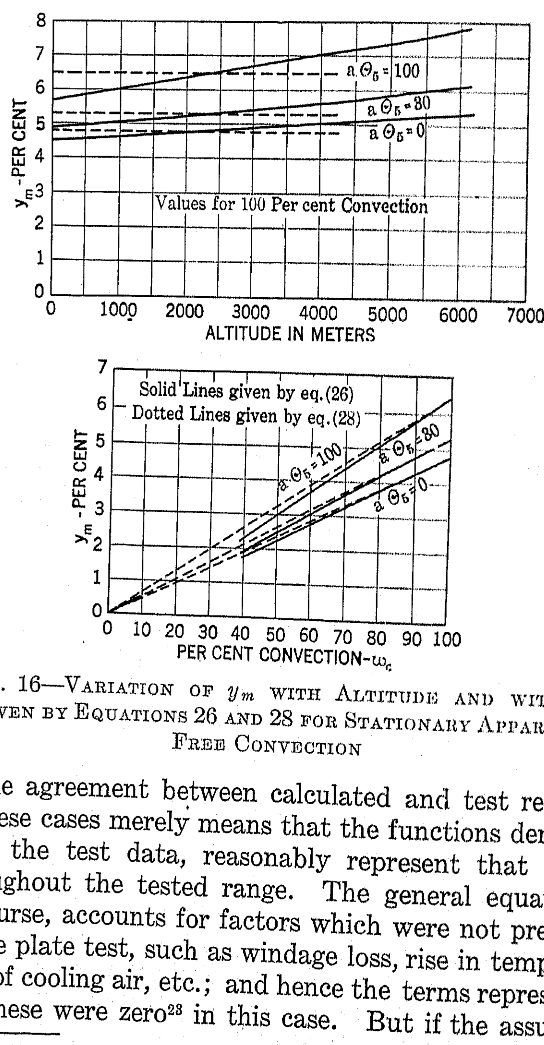

Fig. 16—Variation of y_m with Altitude and with w_c as Given by Equations 26 and 28 for Stationary Apparatus, Free Convection

The agreement between calculated and test results in these cases merely means that the functions derived from the test data, reasonably represent that data throughout the tested range. The general equation, of course, accounts for factors which were not present in the plate test, such as windage loss, rise in temperature of cooling air, etc.; and hence the terms representing these were zero[23] in this case. But if the assump-

22. In eq. (38) and (39), pressure is expressed in terms of both altitude and inches of mercury. The relation between these is shown in Fig. 6.

23. Since the test values of y were taken at constant watts dissipation, $a = 0$; and since the rise in temperature of the cooling air was negligible, $\theta'_s = 0$.

tions regarding these latter factors are sound, and if the tests show, as they do, that the former check with facts, one may have reasonable confidence in applying the general equation to various apparatus.

2. *Motor Tests.* In order to determine whether the calculations would give reliable results for more complicated commercial apparatus, a 7½-kv-a. synchronous motor, Fig. 21, was placed in the drum and tested at various pressures, namely, 30 in., 22 ½ in., 15 in. and

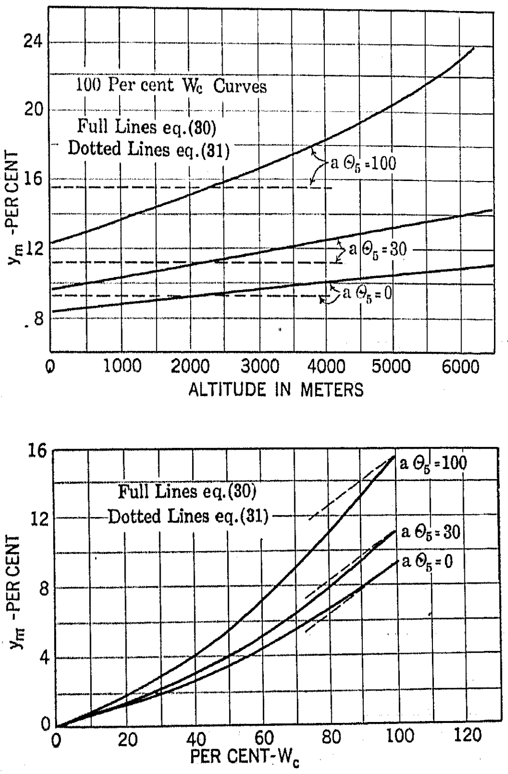

FIG. 17—VARIATION OF y_m WITH ALTITUDE AS GIVEN BY EQUATIONS 30 AND 31. THESE CURVES APPLY TO STATIONARY APPARATUS WITH FORCED CONVECTION

7 in. of mercury, absolute. The temperature of the armature was taken at several points by detectors placed in the slots *between coils*; and the temperature of the field copper was taken by resistance. Figs. 22 and 23 show the temperature rise of the armature and field respectively (above ingoing air temperature) vs. line current. A curve is drawn through the 30 in. points giving the temperature rises found on the machine by test at sea level conditions. The ordinates of this curve were increased by calculation with the equations derived in the paper. The new curves, with reference to the test points, show the agreement.

The curves were arrived at as follows: It is very roughly estimated that an open-type motor such as this would have about 80 per cent convection; average values[24] $a\,\theta_s = 30$ and $\theta_s'/(\theta_s + \theta_s') = 1/4$. From Fig. 6, 22½ in. corresponds to 2560 m. and 15 in. corresponds to 6180 m.

24. $a = 0.75$ and $\theta_s = 40$ deg. under the conditions of test.

Eq. (**34**)[25] gives the correction x_m which should be applied to the surface temperature rise at 30 in., to obtain the rise at 22½ in. Thus, at 22½ in., $x = A\,x_m = 11.6\,a\,w_c = 11.6 \times 2.56 \times 0.80 = 23.8$ per cent.

For 15 in., the general equation (**32**), plotted in Fig. 18, gives $x_m = 14.7$ per cent; and for 7 in., direct calculation gives the total correction $x = 193$ per cent. Thus, for 15 in. $x = 14.7 \times 6.18 \times 0.80 = 72.5$ per cent and for 7 in. $x = 193$ per cent.

These corrections apply to surface temperatures. The plotted points in Fig. 22 were very nearly[26] equal to the copper temperature rise θ_c. It is estimated that the surface temperature was 5 deg. lower[27] than that shown by the detector, at an armature current of 50 amperes, and this temperature difference is reduced as the square of current for other values. The corrections x given above were applied to the surface temperatures thus estimated, and then the insulation drop was again added to obtain the curves as shown in Fig. 22.

The temperature rises of the field winding for various air pressures were similarly analyzed. Here, the average temperature of the copper was taken by resistance, and it is assumed that at the load corresponding to 50 amperes-line, (3.1 amp. field), the surface tempera-

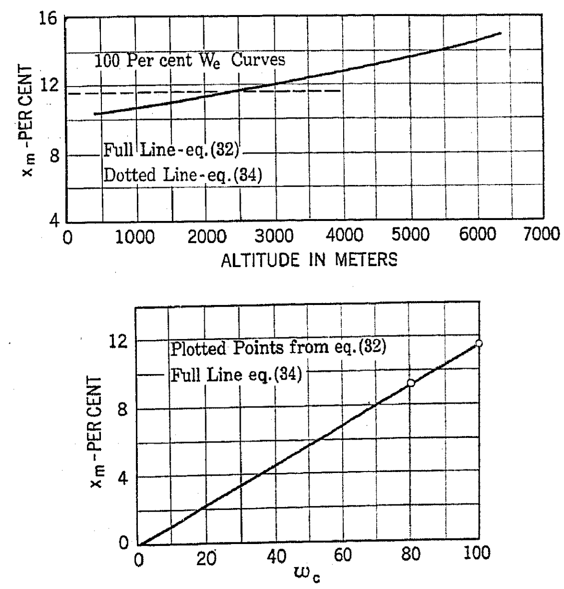

FIG. 18—VARIATION OF x_m WITH ALTITUDE AND WITH w_c AS GIVEN BY EQUATIONS 32 AND 34. THESE CURVES APPLY TO STATIONARY APPARATUS WITH FORCED CONVECTION AND ARE BASED ON $a\,\theta_s = 30$ AND $\theta_s'/\theta_s = 1/4$

ture rise is 3/4 of that of the copper. From these assumptions and following a similar procedure as in the armature test data, the curves Fig. 23 were drawn.

In considering these tests, it is worth noting that the

25. This is the approximate equation which gives practically the same results in the range 20 in. to 30 in., as the general eq. (24).

26. The temperature detectors were placed between the coils, the coils being insulated for low voltage—220 volts.

27. Insulation drop, which is not affected by altitude.

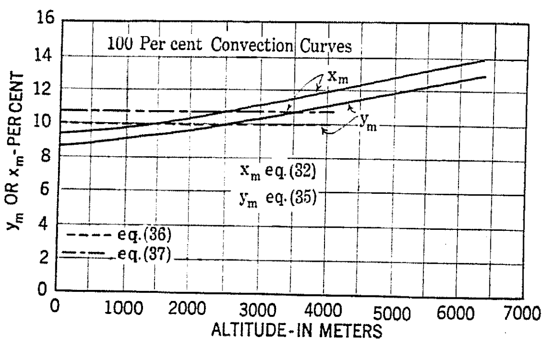
7-in. pressure corresponds to an altitude of about 43,000 ft.

3. *Cerro De Pasco Synchronous Motor.* Rated ATI-2-2550-h. p. 2000-kw.—3600-rev. per min.—2300-volt.

Tests at Aroya Plant of Cerro De Pasco Corp., taken by A. Giese.

This motor was installed at an altitude of 12,200 ft. (3700 m.). It had been given very careful tests at Lynn, Mass. (sea level) and these were repeated at the altitude. However, the latter were very unsatisfactory for the following reasons:

1. The temperature indicator was out of order; hence the only temperatures taken were surface temperatures, which were read immediately after the shut-down.



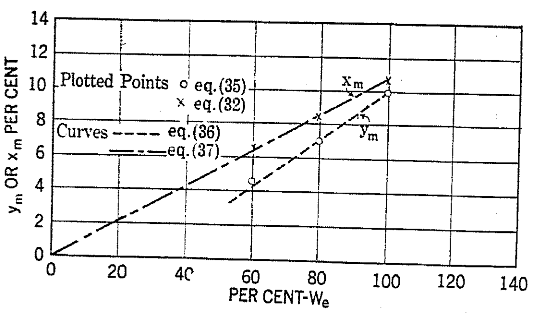


FIG. 19—VARIATION OF y_m WITH ALTITUDE AND w_c AS GIVEN BY EQUATIONS 35 AND 36. VARIATION OF x_m WITH ALTITUDE AS GIVEN BY EQUATIONS 32 AND 37

These curves apply to rotating apparatus, forced convection and are based on $a\,\theta_s = 30$, $\theta_s'/\theta_s = 1/4$ and $b = 0.10$.

2. Full load could not quite be obtained on the motor.

3. The power factor was not reported.

4. The field resistance was taken only after shut-down.

5. The field current was more, the armature voltage less, than at Lynn.

On the other hand, a small amount of information was given as follows:

1. Accurate temperatures were taken for the rise in temperature of the air passing through the machine.

2. The shut-down temperatures allow a rough sort of comparison for the field temperature rise.

3. Shut-down temperatures at Lynn and Cerro De Pasco can be compared.

Barometer Reading		Volts line	Amperes line	Amperes field	Kw.
Lynn	29.6 in.	2300	498	93.5	1990
Cerro De. Pasco	19.4 in.	2240	495	100.0	1900

Difference is 10.2 in., corresponding to $A - 3.7$.

$$z = \frac{\Delta p}{p_a} = \frac{10.2}{19.4} = 52.5 \text{ per cent} \quad x_m = 11.5 \text{ per cent}$$

(Fig. 18)

$$x = 11.5\,A\,w_c = 11.5 \times 3.7 \times 1.0 = 42.5 \text{ per cent.}$$

COOLING AIR

Lynn						Cerro de Pasco		
Test at 1990-kw. load Temp. deg. cent.			Lynn rise corrected for 1900 kw.	z	Calc. rise	Test at 1900-kw. load Temp. deg. cent.		
In	Out	Rise				In	Out	Rise
28.7	45.7	17.0	16.0	52.5	24.4	20.7	44.5	23.8

FIELD TEMPERATURE

—LYNN—

Ambient	Field copper	rise	Temp. Rise corrected for 1900 kw.	Estimated * surface Temp. rise
28.2	69.8	41.6	40	20

CERRO DE PASCO

x	Calc. Surface Rise	Calc. Copper Temp. Rise	Ambient Temp. (test)	Shut down Temp.	
				Calc.	Test
42.5	28.5	48.5	19.7	68.2	65.4

*This is merely a rough guess. These field temp. data are not of great value because the surface temperature is not definitely known.

The following shows a comparison of the maximum readings of thermometers placed on motor after shut-down:

LYNN

	Temp.	Room Temp.	Rise θ	x
Arm. core avg	52.9	28.2	24.7	42.5 per cent
Arm. core max	57.0		28.8	
Vent ducts avg	54.8		26.6	
Vent ducts max	55.0		26.8	
Ribs avg	51.0		22.8	
Ribs max	52.0		23.8	

CERRO DE PASCO

	θ_a	θ_a corr. 1900 kw.	Room Temp.	Calc. Temp.	Test Temp.
Arm. core Avg	35.2	33.6	19.7	53.3	59.7
Arm. core max	41.0	39.1		58.8	62.0
Vent ducts avg	37.9	36.2		55.9	55.3
Vent ducts max	38.2	36.5		56.2	57.0
Ribs avg	32.5	31.0		50.7	49.8
Ribs max	33.9	32.4		52.1	50.0

Of the above data, those relating to air temperatures are of the greatest value as definite, carefully taken readings. They also afford the best check on calculations. The thermometer readings show as good agreement with calculations as might be expected. It should be noted that the temperature corrections are of the order of 40 to 50 per cent.

E. Calculation of Temperature Correction for Various Types of Apparatus

1. *Transformers*:

(*a*) *Oil-immersed, self-cooled, Plain tank. Free Convection.*

Assume:

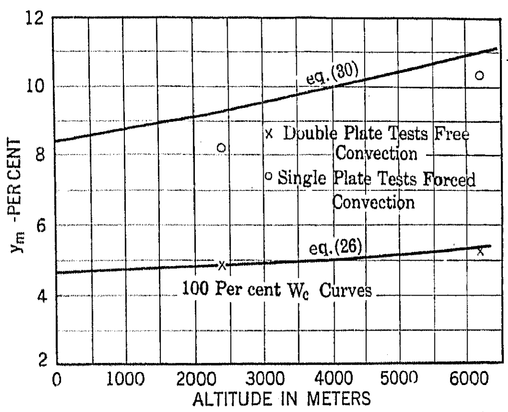
$$a = 2/3; \quad \theta_s = 40; \quad w_c = 0.45; \quad \theta_{cs} = 55$$

From Fig. 16B, taking $a\ \theta_s = 30$, $y_m = 2.2$ per cent. Based on $\theta_{cs} = 55$ deg., $y_m' = 1.6$ per cent.

Corrugated, tubular and radiation tanks. Free Convection.

Assume:

$$a = 2/3; \quad \theta_s = 40; \quad w_c = 0.8; \quad \theta_{cs} = 55$$



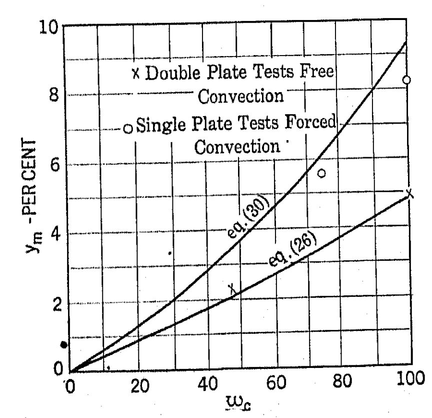


Fig. 20—Comparison of Test Points with Calculated Curves for Free and Forced Convection—Plate Tests

From Fig. 16B,

$$y_m = 4.2 \text{ per cent}; \quad y_m' = 3.06 \text{ per cent}$$

(*b*) *Water-cooled.*

Correction = 0

(*c*) *Natural Draft.*

Free Convection. Here, the hot spot temperature of the coil surface may be practically as high as the average temperature of the copper, as measured by resistance.

Thus $\theta_s = \theta_{cs} = 50$

Assume further:

$$a = 1.0; \quad w_c = 0.8$$

Question arises whether correction should be made on account of temperature rise θ_s' of cooling air above ingoing air. Eq. (**24**) for x is based on *constant* velocity of cooling air, as produced by a fan, and is

$$x = y \frac{\theta_s'}{\theta_s + \theta_s'} (z - y) \qquad (\mathbf{24})$$

But in the natural draft transformer the velocity increases with temperature rise. For constant velocity

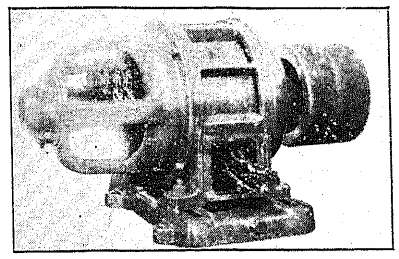

Fig. 21—Synchronous Motor which Was Tested in the Drum Fig. 1. Rated: 7.5-Kv-a. 60-Cycles 1800-Rev. per Min. 110-Volts

z is always *slightly* greater than y. Increased velocity would, of course, decrease z. In the absence of definite data, it is assumed that in this case

$$z = y.$$

Hence, the second term in (**24**) vanishes, that is, the correction in y for θ_s' is zero.

Thus, from Fig. 16B,

$$y_m = 4.6 \text{ per cent} \qquad y_m' = 4.6 \text{ per cent}$$

(*d*) *Air Blast.*

Forced Convection.

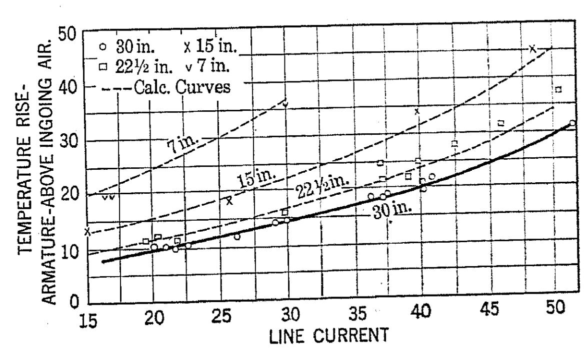

Fig. 22—Comparison Test Results with Calculated Curves. Temperature Rise of Armature Coils (as Given by Detectors in the Slots) above Ingoing Air Temperature vs. Line Current

Assume:

$$a = 1.0; \quad w_c = 1.0; \quad \theta_s + \theta_s' = 50 \text{ deg. cent.};[28] \quad \theta_{cs} = 50 \text{ deg. cent.}$$

$$T_c = 354 \text{ deg. cent.}; \quad b = 0.10; \quad T_s = 20.$$

Total temperature rise of air $0 = 25$ deg. cent. Taking half of this for θ_s' the average rise of cooling air,

$$\theta_s = 37.5; \quad \theta_s' = 12.5; \quad \frac{\theta_s'}{\theta_s + \theta_s'} = 1/4$$

28. As in natural draft transformer, the spot surface temperature may be practically equal to the copper temperature.

Applying eq. (**29**) and (**32**),[29]

$y_m = 10.7$ per cent $x_m' = x_m = 11.2$ per cent

2. *Reactors and Bus Bars*:

Free Convection.

Assume:

$a = 1.0$ $w_c = 0.8$ $\theta_s = \theta_{cs} = 60$ deg. cent.

From Fig. 16B,

$y_m = 4.7$ per cent $y_m' = 4.7$ per cent

3. *Rheostats, Meters, Relays and Miscellaneous Stationary Apparatus.*

Free Convection.

Assume:

$a = 0.5$ $\theta_s = 50$ deg. $w_c = 0.8$

From Fig. 16B,

$y_m = 4.2$ per cent

4. *Totally Enclosed Motors*:

The surface temperatures of the iron and coils are considered. The total temperature drop between these surfaces and the outside air, comprises

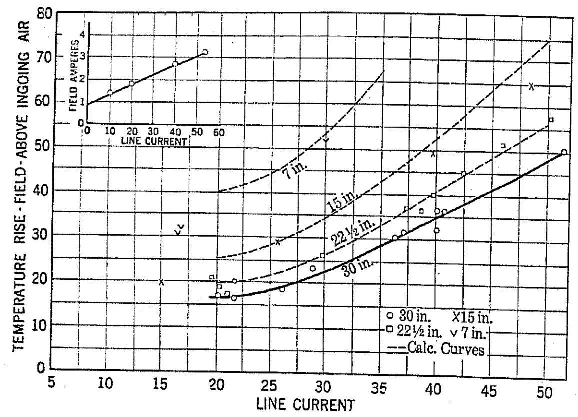

FIG. 23—COMPARISON TEST RESULTS WITH CALCULATED CURVES, TEMPERATURE RISE OF FIELD, BY RESISTANCE, ABOVE INGOING AIR TEMPERATURE VS. LINE CURRENT

(a) drop from hot surface to inside air;
(b) drop from inside air to casing;
(c) drop through casing;
(d) drop from casing to ambient air.

(a) and (b) are forced convection; (c) independent of altitude; (d) free convection. Assuming the following distribution of these at sea level,

(a) 10 deg., (b) 10 deg., (c) 5 deg., (d) 35 deg.

the following resultant correction, applicable to coil surface rise, is calculated.

$x_m = 5.35$ per cent

5. *Open Type Rotating Apparatus.*

Forced Convection.

(*a*) *Stator Coils.*

Assume:

$a = 0.7$ $\theta_s \times \theta_s' = 40$ $w_c = 0.9$ $\theta_s' = 10$ $\theta_{cs} = 55$

From eq. (**35**),

$y_m = 8$ per cent

and eq. (**32**)

$x_m = 8.94$ per cent $x_m' = 6.5$ per cent

(*b*) *Rotor Coils, Insulated.*

Same as (*a*), $x_m = 8.94$ per cent $x_m' = 6.5$ per cent

(*c*) *Rotor Coils, Bare Copper Strip.*

Assume:

$a = 1.0$ $w_c = 0.9$ $\theta_s \times \theta_s' = 55$ $\theta_{cs} = 55$ $\theta_s' = 10$

From (**35**) and (**32**)

$y_m = 9$ per cent

and

$x_m = 9.5$ per cent $x_m' = 9.5$ per cent

6. *Enclosed Type Rotating Apparatus with Directed Ventilation.*

Forced Convection.

(*a*) *Turbo-Generators*:

Armature Coils:

Assume:

$a = 0.7$ $w_c = 1.0$ $\theta_s + \theta_s' = 35$ $T_s = 20$
$\theta_{cs} = 60$ $T_c = 314$ $\theta_s' = 12$

By eq. (**35**) and (**32**)

$x_m = 10.69$ per cent $x_m' = 6.25$ per cent

Rotor:

Assume:

$a = 1.0$ $w_c = 1.0$ $\theta_s + \theta_s' = 52$ $\theta_s' = 12$
$\theta_{cs} = 80$ $T_s = 20$ $T_c = 334$

Thus,

$x_m = 11.07$ per cent $x_m' = 7.15$ per cent

(*b*) *Other Apparatus in Class* (6)

Stator Coils. Same as (*a*)

$x_m = 10.69$ per cent $x_m' = 6.25$ per cent

Rotor Coils, insulated.

Same as stator coils.

$x_m = 10.69$ per cent $x_m' = 6.25$ per cent

x_m same as for surface rise of stator coils.

$x_m = 10.69$ per cent $x_m' = 10.69$ per cent

F. ACKNOWLEDGEMENTS

The authors gratefully acknowledge the valuable assistance of C. W. Cutler and R. F. Franklin in making tests and analyzing the data; also, of W. F. Dawson and A. Giese, in making tests on the 2250-h. p. synchronous motor.

G. NOTATION

A = altitude in thousands of meters

a = fraction of total heat dissipated from surface due to copper loss.

b = fraction of total heat dissipated from surface due to windage loss.

c = fraction of total heat dissipated from surface due to core loss and other losses.

$D = 1 - \left(\frac{P_a}{P_s}\right)^m$

e = emissivity constant in Stefan-Boltzman Law.

θ = temperature rise deg. cent. of the surface above the cooling air (cooling air may be of higher temperature than ambient air, as in machines with enclosed ventilation).

29. The unit correction, y_m = per cent correction per 1000 m. is based on values obtained for 23 in. pressure, $A = 2.4$. This approximation is made throughout the paper.

θ_s = θ at sea level.
θ_a = θ at altitude.
$\Delta\,\theta$ = $\theta_a - \theta_s$
θ' = temperature rise of the cooling air, above ambient air.
θ_s' = θ' at sea level.
θ_a' = θ' at altitude.
$\Delta\,\theta'$ = $\theta_a' - \theta_s'$
θ_{cs} = temperature rise of copper above ambient air temperature at sea level.
θ_{ca} = temperature rise of copper above ambient air temperature at altitude.
θ_i = temperature drop through insulation.
$\Delta\,\theta_c$ = $\theta_{ca} - \theta_{cs}$
p = absolute pressure, inches of mercury.
p_s = p at sea level (assumed to be 30 in.)
p_a = p at altitude.
$\Delta\,p$ = $p_s - p_a$
T_a = temperature ambient air deg. cent. at altitude.
T_c = $234 + T_s + a\,\theta_{cs}$.
T_2 = temperature heated surface deg. cent. absolute.
T_1 = temperature walls deg. cent. absolute.
T_s = " ambient air deg. cent. at sea level.
$\Delta\,T$ = $T_a - T_s$
W = total watts dissipated.
W_0 = W when copper temperature equals ambient temperature, T_s.
W_s = W at sea level.
W_a = W at altitude.
W_c = watts per square inch dissipated by convection.
W_r = " " " " " " radiation.
W_{cs} = W_c at sea level.
W_{ca} = W_c at altitude.
W_{rs} = W_r at sea level.
W_{ra} = W_r at altitude.
w_c = fraction of total watts, dissipated by convection at sea level = W_{cs}/W_s.
w_r = fraction of total watts, dissipated by radiation at sea level = W_{rs}/W_s.
$w_r + w_c = 1.0$.
x = fractional increase of surface temperature rise above ambient temperature $= \dfrac{\Delta\,\theta + \Delta\,\theta'}{\theta_s + \theta_s'}$
x_m = x per 1000 m.
$x_m' = \dfrac{\theta_s}{\theta_{cs}}\,x_m$
y = fractional increase of θ with altitude = θ/θ_s.
y_m = y per 1000 m.
$y_m' = \dfrac{\theta_s}{\theta_{cs}}$ = per cent temperature correction based on copper temperature.
z = fractional increase of θ' with altitude = θ'/θ_s'

Appendix A

1. Derivation of General Equation

The total power W from the surface considered, is dissipated by convection and radiation. Thus,

$$W = W_c + W_r \tag{1}$$

$W_0 = W$ when copper temp. = ambient air temperature T_s. Let,

a = fraction of W_0 due to copper loss, when the copper temperature = ambient temperature T_s.
b = fraction of W_0 due to windage loss.
c = " " " " " iron and other losses.

Thus,

$$a + b + c = 1.0 \tag{2}$$

The dissipated loss due to $i^2\,r$ at a copper temperature equal to the ambient temperature T_s is $a\,W_0$. At a temperature rise θ_{cs} of the copper above T_s, under operating conditions at sea level, the dissipated $i^2\,r$ loss at the same current would be[30]

$$a\,W_0\left(\frac{234 + T_s + \theta_{cs}}{234 + T_s}\right) = a\,W_0\left(1 + \frac{\theta_{cs}}{234 + T_s}\right) \tag{3}$$

At altitude, with an ambient temperature T_a, and a temperature rise θ_{ca} of the copper, the copper loss to be dissipated would be,

$$a\,W_0\left(\frac{234 + T_a + \theta_{ca}}{234 + T_s}\right) = a\,W_0\left[1 + \frac{(T_a - T_s) + \theta_{ca}}{234 + T_s}\right] \tag{4}$$

The component of W_0 due to windage loss at sea level is

$$b\,W_0 \tag{5}$$

and at altitude,

$$b\,W_0\,\frac{p_a}{p_s} = b\,W_0\left(1 - \frac{p_s - p_a}{p_s}\right) \tag{6}$$

Likewise, the component due to core loss, etc. at *any* altitude is

$$c\,W_0 \tag{7}$$

Consequently, the total dissipation at sea level is

$$W_s = a\,W_0\left(1 + \frac{\theta_{cs}}{234 + T_s}\right) + b\,W_0 + c\,W_0$$

or, by (2)

$$W_s = W_0\left[\frac{234 + T_s + a\,\theta_{cs}}{234 + T_s}\right] \tag{8}$$

Thus, the total dissipation at altitude is

$$W_a = W_0\left[\frac{234 + T_s + a\,(T_a - T_s) + a\,\theta_{ca} - b\,\dfrac{p_s - p_a}{p_s}\,(234 + T_s)}{234 + T_s}\right] \tag{9}$$

30. Greater in proportion to temperature of copper.

Dividing (8) by (9) and also adding and subtracting $a\ \theta_{cs}$ in the numerator of (9),

$$W_a = W_s\left[1 + \frac{a\ \Delta\ T + a\ \Delta\ \theta_c}{234 + T_s + a\ \theta_{cs}} - b\,\frac{\Delta\ p}{p_s}\ \frac{234 + T_s}{234 + T_s + a\ \theta_{cs}}\right] \qquad (10)$$

Equation (10) gives the total watts loss W_a dissipated at altitude, in terms of that at sea level. The next step is to deduce separate expressions for the power dissipated by convection and radiation, that is,

W_c and W_r

and to equate their sum to (10), in accordance with (1). Convection,

$$W_c \sim \theta^l\ p^m \qquad (11)$$

and radiation[31]

$$W_r \sim \theta^n$$

Thus it follows,

$$W_{ca} = W_{cs}\left(\frac{\theta_a}{\theta_s}\right)^l\left(\frac{p_a}{p_s}\right)^m$$

and

$$W_{ra} = W_{rs}\left(\frac{\theta_a}{\theta_s}\right)^n$$

Therefore,

$$W_a = W_{cs}\left(\frac{\theta_a}{\theta_s}\right)^l\left(\frac{p_a}{p_s}\right)^m + W_{rs}\left(\frac{\theta_a}{\theta_s}\right)^n \qquad (12)$$

In order to express results in terms of the fractional increase in temperature rise due to altitude, that is, in terms of

$$\frac{\theta_a - \theta_s}{\theta_s} = \frac{\Delta\ \theta}{\theta_s},$$

Expand $\left(\frac{\theta_a}{\theta_s}\right)^l$ by the binomial theorem. Thus,

$$\left(\frac{\theta_a}{\theta_s}\right)^l = \left(1 + \frac{\Delta\ \theta}{\theta_s}\right)^l = 1 + l\,\frac{\Delta\ \theta}{\theta_s} + \frac{l\,(l-1)}{2}\left(\frac{\Delta\ \theta}{\theta_s}\right)^2 + \ldots$$

or,[32] approximately,

$$\left(\frac{\theta_a}{\theta_s}\right) \cong 1 + l\,\frac{\Delta\ \theta}{\theta_s}$$

Similarly,

$$\left(\frac{\theta_a}{\theta_s}\right)^n \cong 1 + n\,\frac{\Delta\ \theta}{\theta_s} \qquad (13)$$

Substituting (13) in (12),

$$W_a = W_{cs}\left(\frac{p_a}{p_s}\right)^m\left(1 + l\,\frac{\Delta\ \theta}{\theta_s}\right) + W_{rs}\left(1 + n\,\frac{\theta}{\theta_s}\right) \qquad (14)$$

Equating (10) and (14), and substituting the following:

$$n\ w_r = n - n\ w_c$$

$$\Delta\ \theta' = z\ \theta_s' = \frac{\Delta\ p}{p_a}\ \theta_s' \quad \text{(by eq. 20)}$$

$$\Delta\ \theta_c = (\theta_a + \theta_a' + \theta_i) - (\theta_s + \theta_s' + \theta_i) = \Delta\ \theta + \Delta\ \theta' \qquad (15)$$

The drop θ_i through the insulation is not affected by altitude, and hence cancels out.

We have,

$$y = \frac{\Delta\ \theta}{\theta_s} = \frac{w_c\,D - b\,\dfrac{\Delta\ p}{p_s}\,\dfrac{234 + T_s}{T_c} + \dfrac{\Delta\ p}{p_a}\,\dfrac{a\ \theta_s'}{T_c} + \dfrac{a\ \Delta\ T}{T_c}}{w_c\,[l\,(1-D) - n] + n - \dfrac{a\ \theta_s}{T_c}} \qquad (16)$$

where

$$D = 1 - \left(\frac{p_a}{p_s}\right)^m$$

Expressing as k_s' those terms which are not functions of altitude, we get

$$y = \frac{\Delta\ \theta}{\theta_s} = \frac{w_c\,D - k_1\,\dfrac{\Delta\ p}{p_s} + k_2\,\dfrac{\Delta\ p}{p_a} + k_4}{w_c\,[l\,(1-D) - n] + n - k_3} \qquad (17)$$

where

$$k_1 = b\,\frac{234 + T_s}{T_c} \qquad k_2 = \frac{a\ \theta_s'}{T_c}$$

$$k_3 = \frac{a\ \theta_s}{T_c} \qquad k_4 = \frac{a\ \Delta\ T}{T_c}$$

If the ambient temperature at altitude and at sea level is the same, then

$$k_4 = 0$$

Then the general equation of the increase, y, in the *surface* temperature rise *above the cooling air is*,

$$y = \frac{\Delta\ \theta}{\theta_s} = \frac{w_c\,D - k_1\,\dfrac{\Delta\ p}{p_s} + k_2\,\dfrac{\Delta\ p}{p_a}}{w_c\,[l\,(1-D) - n] + n - k_3} \qquad (18)$$

2. Correction for Temperature Rise of Cooling Air above Temperature of Ingoing Air

A fan running at constant speed develops a pressure proportional to the inlet density of the air. The pressure drop due to the rate of flow of a given volume of air through given passages, is also proportional to the air density. The volume of air forced through the machine by fans would, therefore, not be changed significantly

31. See Fig. 15, in which it is shown that, in the range 0 to 100 deg. cent., n is approximately 1.25.

32. The error in neglecting the third term is as follows: if l is 1.0, as in forced convection, error is zero; if l = 1.25, as in free convection, and $\frac{\Delta\ \theta}{\theta_s}$ = 0.1, error = 1.5 per cent of *second term*; when $\frac{\Delta\ \theta}{\theta_s}$ = 0.3, it is 3.7 per cent. Thus, the error is within the accuracy with which l is known.

when the density of the air decreases; but the weight of air passing will decrease directly with the pressure. Therefore, if the losses in the machine are unchanged so that the same amount of heat must be carried away by the air, temperature rise of the air will be inversely proportional to its density, or to the atmospheric pressure.

Thus,

$$\frac{\theta_a'}{\theta_s'} = \frac{p_s}{p_a} \qquad (19)$$

by definition,

$$z = \frac{\theta_a' - \theta_s'}{\theta_s'} = \frac{p_s}{p_a} - 1 = \frac{\Delta p}{p_a} \qquad (20)$$

The correction y for rise above cooling air temperature is given by equation (18). It is now necessary to combine y and z so as to give x, the increase in the surface temperature rise above ingoing air. By definition,

$$x = \frac{\Delta \theta + \Delta \theta}{\theta_s + \theta_s'} \qquad (21)$$

$$\left.\begin{aligned} \theta_a &= (1 + y)\,\theta_s \\ \theta_a' &= (1 + z)\,\theta_s' \end{aligned}\right\} \qquad (22)$$

$$\theta_a + \theta_a' = (1 + x)\,(\theta_s + \theta_s') \qquad (23)$$

Substituing (22) in (23)

$$x = y\frac{\theta_s}{\theta_s + \theta_s'} + z\frac{\theta_s'}{\theta_s + \theta_s'} = y + \frac{\theta_s'}{\theta_s + \theta_s'}(z - y) \qquad (24)$$

3. Special Cases

(a) *Stationary Apparatus—free convection.*

$m = 1/2 \quad l = 1.25 \quad n = 1.25 \quad b = 0 \quad \theta_s'^{33} = 0$

Substituting these values in (18),

$$y = \frac{\Delta \theta}{\theta_s} = \frac{w_c\, D}{1.25\,(1 - w_c\, D) - k_3}$$

$$= \frac{w_c\, D}{1.25\,(1 - w_c\, D) - \dfrac{a\,\theta_s}{T_c}} \qquad (25)$$

In terms of y_m,

$$y_m = y/A = \frac{w_c\, D}{A\left[1.25\,(1 - w_c\, D) - \dfrac{a\,\theta_s}{T_c}\right]} \text{ as fraction} \qquad (26)$$

Equation (26) is plotted in full lines in Figs. 16. Fig. 16A is for 100 per cent convection, that is, $w_c = 1.0$, with $a\,\theta_s$ as parameter, and A as abscissa. The relation between A and p is given on Fig. 6. It will be noted that these curves can be closely approximated within the range $A = 0$ and $A = 3.5$, *i. e.*, 3500 meters, by the dotted lines, which cut the curves at 2400 m. = 23 in. pressure. This, of course, covers the practical range. The dotted lines are expressed by,

$$y_m \cong 4.8 + \frac{a\,\theta_s}{60} \text{ in per cent} \qquad (27)$$

In 16B, equation (26) is plotted, y_m vs. w_c, with $a\,\theta_s$ as parameter. Here the 2400-m. point, established in 16A, is taken as the basis for approximation. It is seen that the full line curves may be approximated by the dotted lines, which are expressed by

$$y_m \cong w_c\left(4.8 + \frac{a\,\theta_s}{60}\right) \text{ in per cent} \qquad (28)$$

This is the final, approximate equation for the special case of stationary apparatus with free convection.

(b) *Stationary Apparatus—forced convection.*

$m = 3/4 \quad l = 1.0 \quad n = 1.25 \quad b = 0$

Substituting these values in (18),

$$y = \frac{\Delta \theta}{\theta_s} = \frac{w_c\, D + \dfrac{a\,\theta_s'}{T_c}\,\dfrac{\Delta p}{p_a} - k_1\,\dfrac{\Delta p}{p_s}}{1 - w_c\, D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}}$$

and

$$y_m = y/A$$

$$= \frac{w_c\, D + \dfrac{a\,\theta_s'}{T_c}\,\dfrac{\Delta p}{p_a} - b\,\dfrac{234 + T_s}{T_c}\,\dfrac{\Delta p}{p_s}}{A\left[1 - w_c\, D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}\right]} \qquad (29)$$

If θ_s' and b are negligible,

$$y_m = \frac{w_c\, D}{A\left[1 - w_c\, D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}\right]} \text{ as fraction} \qquad (30)$$

Plotting, by equation (29), y_m vs. A, and also vs. w_c, as in the case of free convection, the full line curves on Figs. 17A and 17B are obtained. These curves are approximated, *within the range* $w_c > 0.75$, by the dotted lines, which are expressed by

$$y_m \cong 14\, w_c + \frac{a\,\theta_s}{16} - 4.7 \text{ in per cent} \qquad (31)$$

The above corrections apply to the *surface* temperature rise. If there is an appreciable rise in temperature of the cooling air, as in apparatus with enclosed ventilating systems, then further correction is necessary. Thus the total correction x of surface temperature rise above the temperature of ingoing air is, by eq. (24)

$$x = y + \frac{\theta_s'}{\theta + \theta_s'}(z - y)$$

and

$$x_m = x/A = y_m + \frac{\theta_s'}{\theta_s + \theta_s'}(z/A - y_m) \qquad (32)$$

33. θ_s' modifies the k_2 term in (18). Since T is of the order of 275 deg., each degree of θ_s' would change the value of

$$k_2\,\frac{\Delta p}{p_a} = \frac{a\,\theta_s'}{T_c}\,\frac{\Delta p}{p_a}$$

by about ⅓ of a per cent; and this term is small compared with the $w_c\, D$ term. Therefore, since θ_s' is small in any case except, perhaps, corrugated surfaces, or natural draft transformers, it will be neglected except in these two cases, which will be discussed in section E of the paper.

In order to obtain approximate numerical values of x for apparatus with forced cooling, such as air blast transformers, assume:

(1) total temperature rise of air = 25 deg. cent.
(2) surface rise 50 deg. cent.
(3) $a = 0.8$
(4) $w_c = 1.0$

Thus

$$\theta_s' = 25/2 = 12.5 \text{ deg. cent.}$$
$$\theta_s = 50 - 12.5 = 37\tfrac{1}{2} \text{ deg. cent.}$$
$$a\,\theta_s = 30$$

$$\frac{\theta_s'}{\theta_s + \theta_s'} = \tfrac{1}{4}$$

As in previous cases, basing the approximate correction y_m on the value at $p_a = 23$ in., $A = 2.4$, the full-line curves, Figs. 18A and 18B for x_m are obtained by substituting the above data in (29) and (32).

For altitudes up to 3500 m. the full-line curve Fig. 18A for $w_c = 1.0$ can be roughly approximated by the constant value

$$x_m \cong 11.6 \tag{33}$$

and Fig. 18B, almost exactly by

$$x_m \cong 11.6\, w_c \tag{34}$$

(c) *Rotating Apparatus—forced convection.*

Assuming that the air velocity in any rotating apparatus is high enough to be regarded as forced convection, the constants which apply in this case follow:

$$m = 3/4 \quad l = 1.0 \quad n = 1.25 \quad b = 0.1$$[34]

Assume

$$T_s = 20 \text{ deg. cent.} \qquad T_c = 275 \text{ deg. cent.}$$

Substituting in (18),

$$y_m = y/A = \frac{w_c D - 0.09\dfrac{\Delta p}{p_s} + \dfrac{a\,\theta_s'}{T_c}\,\dfrac{\Delta p}{p_a}}{A\left[1 - w_c D + 0.25\, w_r - \dfrac{a\,\theta_s}{T_c}\right]} \quad \text{as fraction} \tag{35}$$

Using values of $a\,\theta_s'$, θ_s', etc. assumed for (b), thus obtaining y_m from (35) and then x_m from (32), Fig. 19 is plotted. Fig. 19A shows the increase in temperature correction due to increased temperature rise of cooling air.

These curves are practically straight lines, and hence can be closely approximated by

$$y_m \cong 14\, w_c - 4 \text{ in per cent} \tag{36}$$

and

$$x_m = 10.7\, w_c \text{ in per cent} \tag{37}$$

(d) *Plate Tests.*

For free convection tests, equation (26) applies. Since temperature rise θ at *constant watts* is considered at different pressures, $a = 0$. Thus,

$$y_m = \frac{w_c D}{A\,[1.25\,(1 - w_c D)\,]} \tag{38}$$

This, of course, is the same relation as shown in Fig. 16 for $a\,\theta_s = 0$.

For forced convection, (30) applies, with $a = 0$. Thus,

$$y_m = \frac{w_c D}{A\,[1 - w_c D + 0.25\, w_r]} \tag{39}$$

This is the same relation as shown in Fig. 17 for $a\,\theta_s = 0$.

Appendix B

Description of Apparatus

Drum. Dimensions and the general arrangement are shown in Figs. 1 and 2.

The drum was exhausted by motor driven pump; the pressure was measured by the *U*-tube shown in Fig. 1; the air temperature inside of the drum was controlled by water pipes; the wires were brought out at the top; drum was kept sealed by paraffin.

Plates. The "single plate" is shown in Fig. 3. Surface 10 in. by 15 in. and thickness 7/8 in. Thermo-couples were soldered to the surface. The latter was coated with lamp black.

The "double plate" is shown in position in Fig. 4. On account of the near, end-view, the illustration gives undue prominence to the wires and tape surrounding the plate. Thus, a view directly toward the plate surface, would have shown much less of these than appear in Fig. 1.

The cardboard lining is also shown in Fig. 1.

The plate dimensions, surface 10 in. by 15 in., and thickness, ½ in.

Surface temperatures were measured by thermo-couples soldered to surface. The latter was coated first with lamp black and, for subsequent tests, with aluminum paint.

The plate was suspended by cord to practically eliminate conduction of heat through the supports.

Some conduction through thermo-couple leads was, of course, inevitable; but this was practically negligible, being reduced by using small leads, heavily insulated.

34. Average value too low for high speed, and too high for low speed.

Discussion

TEMPERATURE RISE OF STATIONARY ELECTRICAL APPARATUS AS INFLUENCED BY RADIATION, CONVECTION AND ALTITUDE

(Montsinger and Cooney)

EFFECT OF ALTITUDE ON TEMPERATURE RISE

(Doherty and Carter)

Chicago, Illinois, June 25, 1924

W. J. Foster: For a great many years I have been a party to the effort to obtain correction factors for rotating machinery from data collected at high altitudes and at sea level, thus deriving empirical formula, but I must confess that it seems a hopeless task.

I think Messrs. Doherty and Carter have pursued the only feasible method, that is, establish the conditions of air density by exhausting the air in something similar to the drum they have used. After all this is done, there remains the difficulty of classifying rotating apparatus. There is the wide open machine where no attempt whatever is made to give direction to the movement of air which is the cooling medium, and on the other hand, the totally inclosed machine where practically all the heat is carried off by the air passing through. Between those two there are all kinds of partially inclosed machines, and the effect on temperature rise is often very accidental. That is why it is so difficult to determine the proper correction even though you use a large number of cases between machines that have been tested at approximately sea level and after installation at high altitudes.

One can understand this statement if he is familiar with what often happens on the testing floor of the manufacturer. If for any reason a machine is changed in its position during test (I am now speaking of a machine that is largely open or only partially inclosed) the resultant temperatures with the same conditions of load will vary a few degrees, due to the movement of the air, to the amount of air passing through and to the other machines that happen to be running in the vicinity.

I have seen the same thing in machines installed outside, *e. g.*, in the case of a 5000 kw. direct-connected steam-engine-driven generator at low speed, where temperatures were known at certain times to be considerably higher than at other times. After careful examination it was found due to the accident of the direction of the wind outside the building when the machine was started up.

I have watched Mr. Montsinger with considerable interest during the last ten years in his efforts to obtain proper correction factors for stationary apparatus. I think he has the problem quite well solved, and that Mr. Doherty has attacked the problem in the correct manner.

When I first studied heat many years ago in the secondary schools, we had the dissipation of heat as due to radiation, conduction and convection. I still like to think of the conduction factor and in a totally inclosed machine of the cooling medium, the air which passes through as a carrier is quite similar to what we would have if water or some liquid were used which would have greater capacity for heat than the air—that makes the problem simpler in totally inclosed machines.

When it comes to a matter of establishing standards, I hope to see this whole subject put on the basis of sea level and the formula for convection applied from sea level. It seems to me that is the only scientific way for a body of engineers to proceed in standardization.

E. B. Paxton: The present A. I. E. E. Standards Rule (Paragraph 2215) recommends that the temperature rise of electrical machinery intended for operation at high altitudes shall be reduced at the rate of 10 per cent for each 1000 meters by which the altitude exceeds 1000 meters. A comparison of the values given in the first column of Table I of the paper by Messrs. Doherty and Carter shows this value to be in close agreement with the results given there for rotating machinery, namely, the values: 9 per cent, 10.7 per cent and 11 per cent.

The present A. I. E. E. rule makes no distinction between methods of temperature measurement when applying the altitude correction, whereas strictly speaking a lesser percentage should be employed when correcting for temperature rise measured by embedded temperature detectors than when correcting for temperature rise measured by thermometer on the surface due to the increased percentage base. A graphical interpretation of the present A. I. E. E. rule applied to the limiting temperature rises allowed for Class A and B insulation, which shows the correction in degrees instead of per cent, is given in Fig. 1.

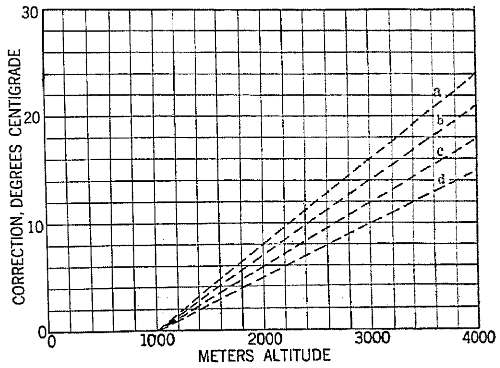

Fig. 1—Present A. I. E. E. Recommendation for Temperature-Rise Correction

This covers machines intended to operate at altitudes above 1000 meters. The curves (*a*) (*b*) (*c*) and (*d*) show the value of the correction in degrees centigrade, which amounts to 10 per cent of the standard temperature rise, applied to machines having:

(*a*)	Class B insulation,	80	deg.	standard rise by	embedded detector.
(*b*)	" B "	70	"	" " "	thermometer.
(*c*)	" A "	60	"	" " "	embedded detector.
(*d*)	" A "	50	"	" " "	thermometer.

Following this rule it is evident that a machine with Class A insulation specially rated for operation at 3000 meters will be given a rating occasioned by:

(1) 50 deg. − (10% × 2 × 50) = 40 deg. rise.
at sea level if the temperature is measured by surface thermometer; or

(2) 60 deg. − (10% × 2 × 60) = 48 deg. rise
at sea level if the temperature is measured by embedded temperature detector.

The correction is 10 deg. in the first case and 12 deg. in the second case. Obviously for a given load the drop from the copper to the surface is the same regardless of the altutude so that the number of degrees correction should be the same in

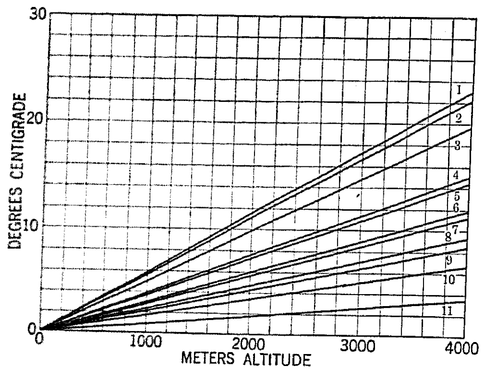

FIG. 2—INCREASE IN TEMPERATURE RISE OF VARIOUS MACHINES WITH ALTITUDE

The increase is given in degrees C. The values are computed from the values in the Doherty and Carter paper.

(1) Turbine generator fields (rotors), enclosed ventilation. 11 per cent of 52-deg. surface rise or 7.15 per cent of 80-deg. internal rise.

(2) Air-blast transformers. 11 per cent of 50-deg. rise, surface or internal.

(3) Generator and motor bare-copper-strip fields, open type. 9 per cent of 55 deg. rise.

(4) Turbo-generator armatures, enclosed ventilation, and generators and motors, enclosed type. 10.7 per cent of 35-deg. surface rise or 6.25 per cent of 60-deg. internal rise.

(5) Generators and motors with insulated fields and armatures, open type. 9 per cent of 40-deg. surface rise or 6.5 per cent of 55-deg. internal rise.

(6) Totally enclosed motors. 5.35 per cent of 55-deg. rise.

(7) Reactors and bus bars. 4.7 per cent of 60-deg. rise.

(8) Natural-draft transformers. 4.6 per cent of 50-deg. rise.

(9) Rheostats, meters and miscellaneous stationary apparatus. 4.2 per cent of 50-deg. surface rise.

(10) Oil-insulated self-cooled corrugated-tank transformers. 4.2 per cent of 40-deg. surface rise or 3.06 per cent of 55-deg. internal rise.

(11) Oil-insulated self-cooled, plain-tank transformers. 2.2 per cent of 40-deg. surface rise or 1.6 per cent of 55-deg. internal rise.

Based on 10 per cent and 4 per cent of A. I. E. E. Standard temperature rise.

either case. The method of expressing the correction in per cent based on a single percentage base is incorrect to this extent.

Mr. Doherty has recognized this fact in his paper by establishing a lower percentage correction when internal temperature is considered as shown by the second column of values in Table I. Had the corrections been expressed in degrees correction rather than in percentage of rise correction, one set of values would replace the two sets of percentages given for internal and surface measurements for any one class of insulation. For example, the percentage established for Turbine Generator Fields with enclosed ventilation is 11 per cent of 52 deg. surface temperature rise or 7.15 per cent of 80 deg. internal temperature rise = approximately 6 deg. correction per 1000 meters.

Fig. 2 shows the values given by Mr. Doherty expressed in degrees instead of percentages. He arrived at these values by selecting typical cases of temperature rise for a given type of machine and applying the percentage correction. Consideration of the first column of percentages in Table I of the paper or of Fig. 2 shows that all apparatus falls roughly into one of two groups to which the correction percentages of 10 per cent and 4 per cent per 1000 meters for surface temperature may be fairly definitely applied. These two groups are as follows:

Rotating Machines (Except Totally Enclosed Motors) Air Blast Transformers	10%
Transformers (Except Air-Blast Transformers) Reactors and Busbars Rheostats, Meters, Relays and Miscellaneous Stationary apparatus Totally Enclosed Motors	4%

The dotted lines in Fig. 3 show the degrees correction obtained by applying the above percentages to the standard A. I. E. E. temperature rises for Class A and Class B insulation.

The solid lines show a compromise between the dotted lines which should be sufficiently accurate for standardization purposes.

Fig. 4 shows a superposition of the curves in Fig. 1, Fig. 2 and Fig. 3, namely:

The preceding part of this discussion has served to correlate the data at hand and enables a proposition for the numerical values of a standard correction to be made. The remaining problem is one of application in the A. I. E. E. Standards.

The present A. I. E. E. Rule, par. 2215 reads as follows:

"2215 **Altitude.**—*Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which a machine is intended to work in ordinary service, this height is assumed not to exceed 1000 meters (3300 ft.). For machinery operating at an altitude of 1000 meters or less, a test at any altitude less than 1000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. It is recommended that when a machine is intended for service at altitudes above 1000 meters (3300 ft.), the permissible temperature rise at sea level shall be reduced by 1 per cent for each 100 meters (330 ft.) by which the altitude exceeds 1000 meters."

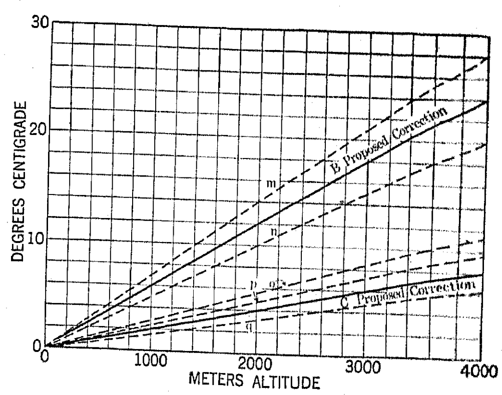

FIG. 3—INCREASE IN DEGREES TEMPERATURE RISE WITH ALTITUDE

Curve	Per Cent	Surface Rise
(m)	10	70
(n)	10	50
(o)	4	70
(p)	4	60
(q)	4	40

The proposed corrections are shown by curves (B) and (C). (B) is 10 per cent of 60-deg. surface rise. (C) is 4 per cent of 50-deg. surface rise.

There are two objections to the rule as stated:

(1) The rule is loose in that a machine tested anywhere under 1000 meters is considered suitable for operation anywhere under 1000 meters. This may lead to a difference in temperature rise of about 6 degrees, thus causing the temperature of a machine to exceed the allowable temperature limit by that amount when operating at 1000 meters in a 40 deg. ambient temperature, if it is tested near sea level at the limiting standard temperature rise, as many machines now are.

(2) The rule states that all machines for operation above 1000 meters shall be regarded as special.

In the interests of economy it is advisable to reduce in so far as possible the special applications of machines. Fundamentally there is no more reason why there should be a multiplicity of ratings for different altitudes than for different temperatures of the air in which a machine must work due to different climatic conditions. The effect of increased temperature, due to increase in temperature rise, of a machine operating at abnormal altitudes is of no more consequence than the same effect, due to an average correspondingly great difference in ambient air temperatures, existing in different localities. Yet in the former instance it has been considered necessary to give the machine a rating based on an entirely different temperature rise. Weather Bureau reports show a difference of 11 deg. cent. for the month of July between the normal surface temperatures of the northern and southern portions of the United States, a difference in temperature which corresponds to the extreme correction necessary for an increase in altitude of 2000 meters, namely that for turbine-generator fields. For this difference of 11 deg., which occurs in innumerably more instances than a similar difference for altitude, there is no provision made in the A. I. E. E. Standards—nor should there be. The mean daily maximum temperature for the month of July for same regions differ by about 17 deg. cent. which corresponds to the extreme correction for an increase in altitude of nearly 3000 meters.

There is also probably the less reason for these different ratings for different altitudes because generally the effect of increased altitudes is offset by lower ambient temperature conditions. A report published by the weather bureau of the United States makes the statement that:

"The observed decrease in temperature with elevation is, on the average about 1 degree Fahrenheit for 330 ft. (5. 5 deg. cent. per 1000 meters): it is more rapid in summer than in winter."

If credence can be attached to the above statement there will be only a very occasional occurrence of such unusual conditions

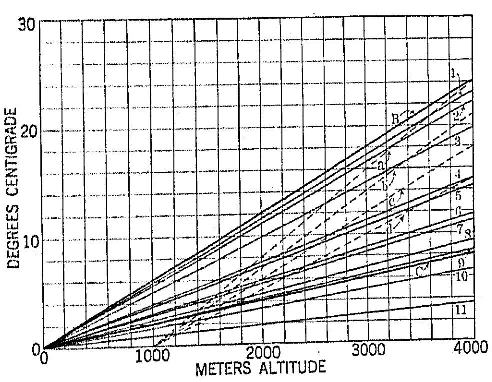

Fig. 4—How Proposed Corrections Compare Numerically with Present A. I. E. E. Recommendation and Experimental Data

This chart is a combination of Figs. 1, 2 and 3. Curves (1) to (11) are calculated from experimental data on various machines as listed under Fig. 1. Curves (*a*), (*b*), (*c*) and (*d*) are the present A. I. E. E. recommendations as shown in Fig. 2. Curve (*B*) is the proposed temperature correction for the kinds of apparatus shown by curves (1) to (5). Curve (*C*) is the proposed correction for kinds of machines shown by Curves (6) to (11). These two curves are shown also in Fig. 3.

of service as to warrant special consideration. It should be borne in mind, however, that in many instances machines are operated in buildings the inside temperatures of which may not correspond closely to the outside temperatures.

The matter of application of machines for high altitudes could be greatly simplified by considering altitude as one of the service conditions that affect the heating of electrical machinery in operation. The correction could be made most simply and effectively by considering it in connection with the limiting ambient temperature in which a machine may safely carry its rated load.

Fig. 5 shows the limiting ambient temperature at various altitudes in which a standard apparatus, rated on a basis of sea level, may be expected to carry its rated load without exceeding the maximum limiting temperature established by the A. I. E. E. Standards. It will be clearly seen that these curves have been

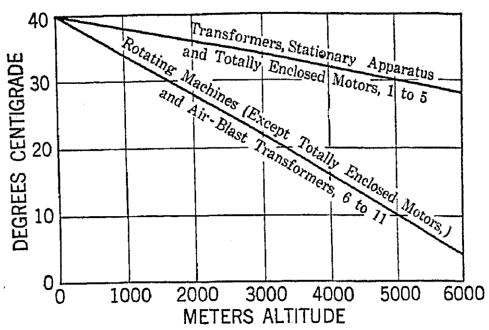

Fig. 5—Proposed Rule Limiting Cooling-Air Temperature at High Altitudes

This chart illustrates the proposed rule which designates the limiting ambient temperature in which standard apparatus rated on a basis of sea level, may be expected to carry rated load without exceeding the maximum limiting temperature.

arrived at by subtracting from a 40-deg. ambient the resultant correction given in Fig. 3.

Expressed in words the proposed guide would be:— Rotating machines (except totally enclosed motors) and air-blast transformers.

These types of apparatus shall be suitable for carrying their rated load provided the ambient temperature does not exceed a value of 40 deg., less 6 deg. for each 1000 meters by which the altitude exceeds sea level.

Transformers (except air-blast transformers)
Reactors and bus bars
Rheostats, meters, relays and
Miscellaneous stationary apparatus
Totally enclosed motors.

These types of apparatus shall be suitable for carrying their rated load provided the ambient temperature does not exceed a value of 40 deg., less 2 deg. for each 1000 meters by which the altitude exceeds sea level.

The effect of the proposed method of applying the rule is to make the correction definite over all altitudes including altitudes less than 1000 meters. But it should be noted as important that a standard apparatus rated on a basis of sea level would be on the proposed basis suitable for operation up to at least 1000 meters under usual conditions of service and that the size or rating of machines applied under these conditions will not be changed. Furthermore, the effect is to regard the application of apparatus at higher altitudes as special either by de-rating or using a larger machine, only when the higher altitude is coupled with unfavorable values of ambient temperatures, as given by the proposed rule.

L. B. Cherry: I wish to ask Messrs. Montsinger and Doherty if, in their research, due consideration was given to the possible effects that varying degrees of humidity might have on the rise of temperature. It is readily seen that even at high altitudes, equipment might be installed in basements or even under-ground enclosures where, with contributing sources of moisture, and under conditions of poor ventilation, sea-level conditions of humidity migh prevail, and thus effect heat radiation. Do varying degrees of humidity seriously effect radiation?

H. M. Hobart: I want to speak in favor of Mr. Paxton's proposition. This is a subject on which we have been working in the Standards Committee for a good many years but we have had to wait for Mr. Paxton to show us the simple and satisfactory way to deal with it.

I don't think that from Mr. Paxton's brief presentation we would all be sufficiently impressed with its merits and I hope that it will be given the most careful study.

There is one little matter that ought to be taken into account in actually working out the way in which Mr. Paxton's plan should be assimilated into the standardization scheme, if it meets with the approval with which I hope it will meet, and that is that all these little refinements when we are able to figure them out to a nicety, result in showing people how to work closer to the so-called approved limit. It comes within the ability of the operating engineers to load their machines for a larger part of the time up to those values that have been described as "approved" limits. Now when these limits were established, they were associated with conditions which practically ensured that the average temperature reached was 10, 15 or more degrees below the established limit. But when people are encouraged to take up this very interesting practise of adjusting the load, putting on more and more load until a limiting value is reached or approached, the deterioration of insulation is bound to be more rapid. The deterioration may still be quite slow, the machine may have a satisfactorily long life, but even though the life may be satisfactory, it is bound to be shorter than if it were running at a lower temperature. Maybe 105 deg. is too conservative or maybe it is just right, but whichever it is, the machine will have a shorter life with this new knowledge that we are getting, tempting us to approach limits, than when we kept further away from those limits, regarding them as sorts of danger signals. I don't say there is any danger in approaching and staying at those limits; that is a point to be investigated but certainly it is a new and comparatively untried thing to operate machines in accordance with this new conception of the limiting values and it is bound to shorten their life. The life may still be entirely satisfactory but it can't help being shorter as far as relates to insulation deterioration. I don't believe insulation deterioration is often a factor determining the life of a machine. Other factors enter in determining when a machine should be thrown out and a new machine put in. Nevertheless, it is a fact if you have a scheme of things that makes you run 5 or 10 deg. higher temperature than you used to run, as far as the insulation is concerned, the life of the machine will be shorter, and that ought to be taken into account in working this scheme into the plan of things. If 105 deg. is the right limit with the old ideas, it ought to be reduced to 100; if 105 is already too conservative on the old ideas, it will probably be about right for the new basis.

J. R. Craighead: I want to put in one little plea for simplicity in this rule. The feature I think that has been most satisfactory in the previous rules has been the fact that virtually there was no rule up to 1000 meters. That allowance was made as representing the general conditions under which apparatus satisfactory at sea level would work reasonably well.

Now Mr. Paxton's rule as shown in Fig. 5 would require that for every foot advanced from sea level there is a definite change in the condition under which a customer can operate his apparatus. I think that is really impracticable. Whether the rules are made this way or not, it will be necessary for the operator, and to some extent the manufacturer, to base their work on the idea that there is a flat step at the start of the curve, a rise over which apparatus for sea level can be used without special investigation or separate temperature limit. And it would seem to me a very desirable thing that the Institute rules should be so worded or arranged that this flat step is taken care of in the rules. At the present time this is up to 1000 meters; possibly that is not the correct value for it, but some flat first step should be assumed.

E. B. Paxton: I would like to say in regard to the point Mr. Craighead made, that the correction up to 1000 meters would generally be so small it might be regarded as negligible in operating the machine, that is, no one who operates the machine is going to worry about whether ambient temperature is 36 deg. or 40 deg.

What I am proposing is that this correction be applied as a matter of operating, as one of the service conditions which will affect the way the machine may be operated rather than to make it apply to the rating of the machine.

There is one further point I would like to make in that same connection and that is that there is a natural tendency for the temperature of the cooling air to be less at the higher altitudes. The weather bureau made the report that the temperature would probably decrease 5½ deg. for every 1000 meters of altitude. Now just how much credence should be given to that for the reason that machines are often operated inside, is a question, but I think very likely the inside temperature drop may be of a corresponding degree.

N. S. Diamant (by letter): In Doherty and Carter's paper the statement appears that the heat transmission by convection was practically unchanged when the surface was painted with aluminum. It would appear as if they imply free convection. If so, their results and their theory would seem to be in contradiction to the tests submitted several years ago by the late John R. Allen of the University of Michigan to the Society of Heating and Ventilating Engineers. Allen found that with aluminum paint the heat transmission by free convection of ordinary house radiators was reduced from 100 per cent for a bare unpainted cast-iron radiator to 75 per cent. The effect of other paints seemed to be on the same side, namely, there was a decrease in free convection for most paints that were tried.

The tests I made several years ago on the effect of paint on forced convection agree with that of the authors, namely, that the paint has no effect on forced convection.

In connection with this subject it may be added that it has been found by Allen and other investigators that it is the last coat of paint that effects heat transmission by free convection.

With reference to the effect of altitude on the cooling of dynamo electric machines of the rotating type or machines cooled by forced convection, some very interesting material will be found in the excellent work done by the Bureau of Standards on the cooling of airplane engines when flying in various altitudes.

F. D. Newbury: I desire to discuss these two papers from the stand-point of their relation to the A. I. E. E. Standards. I have had the privilege of reading Mr. Paxton's valuable discussion, and wish to endorse his suggestion that the altitude correction in the Standards apply to the limiting value of cooling-air temperature rather than to temperature rise. The adoption of this suggestion would completely avoid the necessity for special machines designed for special temperature rises and places this question of altitude correction among service conditions where it properly belongs.

The present Institute Standards, paragraph 2215, provide that no correction for altitude shall be made for altitudes of 1000 meters and less. The data presented by Messrs. Doherty and Carter indicate that for rotating machines the correction at 1000 meters would be in the neighborhood of 6 deg. with proportionately smaller corrections for lower altitudes. In spite of this maximum difference of about 6 deg., I believe the present provision that no correction for altitude be made except for altitudes above 1000 meters should be retained. This suggestion is made in the interest of simplicity, and because this rule has been well-established, not only in this country, but in practically all of the important manufacturing countries. The I. E. C. Rules for Electrical Machinery contain the following paragraph:

"Altitude.—In the absence of any information in regard to the height above sea level at which the machines is intended to work in ordinary service, this height is assumed not to exceed

1000 meters. If the machine is intended to work at an altitude above 1000 meters, a correction to the temperature rise should be applied. The value for this correction has not yet been fixed by the I. E. C."

As an example of British practice, the British Standard Specification for Electrical Performance of Industrial Motors and Generators (No. 168 of 1923 maybe quoted:—

"The Standard Ratings provided in this Specification are suitable for machines operating at altitudes not exceeding 3300 ft. above sea level. Machines for use at higher altitudes are dealt with in Clause 44. Machines intended for service at altitudes above 10,000 ft. are not considered standard."

(Clause 44.) "When a machine intended for service at high altitudes is tested near sea level, the limits of temperature rise given in Table I shall be reduced $1\frac{1}{2}$ per cent for each 1000 ft. above sea level at which the machine is intended to work in service. The correction shall not be appled for altitudes below 3300 ft."

The German Rules (V. D. E. of 1923) apply to "Generators operating at an altitude of 1000 meters or less. Special agreement is necessary for higher altitudes."

As an example of French practice, the French Standards for Electrical Machinery produced, by the heavy-machinery manufacturers and approved by l'Union des Syndicats de l'Electricite, July 22, 1920, contain a paragraph to the same effect as paragraph 2215 of the A. I. E. E. Standards.

It will be observed that the rule providing for no correction up to and including 1000 meters has been adopted by the I. E. C. and by four of the most important manufacturing countries. Any change of the A. I. E. E. Standards in this particular would indoubtedly be difficult to establish internationally, and we should differ from established international standards only when the importance of the matter is very great.

From the standpoint of our every-day work, I believe the present rule providing for a correction only above 1000 meters should be retained. The great bulk of electrical apparatus is operated in locations having an altitude less than 2000 ft. (600 meters). All of the eastern half of the United States (east of 100 deg. longitude, passing through Texas, Oklahoma, Kansas, Nebraska, and the Dakotas), is less than 2000 ft. altitude, except for the higher ridges of the eastern mountains. The experimental data furnished by these two papers show that the correction for 1000 meters amounts to a reduction of 4 deg. to 6 deg. for various parts and types of rotating machines, applied either to the guaranteed temperature rise, or, as proposed by Mr. Paxton, applied to the 40 deg. cooling-air temperature. Probably more than 95 per cent of the rotating machinery built in the United States is installed in locations having altitudes less than 2000 ft., for which the permissible cooling-air temperature would be reduced, according to the papers under discussion, only 2 or 3 deg. For transformers, the reduction in permissible air temperature for altitudes less than 1000 meters would be less than 1 deg. If the proposal for a correction starting at sea-level were adopted, I am confident it would be a dead letter for the great majority of electrical apparatus tested.

The data presented in these papers indicate that some change in the present correction should be made for altitudes sufficiently high to make the correction worth while. As I have indicated, I believe we should retain the present plan of no correction until 1000 meters is exceeded. I believe also that we should adopt Mr. Paxton's suggestion, and apply the altitude correction to the permissible cooling-air temperature, instead of to the guaranteed temperature rise, as now provided for in the A. I. E. E Standards. In order to retain the present rule of no correction until 1000 meters is exceeded, and at the same time make the corrections for higher altitudes agree with the experimental data that has been presented, and further, to avoid odd and fractional values of limiting air temperatures, I suggest that the Standards contain a table of definite limiting cooling-air temperatures for various altitudes, instead of a general rule expressed either by a formula or by a curve.

The following statement is suggested:

SERVICE CONDITIONS

Usual Service Conditions.

Temperature and Altitude.—Machines conforming with these standards shall be suitable for carrying their rated load, when the temperature of the cooling air does not exceed the values, at the corresponding altitudes, given below:

Up to and including 1000 meters (3300 ft.) . .	40 deg. cent.
Above 1000 meters to and including 1500 meters. . . . . (5000 ft.).	35 deg. cent.
Above 1500 meters to and including 2000 meters. . . . . (6600 ft.).	30 deg. cent.
Above 2000 meters to and including 3000 meters. . . . . (10,000 ft.)	25 deg. cent.
Above 3000 meters.	20 deg. cent.

The corresponding values for self-cooled transformers would be:

Up to and including 1000 meters (3300 ft.)	40 deg. cent.
Above 1000 meters to and including 3000 meters. . . . . (10,000 ft.).	35 deg. cent.
Above 3000 meters.	30 deg. cent.

V. M. Montsinger: From the nature of these discussions it is not necessary to comment on the various methods proposed for incorporating the altitude correction in the Standards. This must be considered at some future meeting of the Standards Committee.

In reference to Mr. Cherry's question about the effect of humidity on the temperature rise, the following are the approximate facts.

Humidity of course does not affect the loss of heat by radiation. The loss of heat by free convection is practically unaffected by the moisture unless the air is fog laden. The amount of water ordinarily in the air is so small even though the humidity is high that the effect is in the order of one per cent or less. The question of humidity has been considered but the conclusion was that for practical purposes it can be neglected.

R. E. Doherty: The authors are gratified that the results outlined in their paper may prove useful as a basis for the revision of the A. I. E. E. Rules relating to the subject.

The principle on which Mr. Paxton's plan is based is fundatally sound, and the details of his plan are, in our opinion, the most promising that have been proposed.

Mr. Montsinger has answered Mr. Cherry's inquiry about humidity.

Underground Alternating-Current Network Distribution for Central Station Systems

BY A. H. KEHOE
Associate, A. I. E. E.
Electrical Engineer, United Electric Light & Power Co., New York, N. Y.

Review of the Subject.—*1. Certain experimental arrangements for an underground alternating current distribution system are covered in the paper.*

2. *Low costs and characteristics satisfactory for general utilization of alternating current are contrasted with difficulty of obtaining reliability. The advantage of adopting system characteristics which will make each service suitable for lighting, appliances, and motors is indicated. There is described experience with a combined light and power network on one set of mains. Effect of voltage variation on incandescent lamp illumination is discussed. An appendix covers tests on this subject.*

3. *Reliability in service of standard distribution materials is considered. Tests on cables are described which indicate that for underground distribution conditions, low-voltage cables will eliminate arcing faults while high-voltage cables will not do so. An appendix of arcing tests is attached.*

4. Certain factors are discussed relative to size of mains and location of transformers necessary to make the low voltage network clear its own faults.

5. *There is a description of an experimental system consisting of several radial high-voltage feeders, the distribution transformers of all these being connected on the low-voltage side to a common low-voltage cable network.*

6. The reactance of the transformer circuits is almost three times that of standard distribution transformers.

7. The only protective devices used are automatic circuit breakers installed in the low-voltage cables between the distribution transformers and the network. The switches open on a reversal of energy from the network and close when the transformers are in a condition to supply power to the network. The devices are sensitive enough to open on transformer magnetization energy.

8. Great reliability obtained for the network as a switch failure on a high-voltage fault is the equivalent of a short-circuit on the secondary network.

9. Ability to switch automatically all transformers by controlling the supply end of the feeder to which they are connected, allows a higher all-day efficiency due to the saving of iron loss at periods of light load. This feature also makes it easy to work on high-voltage equipment.

10. A description of the equipment used in this experimental installation and operating results of switch equipment from date of installation in April 1922 to March 1924 are given.

11. It is believed that with low-voltage a-c. underground networks arranged as described, the reliability is the same as the reliability of the sources supplying the various radial high-voltage feeders. The possibility in the future of a protected network arrangement of the supply system is mentioned.

IT is the purpose of this paper to describe the design and operating results of certain experimental distribution arrangements[1] on the 60-cycle system of the United Electric Light and Power Company in Manhattan.

Alternating current distribution has had general use on overhead service because of its economy in first cost and low operating expense, and the underground service has increased rapidly in the past few years because of the above conditions. In general, this system's characteristics for utilization of the service has been satisfactory. The disadvantage found in variable speed motor applications are compensated for to a large extent, by the extremely simple constant speed motors. Other characteristics in most instances have been good.

Reliability of supply and the adoption of system characteristics for services which will make it possible to apply universally lamps, appliances and motors at any service, are the principal subjects considered in this paper.

The practise in this country has been for most central stations to supply general power service at twice the voltage used for lighting or general appliances. In a-c. distribution this resulted in having separate power services for polyphase motors. There are many advantages in having any service capable of supplying all kinds of service. The common problem, in considering the possibility of combining light and power on one set of mains and services, is the permissible variation in illumination of incandescent lamps, due to changes in voltage. The principal cause of voltage variation is the starting current required by motors. The writer was unable to discover in 1921 any published information concerning variation in voltage which was possible without having a visible change in illumination for standard incandescent lamps. Results of tests, made shortly after (described in Appendix A), indicate that two per cent instantaneous variation in voltage cannot be detected and that three per cent is the maximum possible for the highest grade service. Changes of five per cent, however, will not be observed in most conditions found in practise.

A light and power polyphase network on a single set of mains was placed in service with 300-kw. installed transformer capacity feeding from five locations and having 15 elevator motors, as well as a typical city load of apartment lighting, appliances and miscellaneous motors. The calculated maximum lighting voltage variation at the services was three per cent. Experience of 12 months' operation is that such a system will give illumination without flicker at a lower cost and

1. In an endeavor to describe briefly the designs adopted, common terms to explain new conditions have been used. Some of these have broader meanings than are applied herein. It is believed however that the subject matter will not be misleading if these limits are realized.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

that its services will be of the so-called universal type, in that lamps, appliances, or motors can be connected to any of them.

Reliability of supply is of paramount importance to any successful system. It is also desirable in designing a distribution system to use as much standard equipment as possible. Our studies of service reliability contemplated distribution from substations or other sources, with available voltages in excess of 2000 volts, and stepping down to values which were suitable for standard lamps, appliances, and motors.

Service equipment has been developed to a high state of reliability. Edison systems (d-c. network distribution) had a large share in bringing this about. Present apparatus is considered suitable for a highly reliable system.

The other elements entering into an underground a-c. distribution system are—

(a) Cables—(1) for low-voltage and (2) for high-voltage.

(b) Distribution transformers

(c) Protective devices

For reliability in operation standard cables were examined to determine their performance in case of fault. Tests were made (described in Appendix B) which indicate that if an arcing fault develops between copper and sheath, on a 60-cycle single-conductor cable of less than 220 volts, the fault will burn itself off. If an arc develops on a similar high-voltage cable, the fault will continue if the restoring voltage on rupturing the arc is in excess of 1000 volts between conductor and sheath, providing the fault current is at least 500 amperes. At 2000 volts, fault currents as low as 100 amperes will continue to arc. It is thus possible to use a network or grid of low-voltage cables which will rid itself of arcing faults. High-voltage cables, however, must be equipped with protective devices to eliminate faults on them.

If a low-voltage network is designed so that any of the conductors which become short-circuited with a low resistance path will receive enough current from the network to heat the copper of the faulty section causing an arcing fault to be set up, then the network will be able to protect itself against any faults which occur on it. With standard cables, it is necessary to have a minimum voltage gradient in the cable of at least a six volt drop per 100 ft. to melt solder in the joints or damage the insulation, and about four times this amount to melt the copper. These relations set a maximum size of network cable for any given capacity and make it necessary to have certain limiting relations for size and spacing of transformers. (Appendix C deals with solid short circuits on a low-voltage network).

With a low-voltage network which will eliminate its own faults and with high-voltage cables requiring protective equipment to handle faults which may develop, it is possible to feed from the high-voltage sources to the low-voltage network—(a) radially with a single-feeder, (b) from several radial feeders supplied from one or more synchronized sources, or (c) from a high-voltage network which in turn is fed from several feeders from one or more synchronized sources. Obviously, a reliable supply cannot be obtained for a network from a single-radial feeder. As a high-voltage network requires a quantity of expensive protective equipment and extra cable is required to obtain the slight advantage of having somewhat smaller capacity in distribution transformers, the proper arrangement appears to be a network fed in multiple from the secondaries of distribution transformers, a number of each being connected to any one of several radial high-voltage feeders.

With the use of a low-voltage a-c. network, fed from several radial feeders, the distribution of loads between different transformers made it appear desirable to increase the reactance of the standard transformers in order to more nearly balance the loads on transformers, and provide relatively high reactance paths in case a network is fed from two or more separate synchronized sources. Reactance of from two to three times the values now in use on distribution transformers is not considered excessive for such service.

Distribution transformers and, as set up previously, high-voltage cables are liable to develop faults which will persist. In providing protective equipment for the above, it was considered that by installing a circuit breaker in the low-voltage cables between each distribution transformer and the secondary network which which would open on a reversal of energy, any high-voltage fault would be disconnected from the network. The reliability of the system would be much greater than the reliability of any switch, as a failure of one device would never result in more than a shortcircuit on the secondary cables, which can be burned off without interruption to the network. In practise this is accomplished by having high-capacity low-voltage fuses on the network side of the switch, which melt in case of switch failure before the cables feeding to the network are damaged. No other protective devices are used except the customary circuit breakers on the supply end of the various high-voltage cables feeding the network.

Since it is possible to get reverse energy from the network in the form of iron loss to distribution transformers in case the high-voltage supply to any feeder is disconnected, the switches were made sensitive enough to function on these values of reverse energy and were made so that they would close automatically in case the high-voltage feeder was made alive, and circuit conditions were such that the transformers would supply energy to the network after the switches close. With this arrangement it is customary to disconnect high-voltage feeders at the supply end and the switches at each of the distribution transformers on this feeder will open automatically. By doing this at light load periods, the remaining feeders connected to the net-

work are loaded up to their maximum efficiency point, or in other words, most of the usual iron loss of the distribution transformers and regulators now out of service is saved. This also facilitates maintenance work on the high-voltage cables and transformers. It is estimated that the improvement in all-day efficiency on most systems receiving power from steam generating stations will offset a large part of the cost of the protective equipment. The elimination of all the usual protective equipment installed at distribution transformers or at sectionalizing points on the high-voltage cable is also a distinct saving.

The first installation of equipment in Manhattan was made with 29 switches supplied from four high-voltage feeders. Standard distribution transformers were equipped with external reactance, making the total reactance 8.7 per cent on this installation. (It is proposed to use 10 per cent total reactance on additions). The system was started on April 12, 1922 and has been in continuous service up to April 1st of this year.

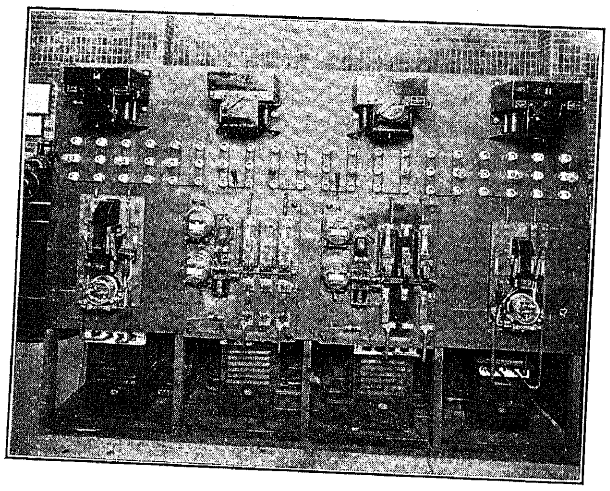

FIG. 1

The automatic switch equipment used consists of a carbon circuit breaker provided with a closing coil, and a latch which is tripped by the armature of a low voltage auxiliary relay. The circuit of the auxiliary relay is controlled by the main or master relay and as its electrical source is from the transformer secondary side of the switch, it is also used to actuate the contacts which make and break the closing coil circuit. The closing coil is thus prevented from receiving energy unless the potential is sufficient to cause the switch to close. The main relay is of the induction disc type and has two current circuits and one potential circuit, so that with the switch open one circuit is shunted across the open contacts of the switch in series with a resistance of the ballast type (tungsten lamps are generally used). The potential coil of the relay is connected across the network and the relay thus closes its contacts only if the transformer is capable of supplying energy to the network. When the switch is closed, this coil is short-circuited by the switch and the second current coil actuates the relay. This is connected to the terminals of a magnetic shunt in the circuit between the distribution transformer and the switch. It receives a large component of the current from the transformer to the network for currents of 5 per cent of switch rating. For larger current values, the magnetic shunt saturates and only allows a slight

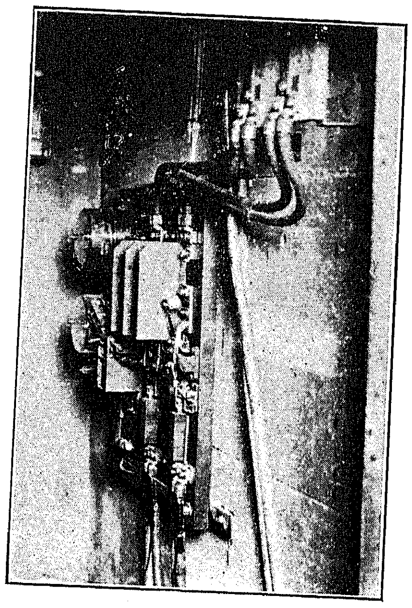

FIG. 2

increase of current in the main relay coil. This coil with the potential coil across the network makes the relay function as an energy directional device and its contacts open the low-voltage auxiliary relay circuit in case of a reversal of energy, even of the magnitude of magnetization energy of the transformer. The relay

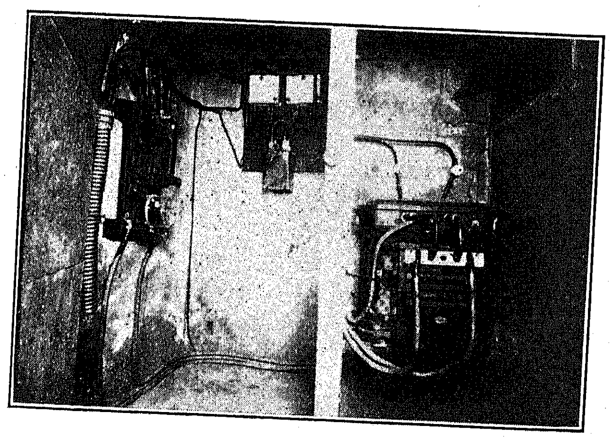

FIG. 3

has spring adjustment to keep closed its contacts with the network dead, and auxiliary electrical circuits to compensate for the spring adjustment when the network is alive and give a positive range in adjustment for either opening or closing the switch.

An auxiliary contact is provided to close a circuit to a resistance across the transformer side of the switch

when the main switch contacts are open. This resistance is used to melt a wax indicator in case the transformer secondary is made alive for several minutes without having the switch close its contacts. A failure of a network switch to automatically close is thus indicated on inspection.

Fig. 1 shows four switches connected for a single-phase demonstration. The end switches on either side are of the first type produced, while the two center switches are of the later three-pole type for three-phase

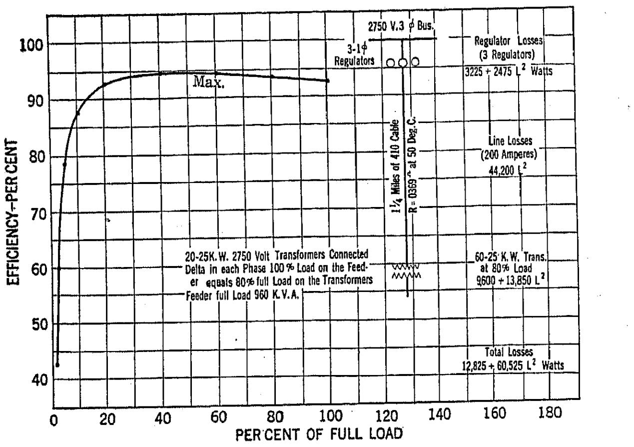

Fig. 4—Distribution Feeder Efficiency from Substation Bus to Distribution Transformer Secondary

service. Connection with the distribution transformers is made at the bottom. (In this case with external reactors in series). The network connections are at the top of the switch through a link fuse. Most of the essential elements are more clearly shown in this figure than in Figs. 2 and 3 which are illustrations of actual installations. The switch has been tested for manhole operation. All of the switches in service to date, however, have been in waterproof vaults.

It is the practise to cut out one or more of the four feeders supplying this service at different times during the day, depending upon the loading conditions. It is not possible to obtain full economy owing to the limited size of the present installation and the necessity of keeping at least two feeders always in service.

Fig. 4 shows the calculated efficiency curve of a radial feeder and its distribution transformers. Dielectric losses and secondary network copper losses are not included. It is evident that maximum efficiency point is about one-half full load kv-a. As long as there are feeders out of service it is desirable to keep the load on feeders in service below the maximum efficiency load indicated, for shorter network cable feeds and to have available capacity in service for reliability of supply.

Fig. 5 is the substation duration curve of the load in kilowatts. It shows the number of hours per year that the load exceeds any given percentage of the peak load. If the capacity of feeders and distribution transformers is assumed to be 20 per cent in excess of the peak (this amount can only be realized in practise on a network) and the kv-a. duration curve of the particular network is assumed to be like Fig. 5, then there is less than 1500 hrs. per year when the feeder loadings will exceed 50 per cent of their capacity, which is assumed above to be the maximum efficiency point. The possible improvement in all-day efficiency is dependent upon the number of feeders supplying the network, but in practise this can fall between eight and twelve on the basis of having two in service at low-load periods.

In the installation of this experimental automatic multiple-feed net-work supply, feeder capacity and amount and arrangement of distribution capacity were made liberal to be certain that all unusual conditions would be met. It was found that with high-reactance transformers it is unnecessary to space distribution transformers so that any particular district is supplied from all the sources of supply, it being sufficient that several sources be adjacent to the district.

The practise of disconnecting feeders at their sources during light load periods has given operating experience and has developed equipment faults which otherwise would have required a long time to develop. Since the principal purpose of this equipment is to give reliability to the supply, it is advantageous to know any switch which will not function on a reversal of energy. When the source is disconnected, the switches are subjected to a relatively small amount of back feed and in case of failure to open, the network will feed back to the source and the particular switch failure can be located on inspection.

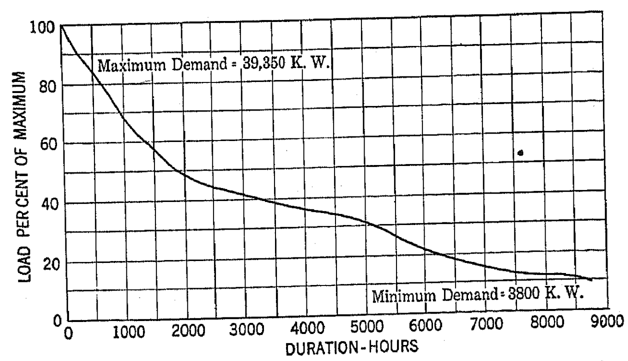

Fig. 5—Duration Curve for U. E. L. & P. Co. 60-Cycle Substations 1923. Data for Wattmeter Readings Taken Each Half Hour Throughout the Year

Since April 12, 1922, the date the network was placed in service, there have been no failures of any kind that affected the service on the network. Three transformers grounded and in each case the feeders were disconnected from their source, which immediately cleared the transformer from the network. Several single and polyphase short-circuit tests were made on the high-voltage feeders in conjunction with tests on some oil circuit breakers. In every case the network supply was continuous and satisfactory. The failures of switches to function with 48,232 total opera-

tions has been 440 (see Table I). Many of the failures are not failures to open, as one-half the total operations are those of closing the switches automatically. Failures to open are in all cases with magnetization of transformers as the load. It is probable that some of these would have functioned if the occasion had been a high-voltage fault. With one or two hand-made sample switches of a new design, much better results have been obtained. A quantity of new switches is being manufactured at present and should be in service early this summer. Many of the faults now occurring will be remedied when it is possible to replace existing equipment on the system and make necessary changes to eliminate the failures which have developed. We expect

this class of equipment to give operating results ultimately which will compare with modern railway signal equipment. At present they are inspected once every two weeks. It is believed that except at heavily loaded periods these will be extended to periods of six weeks. The new switches on order and those now in service when reconstructed will equip to capacity 12 radial high-voltage feeders and place in service about six times the present number of switches.

Our experience indicates that with this design of underground a-c. low-voltage network, fed from several different sources, the reliability will be the same as the reliability of the sources supplying the various radial high-voltage feeders.

With the increased capacity in low-voltage networks, it will be possible to supply the feeders from two or more separate bus sections so that all the sources will not be affected by faults on one section. A development of this arrangement of operating separate bus sections in multiple makes the supply system take on the character of a network, in that it is possible to transmit the entire capacity of the generators to the low-voltage network, yet the capacity concentrated in any part of the system is a relatively small part of the total capacity. It will, of course, be necessary to equip the generating system with the usual protective devices, although of reduced capacity, compared to that required for a system where paralleling of as many supply points as possible on each bus has the effect of increasing the capacity available at that point.

Appendix A

Voltage Variation Effect on Incandescent Lamp Illumination

Tests were made during 1921 and 1922 of the effect of voltage variation on incandescent lamp illumination to determine possible amount and rate of variation without noticeable flicker. The results depend upon the particular observer, but as the object was to obtain the limits, the observers used for final results were the ones that indicated low values consistently.

A slide wire resistance was used to vary the voltage on the lamps. For instantaneous rates the resistance was cut-in and cut-out of the lamp circuit by means of a knife switch. For other rates of change, apparatus was constructed to move the slider on the resistance at various rates of speed. By measuring the volt drop per inch of resistance, the rate of change in volts per second on the lamp was determined. In order to eliminate the effect of starting and stopping, short-circuiting sleeves were put on the resistance so that only definite changes in voltage could be made from start to finish. The observers were located in a dark room with no extraneous source of light remote from the voltage varying device.

Complete sets of tests were made with 25-watt lamps and with 100-watt lamps.

Tests were made with one lamp 18 in. from the observer's paper.

Another set of readings was taken with two lamps 18 in. apart and 18 in. from the observer's paper. One lamp being flickered and the other being held at constant potential.

Similar readings were taken with the lamp source 8 ft. from the floor with the observer sitting under it in a chair reading.

Tests were made with two lamps 8 ft. from the floor, located 18 in. apart, one being flickered and the other held constant.

Under all of the above conditions, one set of tests was made with decreasing voltage, a second with increasing voltage, and a third with decreasing voltage and then restoring the same to original value.

In Fig. 6, there are four curves showing change in voltage necessary before flicker is noticed in respect to rate of change in voltage per second.

The summary of results of above tests is as follows:

1. That within limits the slower the rate of change, the greater the total voltage change necessary before flicker is noticed.

2. That after a certain point the voltage variation is noticed, no matter how slowly the change is made.

3. That at high intensities the candlepower does not make an appreciable difference, but that at low intensities the flicker is less noticeable, the lower the intensity.

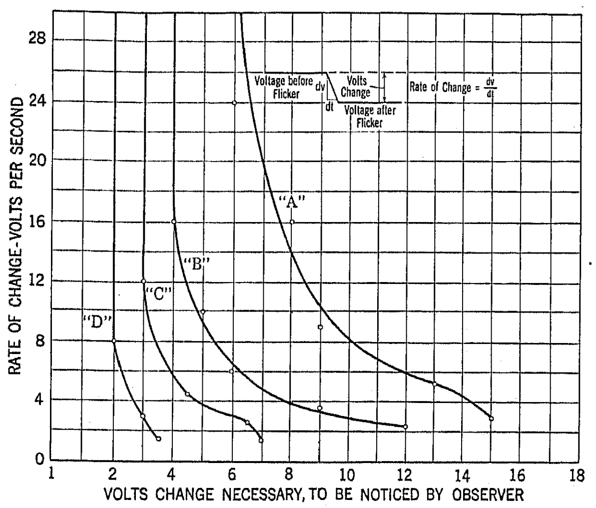

Fig. 6—Incandescent Lamp Flicker Tests, Observer Reading Newspaper

Curve *A*—Two Lamps, 8 ft. from paper and 18 in. apart voltage on one lamp varied.
Curve *B*—Two Lamps, 18 in. from paper and 18 in. apart voltage one lamp varied.
Curve *C*—One Lamp 8 ft. from paper.
Curve *D*—One Lamp 18 in. from paper.
(Mazda Type *B* 115-Volt Lamps were used. The same results were obtained with 25 and 100-Watt Lamps and with increasing and decreasing voltage).

4. The greater the distance to the light source, the larger may be the total voltage change before flicker is noticed.

5. That when there is an additional source of light of constant intensity, a greater voltage change is necessary before flicker is noticed.

6. That the same variations are noticed whether the voltage is increasing or decreasing.

7. That when the drop is made instantaneously the same variations are noticed, if the volts are dropped and allowed to remain at the lower value, as when the voltage is dropped and immediately restored.

8. That at rapid rates of change the maximum allowable variations are from two to six volts and at very slow rates of change from four to eighteen volts, depending upon the condition of illumination.

The above results have been found to be in general agreement with the operating experience of several engineers in using lamps on the same circuits with motors. A recent paper "Voltage Fluctuation and Its Effect upon Lighting" by C. A. Williams, before the Pennsylvania Electric Association in Philadelphia, contains considerable data on the subject.

Appendix B

Alternating Current Arc Tests

Single-conductor cables were tested by removing a section of lead and insulation and setting up an arc between conductor and sheath with a fuse wire short circuit. The circuit arrangements are shown in Fig. 7, resistance being utilized to limit the arc current for all except the larger values of current used. Results of tests are plotted in Fig. 8 to 13 inclusive, and characteristic oscillograph results are also shown on following pages.

Appendix C

SELF PROTECTING A. C. NETWORK

When cables are subject to solid short circuits they heat up to an ultimate limit where the copper melts, provided there is a sufficient potential drop maintained across the shorted conductors. This potential drop is a function of time, which, for fusing in less than one minute, is dependent upon time only, irrespective of copper cross section; while for time of fusing of over one minute, insulation thickness and overall diameter of

sizes which would be used in networks. Thermal capacity curves for this cable are shown in Fig. 27.

Since a minimum limit of six volts per 100 ft. is required to melt soldered joints and break down the

chemical structure of ordinary insulating material, this fixes the maximum transformer spacing. The choice of minimum voltage gradient in the designing of a self-clearing network will lie between the above value and 24 volts per 100 ft., which is the minimum voltage gradient required to fuse the copper conductors.

The maximum transformer spacing for a simple net-

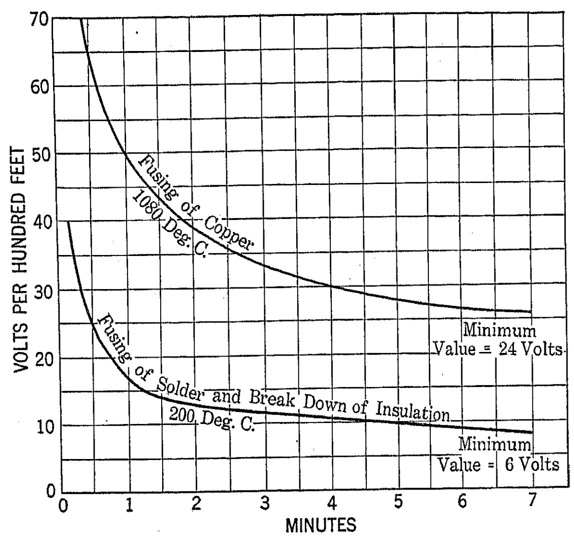

FIG. 27—VOLTAGE REQUIRED TO CLEAR SHORT CIRCUITS ON 200,000-500,000 CIR. MIL CABLES

work is numerically equal to the phase voltage of the network, divided by the chosen voltage gradient.[1] This spacing may be increased by making the network more complex, for example, the transformer spacing may be doubled by employing parallel mains tied together midway between transformer points. The configuration of the network grid is fixed usually by the arrangement of streets in the district. It is desirable to have transformer spacing and junction points of the grid coincide for the purpose of economy and regulation.

Determination of the maximum transformer size can be made from the load density and maximum spacing.

In order that destruction of copper under network short circuit may occur in the cable and not in the transformer, it is desirable that fusing current of the cable shall not be more than twice the current which can be carried safely for the required time by the adjacent transformer bank.

The maximum limits of transformer size, spacing and cable size are thus established for a self-protecting network.

Cross section of the cables may then be reduced to a size which will give the allowable regulation with the maximum instantaneous increment of current likely to be obtained. Transformer size may then be reduced, with the accompanying reduction in spacing and cable size until an economic balance is reached between transformers and cable, keeping in mind the ultimate growth in the district. Any reduction made in transformer size and spacing or in cable size will not affect the ability of the network to burn off short circuits.

For the district of Manhattan where the experimental network installation was installed, the system contemplated 200,000-c. m. single-conductor cables on both sides of all streets, transformers located at each street intersection, and a maximum grid spacing of 880 ft. in one direction and 280 ft. in the other. It was found that with 10 per cent reactance transformers, at least 25 kv-a. per phase would be required to give sufficient current to maintain more than the required six-volt drop for the extreme case of secondary short-circuit. This is considerably lower than the load density of the district requires.

Discussion

For discussion of this paper see page 869.

1. On the basis of maintaining constant secondary voltage at transformers.

General Light and Power Supply of Chicago

BY G. M. ARMBRUST AND J. B. JACKSON
Member, A. I. E. E. Associate, A. I. E. E.
Commonwealth Edison Company, Chicago, Ill

***Review of the Subject.**—The development of a distribution system is largely determined by the load density and its rate of change. The following is a discussion of these factors and their influence on the Chicago distribution system:*

The d-c. system which supplies the central part of the city includes an area of about one sq. mi. in which the load is expected to reach 200,000 kw. in 20 years. This would economically require substation supply of about 10 substations of 25,000 kw. each.

Surrounding the small d-c. area the general light and power supply over the city is by means of 60-cycle, 4,000-volt circuits, except for the larger industrial loads which are supplied from 12,000-volt lines. The load density of the greater part of the 4,000-volt system is about 4,000 kv-a. per square mile, and the economical supply would be from 7,000 kv-a. remote controlled substations spaced about 1.3 miles. The maximum density of load on this system is 10,000 kv-a. which would require 10,000-kv-a. substations.

Calculations indicate that, with increasing load densities, the economy of this intermediate distribution voltage disappears, and in the ultimate development higher distribution voltages are necessary.

THE design of a distribution system for a city or community is naturally influenced by local conditions, such as the civic and architectural character, arrangement of streets, nature of load, construction costs, etc. Under the conditions existing, the development of a distribution system is then determined by the load density of a considerable area and its rate of change. The purpose of the following discussion is to describe the load distribution and density which influence the development of distribution systems in Chicago. The system discussed is for supply to general light and power and does not include that for railway or large units of power, which require special supply from the generating stations.

Energy is distributed by 4000 volt, three-phase, 60-cycle circuits over all of the area of the city for units of load up to 300 or 400 kv-a., except the "downtown" portion, which is supplied by the low-tension, direct-current network. Large single demands are supplied through individual transformer installations directly from the 12,000-volt, 60-cycle system.

Direct Current Distribution

The direct-current system at present covers eight square miles and distributes about 150,000 kw. maximum. About five square miles of the outer area of this system is being transferred to the a-c. system for better distribution economy, and to restrict the growth of the 25-cycle generating system which carries most of this load. The area to be cut over comprises about 20 per cent of the d-c. load and the density is about that of the more heavily loaded 60-cycle districts. The remaining area of three square miles in the congested business district will continue to be supplied from the d-c. net work, because of the great investment in the existing equipment and the desire of some of us for battery reserve.

The design of the present d-c. distribution system, particularly in the congested areas, is limited by physical conditions, such as space available for distribution cables, sites, and capacities of substations available, etc., necessary to supply the demand. Of the total present load on this system, about 75,000 kw. is concentrated in about one square mile in the downtown loop district. Studies have been made of the demands, load, characteristics of the classes of business and their probable growth, to determine the future requirements of the distribution system.

About one-sixth of the area of the congested business district is covered by large retail stores, the average load of which, when developed with modern buildings, will ultimately be about 2500 kw. per square block. Most of the district is covered with large office buildings, hotels, and theatres. The modern office building load is about 2800 kw. per square block, and under the present permitted height of buildings may reach 6000 kw. per square block in certain locations where exterior flood lighting is also used. The modern large hotels average about 2800 kw. per square block, and the theatres about 1500 kw. Railroads and terminals now occupying considerable space in the downtown district will, after electrification, have high buildings above them, probably of the office building type with loads of 2800 kw. per square block. A small portion of the area is occupied by wholesale stores, warehouses, small manufacturing, etc., which will not average over 500 kw. per block. These demands for various classes of buildings with their diversities, indicate a possible load of 200,000 kw. in this square mile in the next twenty years. If such a system was being laid out new, with sufficient space available for substations and distribution feeders, the most economical supply would be from 8 or 10 substations of 25,000 kw. capacity, each distributing over a radius of two blocks. However, as there is not sufficient space in the average downtown street for the number of feeder cables required for the larger substations, it would probably be necessary to install 20 or more substations of smaller capacity. With this arrangement, 10 or more would probably be automatically-operated or remote-controlled from the remaining manually-operated substations.

60-Cycle Distribution

The 60-cycle, 4000-volt general light and power supply covers an area of about 150 sq. mi. and supplies 330,000 kv-a. over about 375 circuits of 1000-kv-a. capacity each. These circuits are operated radially, but are provided with emergency switching centers for the transfer of load between circuits. Customers whose load is of a special nature are being provided with supply from two circuits with oil switch throw-over. Feeders are practically all underground and

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

primary and secondary distribution principally overhead from 22 attended substations of 10,000 to 20,000 kv-a. capacity and 19 remote control substations of 3000 to 6000 kv-a. capacity. The remote-control substations are supplied and controlled from the attended substations, and it is planned to make all future substations of this type. The rate of increase of load supplied by this system is about 18 per cent per year, and the detailed connections for its supply are continually undergoing changes in design necessary to provide for increased capacity and to improve economy.

The average load density is about 2000 kv-a. per sq. mi. and if uniformly distributed, the economical size of substation would be about 5000 kv-a. The maximum present load density is 10,000 kv-a. per sq. mi. and occurs in residence district solidly built up with high-grade apartment buildings, hotels, theatres, etc. The most economical size of substation to supply 4000-volt distribution for this density of load is about 10,000 kv-a. spaced about one mile apart. This capacity is also about the maximum unit of capacity of the present transmission cables. While at present only a few spots of comparatively small area have such dense loads, the present rate of increase and the development of high-class residence and hotel districts indicate an area of some 10 sq. mi. will have reached such density within a few years. Measurements made of loads of test blocks of various typical areas in the city over a period of years indicate the load density has, by no means, reached saturation.

The density of a very large part of the area served from this system is about 4000 kv-a. per sq. mi., and in general, the economical design of distribution circuits for this loading would determine the standard size and arrangement of circuits. Calculations show the economical size of substation is 7000 kv-a., spaced about 1.3 mi., and the economical size of feeder is 350,000 cm. This is influenced also by the decrease in the amount of feeder regulation required for the shorter and more uniform length of feeders, as compared with the original standard size of 1/0.

As the density increases, the economy of the 4000-volt intermediate system between the 12,000-volt transmission and the secondary distribution voltage is lessening. In the area of present maximum density of the system, there is a number of square blocks having loads of from 500 to 2000 kv-a. which could be supplied from a single transformer installation and secondary mains. The increasing number of such cases in these more densely loaded areas make it desirable to extend the 12,000-volt system into these districts, taking over the existing load in certain heavily loaded blocks, and as the load of the district, as a whole, increases, ultimately eliminating the 4000-volt system in the district.

Details of schemes for supplying secondary low-tension mains direct from the 12,000-volt system have been worked out and it is proposed to install 12,000-volt feeders of about 4000-kv-a. capacity, supplying transformers to be located in the vaults. These feeders are to be from the 12,000-volt attended substations and two lines brought into each vault with provision for automatically disconnecting a faulty line.

The cost of regulation is materially decreased by this scheme, as compared with 4000-volt distribution, where the entire load is regulated on practically every feeder. Regulation can be provided in the transformer vaults and usually would be necessary on only a small part of its total load.

Industrial power loads of 400-kv-a. or more are supplied at 12,000 volts from lines subsidiary to the 12,000-volt transmission system. These lines, where possible, are arranged in loops usually of 4000-kv-a. capacity from attended substations. There are a total of about 125 such installations with an average maximum load of between 500 and 600 kv-a. The loop arrangements offer a convenient and economical scheme where the customers are grouped, as they usually are, and provide means of protecting the general transmission system from interruption due to trouble on loops or in the customer's vaults, and at the same time providing the customer with two sources of supply, and automatic reserve in case of line failure. Current-limiting reactors are installed in the supply to the loops, to prevent an excessive rush of current into damaged equipment, and sections of the loops are controlled by relays, which automatically sectionalize or cut out a damaged link without interruption.

Another arrangement under consideration provides for two or more tap feeders to a group of customers, each one being provided with taps on two feeders with throw-over oil switches, automatically-operated. This scheme would require less switching equipment and often a more economical cable arrangement.

In general, the rapid increase in loads of central station companies during the past few years has made necessary radical changes in the distribution systems to meet the demands with the best possible economy. The problems of redesigning are often complicated by the large amount of investments already made and which must be used to the best advantage. The great increase in investment required for distribution makes necessary a continual and thorough study of the characteristics and rate of change of loads for some years ahead.

In accordance with the request of the Meetings and Papers Committee to shorten papers as much as possible the above is presented as some conclusions from detailed calculations. It is hoped that an opportunity will be given in the discussion to present the data on which they are based.

We appreciate that distribution systems in Chicago are in a transient stage and much study and a long sight ahead is necessary for their development. We recognize also with the increasing loads the tendency for higher distribution voltages.

Discussion

For discussion of this paper see page 869.

A Study of Underground Distribution Systems
for the City of New Orleans

BY W. R. BULLARD
Associate, A. I. E. E.
Electric Bond & Share Co., New York City

Review of the Subject.—Recent developments in alternating current low-voltage networks have aroused a considerable amount of interest as to the application of a-c. distribution to the service requirements of business centers of large cities. Therefore, when the New Orleans Public Service Inc. was recently confronted with the necessity for rehabilitating its underground distribution system, it was decided that a thorough investigation should be made to determine the economics and advantages of various a-c. systems as compared with d-c. distribution. This paper gives the results of the investigation which was made, and describes the system which was selected to form the basis for serving the future growth of load in the underground district of New Orleans and for eventually displacing the present distribution system.

* * * * *

Part I

COMPARISON OF DIFFERENT TYPES OF SYSTEMS AND GENERAL DISCUSSION OF THE PREFERRED SYSTEM

THE distribution of electrical energy to business districts of large cities, or other similar districts having exceptionally high-load densities, involves service of the highest order, and presents conditions and requirements which differ widely from those of electrical distribution in the far more numerous and extended territories having moderate-load densities. The three-wire Edison d-c. system during many years of operation has established for itself an excellent record of reliability of service. Furthermore, the load characteristics of metropolitan districts are more favorable to the economics of d-c. distribution than those of other territories. This system has therefore continued since the early beginnings of the industry to serve the large business centers, while a-c. distribution has obtained a firm foothold in nearly all other portions of the central station's domain.

Within recent months, however, important developments have been made in the adaption of a-c. distribution to the peculiar requirements of heavily loaded business districts, and an unusual amount of interest in the possibilities opened up by these developments has been aroused. In consequence of this, when it was recently found necessary to completely rehabilitate a large underground low-voltage distribution system serving the business district of New Orleans—namely, that of the New Orleans Public Service Inc.—It was decided that a thorough study should be made of both present systems and new developments in underground distribution before selecting the type of system which would form the basis of the proposed rehabilitation. An investigation was therefore made of a number of distribution systems throughout the country, and a study as to economy and practicability was worked out for typical systems in their application to New Orleans conditions. The purpose of this study was to determine what combination of the features of systems now in use, both old and new, would be the most suitable for reliably and economically serving the business district of New Orleans.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

The system selected as a result of this study contains several of the more radical features of certain existing systems in different parts of the country. It is not yet in operation, but when installed will perhaps be the first system to utilize all these features in combination. However, no one feature is proposed which has not been tried in actual service. Briefly described, the system which was adopted comprises the following main features which may be better understood by referring to the diagram Fig. 1:

1. Direct transmission of energy from generating station to distribution transformers at 13,200 volts. The distribution substation is eliminated, and only one transformation is used, the voltage of each feeder being controlled by separate automatic induction regulators located in the generating station.

2. Use of an interconnected network of a-c. low-voltage mains served by a multiplicity of distribution transformers and by a number of 13,200-volt feeders as mentioned above. All protective devices external to the generating station are eliminated except one—namely, a reverse energy opening, automatic reclosing network switch, one unit being installed in the secondary leads of each distribution transformer bank.

3. Use of one system of secondary mains for both lighting and power service. This combination is effected by the selection of a three-phase four-wire Y-connected low-voltage system with 115-volt service between each live leg and neutral, giving 200-volts as the delta voltage.

The purpose of this paper is to set forth the results of the above-mentioned study and to discuss the various factors which entered into the selection of this particular system. Before going into details, however, it will be well to give a brief description of the existing systems which now serve the underground district of New Orleans.

Brief Description of the Present System. The underground district of New Orleans is shown on the map of Fig. 2. While somewhat irregular in shape, it is roughly twenty city blocks long and ten blocks wide.

The total present load in this district is served almost entirely by two 120/240 volt d-c. systems which parallel each other. Of these we shall consider only the system operated by the New Orleans Public Service Inc. This system is served by three substations, all within the underground district and reasonably well located with respect to the distribution of load. The center of the underground district is some two miles from the main generating station of the New Orleans Public Service Inc. While the present transmission feeders consist of 6600-volt underground cable, a 13,200-volt bus will be established in the generating station in the near future and a portion of the transmission system will be changed to this voltage.

The d-c. system of the New Orleans Public Service Inc. is now partly overhead and partly underground. The overhead portions are located at the two extreme ends of the underground district, and while they represent a considerable portion of the territory served by the d-c. system, nevertheless the load carried by these overhead portions is small. The underground portion of the d-c. system consists of the familiar network of mains tapped at various points by feeders. The feeders consist largely of 1,000,000-cm. single-conductor cable and are tied into the mains through a novel type of junction box. This junction box has the appearance of a large fire plug and is usually located at street intersections. It was designed to overcome difficulties, due to lack of drainage of duct systems which, however, have been largely overcome. Both feeders and mains are fused. The mains consist largely of 500,000-cm. cable for the outside legs, the neutral being of a smaller cross section in most cases. Load characteristics and other similar features of the system will be described in another part of the paper.

Brief Description of Systems Considered in the Study. It was assumed throughout the entire study that with the introduction of any new system an extended period of time will be required in order to entirely displace the system now in service. For purposes of calculation, a 30-year period was assumed—that is, that it would require 30 years to completely replace the existing system with a new system, the latter in the meantime being extended so as to parallel the old system throughout the district. The calculations cover the first 10 years of

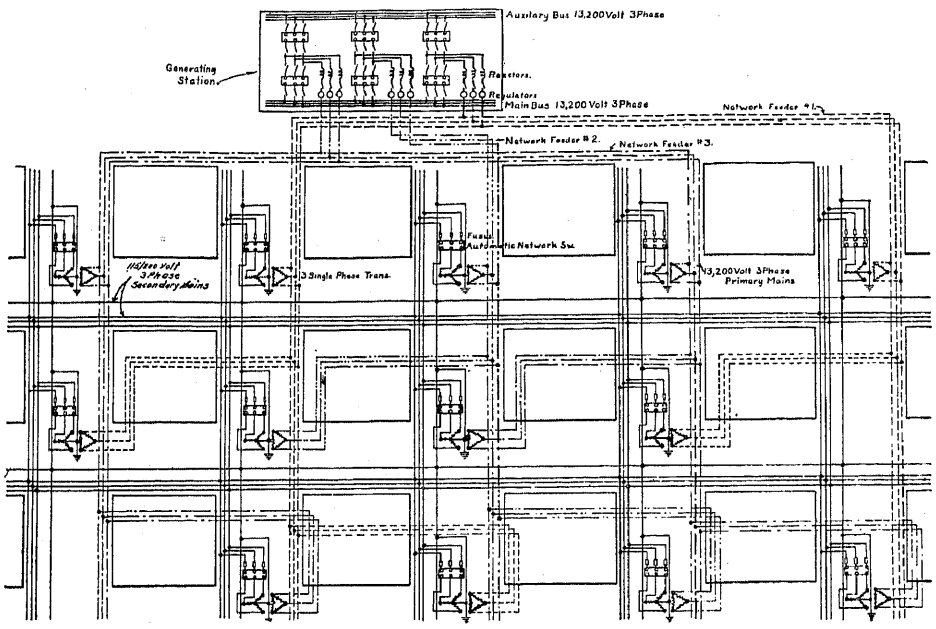

Fig. 1—Elementary Diagram Showing General Arrangement of Cable and Apparatus in the Type of Distribution System Selected for Serving the Underground District of New Orleans

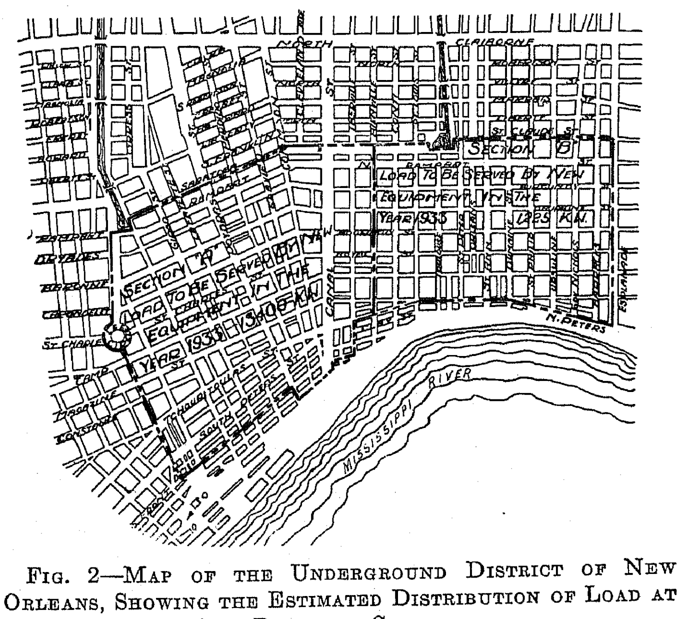

Fig. 2—Map of the Underground District of New Orleans, Showing the Estimated Distribution of Load at the End of a 10-Year Period of Growth

this period and are therefore based on a load equivalent to one-third of the present load of the underground district plus the total growth for the 10 year period.

Before presenting the tabulated cost data, a brief description will be given in the following of each of the systems which were considered. Five types of distribution systems were included in the study and these may be briefly described as follows:

1. *13,200-volt primary with network secondary.*

This is the system which was selected for New Orleans and shows the greatest economy of all those considered. No details, additional to those given above, need be included at this point. In this system, as in all the other a-c. systems considered, the service was assumed to be 3-phase 4-wire 115/200 volt.

2. *13,200-volt radial.*

This system differs from the first in that each transformer bank feeds an isolated section of secondary mains and no attempt is made to operate the transformers in parallel.

3. *4,000-volt primary with network secondary.*

This system is similar to the first-mentioned system, except that the distribution is at 4000 volt instead of 13,200 volt necessitating in this case, the usual step-down transformer substation to convert from 13,200 volt to 4000 volts.

4. *4000-volt Radial.*

This system is the familiar 4000-volt 4-wire grounded neutral system. Each 4000-volt feeder serves an individual district and each distribution transformer bank serves an isolated section of secondary mains.

5. *Combined d-c. and a-c.*

In connection with a previous study of distribution in New Orleans, the engineering features of the problem of maintaining d-c. service in the main business district were thoroughly investigated. This investigation, however, contemplated the change-over of the outlying sections from d-c. to a-c. service. For purposes of comparison with the above systems, which contemplate eliminating d-c. entirely, the economics of the combined d-c. and a-c. system are included. This, of course, presents the d-c. system under the most favorable conditions. Furthermore, the presence of an existing d-c. network eliminates a large item of investment in this case, tending still further to favor the economics of d-c. service. The division of territory between a-c. and d-c. service is shown in Fig. 2, together with the estimated load densities. The a-c. territory comprises a portion of the old French Quarter designated as Section B on the map. The a-c. system in this case is the same as No. 4 above—namely, 4000 volts radial.

Tabulated Summary of Results. The calculations are all based on cable and apparatus necessary to serve a total load equivalent to the growth of the load in the underground district for ten years plus one-third of the existing d-c. load in Section A (See Fig. 2) and all the existing d-c. load in Section B. This is equivalent to assuming that in ten years, with no renewals and replacements, one-third of the present d-c. equipment in Section A will be unfit for service, and that in the case of the a-c. systems a corresponding amount of load must be transferred to the new a-c. equipment. The investment figures for the d-c. system, therefore, include what might properly be called renewals and replacements for the present system, but which for convenience have been combined with the investment in new equipment to obtain the investment totals shown in the tables.

Before working out the detailed analysis of the four a-c. systems a preliminary study was made of the economics of transformer spacing and sizes of secondary mains for each of the four systems. This was done in order to have the comparison based on the most economical equipment for each system. The load densities in the two sections shown in Fig. 2 are so greatly different that the equipment for each of these sections was considered independently, and the transformer spacing and sizes of secondary mains were worked out separately for each of these two districts.

The figures for total investment, overall efficiencies, etc., include all of the distribution system between generating station feeder circuit breakers and the point of connection of the service laterals to secondary mains. The service laterals and service equipment were not included in calculations, since these in general would be the same for all five systems except for certain differences in the cost of meters, etc. between a-c. and d-c. service, and these differences would be in favor of the a-c. systems.

It should be noted particularly that throughout the calculations the investment figures were intentionally made liberal for the more novel systems, thus placing a handicap on these systems and favoring the others.

The totals shown in Table I are intended to provide a complete economic comparison between the various types of systems. They include fixed charges on new investment, energy and demand charges for electrical losses in the system, substation operators' salaries for the systems which have manually-operated substations, and maintenance of automatic switches for the network systems, all being based on the characteristics of the new equipment at the end of a ten-year period of growth. To facilitate the comparison, figures showing the differences between the annual charges of particular types of systems have been added.

Table II gives the estimated aggregate new investment to the end of the ten-year period, itemized to show individual totals for each of the various kinds of equipment. To facilitate the comparison, figures showing the differences between the total new investments of particular types of systems have been added. The investment figures are based on equipment which would be necessary if there were no losses in the system. The investment in additional equipment made necessary by the losses is included separately in the table showing "Demand Charges for Losses" which also includes some generating station charges.

TABLE I

SUMMARY OF TOTAL ANNUAL CHARGES

	Network 13,200 Volts	Radial 13,200 Volts	Network 4000 Volts	Radial 4000 Volts	Combined A-C. and D-C.
Charges on New Investment at 14 per cent	$193,000	$233,000	$277,500	$306,500	$335,300
Energy Charges for Losses	18,920	22,730	37,680	40,440	103,206
Demand Charges for Losses	32,310	27,490	61,170	52,050	123,980
Substation Operators' Salaries			11,900	11,900	Automatic
Maintenance of Network Switches	1,780		2,560		
Total Annual Charges	$246,010	$283,220	$390,810	$410,890	$562,486

SAVINGS IN TOTAL ANNUAL CHARGES

	Savings in Dollars	Savings in Per Cent of Total for Network 13,200-Volt System
Network 13,200 Volts vs. Combined d-c. and a-c.	$316,476	128 per cent
Network 13,200 volts vs. Network 4000 volts	144,800	59 per cent
Radial 13,200 volts vs. Radial 4000 volts	127,670	52 per cent
Network 13,200 volts vs. Radial 13,200 volts	37,210	15 per cent
Network 4000 volts vs. Radial 4000 volts	20,080	8 per cent

TABLE II

SUMMARY OF NEW INVESTMENT FOR VARIOUS PARTS OF THE SYSTEM

	Network 13,200 Volts	Radial 13,200 Volts	Network 4000 Volts	Radial 4000 Volts	Combined A-C. and D-C.
Secondary Mains and Ducts	$596,000	$596,000	$492,000	$492,000	$262,000

*Based on the assumption that rotating machines will be operated with sufficient leading current to produce unity power factor at the generating station.

The figures given in Table IV represent fixed charges on investment in equipment in various parts of the system, which investment is made necessary by the losses (including wattless kilovolt-ampere due to reduced power factor) at the peak load of the system. Generating station investment is included in these charges, and also certain portions of generating station operating charges, as explained in the latter part of this paper.

Table V shows the estimated yearly losses in

TABLE VIII—PHYSICAL CHARACTERISTICS OF VARIOUS DISTRIBUTION SYSTEMS CONSIDERED IN THE STUDY

	Network 13,200 Volts	Radial 13,200 Volts	Network 4000 Volts	Radial 4000 Volts	Combined D-C. and A-C. System
Secondary Mains	Both Sections, 3-phase, 4-wire, 115/199-volt, single-conductor cable Section A, 500,000-cm., Section B 4/0-A. w. g. (The above voltages are those at lamp socket and motor terminals).	Both Sections, 3-phase, 4-wire, 115/199-volt, single-conductor cable, Section A, 500,000-cm., Section B 4/0-A. w. g. The above voltages are those at lamp socket and motor terminals.	Both Sections, 3-phase, 4-wire, 115/199-volt, single-conductor cable, Section A, 350,000-cm., Section B 2/0-A. w. g. The above voltages are those at lamp socket and motor terminals.	Both Sections, 3-phase, 4-wire, 115/199-volt, single-conductor cable, Section A, 350,000-cm., Section B 2/0-A. w. g. The above voltages are those at lamp socket and motor terminals.	Section A 3-wire, 120/240 volt d-c. single-conductor cable, Section B, 3-phase, 4-wire, 115/199 - volt, single-conductor cable 2/0-A. w. g. The above voltages are those at lamp socket and motor terminals.
Secondary Junction Boxes	None	Both Sections, 3-pole, 5-way, sizes to suit secondary mains.	None	Both Sections, 3-pole, 5-way, sizes to suit secondary mains.	Section A, ornamental casting, street type similar to existing, Section B, 3-pole 5-way, sizes to suit secondary mains.
Automatic Network Switches	Both Sections, Westinghouse, reverse energy opening, automatic reclosing with no voltage release 3 - pole, 115/199-volt, Section A, 1000-ampere, Section B, 500-amperes.	None	Both Sections, Westinghouse, reverse energy opening, automatic reclosing with no voltage release 3 - pole, 115/199-volt, Section A, 750-amperes, Section B, 250-amperes.	None	None
Distribution Transformers	Both Sections, single-phase, subway type, 13,200/115 - volt, 10 per cent reactance, 3 per bank, Section A, 100-kv-a. each, Section B, 50-kv-a. each.	Both Sections, single-phase, subway type, 13,200/115 - volt, standard reactance, 3 per bank, Section A, 100-kv-a. each, Section B, 50-kv-a. each.	Both Sections, single-phase, subway type, 2300/115 - volt, 10 per cent reactance, 3 per bank, Section A, 75-kv-a. each, Section B, 25-kv-a. each.	Both Sections, single-phase, subway type, 2300 / 115 - volt, standard reactance, 3 per bank, Section A, 75-kv-a. each, Section B, 25-kv-a. each.	Section B, single-phase, subway type, 2300/115 - volt standard reactance, 3 per bank 25 kv-a. each.
Primary Junction Boxes and Fused Cutouts	None	Both Sections, 3-pole, 2-way, 13,200 - volt, junction boxes for sectionalizing primary mains and special 13,200-volt fused cutouts in transformer primary leads.	None	Both Sections, 3-pole, 2-way, 4000 - volt, junction boxes for sectionalizing primary mains and single-pole fused cutouts in transformer primary leads.	Section B, 3-pole, 2-way, 4000 - volt junction boxes for sectionalizing primary mains and single pole fused cutouts in transformer primary leads.
Primary Mains	Both Sections, 3-phase, 4 - wire, 13,200 - volt, single-conductor cable 4/0 and 2/0 A. w. g.	Both Sections, 3-phase, 4 - wire, 13,200 - volt, single-conductor cable 4/0 and 2/0 A. w. g.	Both Sections, 3-phase, 4 - wire, 2300 - volt, single-conductor cable 4/0 and 2/0 A. w. g.	Both Sections, 3-phase, 4 - wire, 2300 - volt, single-conductor cable 4/0 and 2/0 A. w. g.	Section B, 3-phase, 4-wire, 2300-volt, single-conductor cable 4/0 and 2/0 A. w. g.
Primary Automatic Double Throw Switches	None	Special 3-pole, 13,200 volt, automatic double-throw switches with no voltage control and including the necessary potential transformers.	None	Westinghouse, 3 - pole, 4000-volt, automatic double-throw switches with no voltage control and including the necessary potential transformers.	None
Distribution Feeders	Both Sections, 3-phase, 13,200 volt, 3-conductor cable 4/0 A. w. g.	Both Sections, 3-phase, 13,200 - volt, 3-conductor cable 4/0 A. w. g.	Both Sections, 3-phase, 4 - wire, 4000-volt, 3 - conductor cable 300,000 - cm. (secondary neutral used).	Both Sections, 3-phase, 4 - wire, 4000-volt, 3 - conductor cable 300,000 - cm. (secondary neutral used).	Section A, 240 volt d-c., 1,000,000 - cm. single-conductor cable. Section B, 3-phase, 4-wire, 4000 - volt, 3-conductor cable 300,000-cm. (secondary neutral used).
Regulators	Single - phase, 13,200-volt, 150-amperes, 10 per cent, buck or boost, 3 regulators per feeder.	Single - phase, 13,200-volt, 150-amperes, 10 per cent buck or boost, 3 regulators per feeder.	Single - phase, 2300-volt, 200-amperes, 10 per cent buck or boost, 3 regulators per feeder.	Single - phase, 2300-volt, 200-amperes, 10 per cent buck or boost, 3 regulators per feeder.	Single -phase, 2300-volt, 200-amperes, 10 per cent buck or boost, 3 regulators per feeder.
Substations	None	None	13,200/4000 volt step-down transformer substations with necessary switching equipment and auxiliary apparatus.	13,200/4000-volt step-down transformer substations with necessary switching equipment and auxiliary-apparatus.	13,200-volt, a-c., to 120/240-volt d-c. substations including motor generator sets and apparatus for automatic operation. Also equipment necessary to supply small amount of 4000-volt a-c. load.
Transmission Feeders	None	None	3 - phase, 13,200 volt, 3 - conductor cable, 350,000-cm. each conductor.	3 - phase, 13,200 - volt, 3 - conductor cable, 350,000-cm. each conductor.	3 - phase, 13,200 - volt, 3 - conductor cable, 350,000-cm. each conductor.

Note: The above is based on a load in the underground district corresponding to ten years' growth plus 1/3 the present d-c. load.
Section A is the section of the underground district uptown from Bienville St.
Section B is the section of the underground district downtown from Bienville St.

thousands of kilovolt-hours in the various parts of the system. The overall efficiency of each type of system as calculated from these losses is also shown.

Table VI shows the estimated losses in kw. at the annual system peak load, and also the peak efficiency of each type of system as calculated from these losses.

Table VII shows the kilovolt-ampere peak load at the customer's service laterals and the increase in kilovolt-ampere as this load passes through the various parts of the system. The generating station power-factor at the peak load is also shown for each type of system. The kilovolt-ampere increases were all worked out vectorially and the individual figures represent the arithmetical differences between kilovolt-ampere input and kilovolt-ampere output for the particular parts of the system.

Table VIII is included in order to provide a ready reference to the cable sizes, apparatus ratings, etc. for the five types of systems.

TABLE IX
NUMBER OF UNITS IN MOST IMPORTANT PARTS OF SYSTEM

	Net-work 13,200 Volts	Radial 13,200 Volts	Net-work 4000 Volts	Radial 4000 Volts	Com-bined A-c. and D-c.
Transformer Banks......	74.1	104.0	106.5	154.7	32.0
Distribution Feeders.....	6.28	6.28	15.6	15.6	150.0
Substations............			2.0	2.0	4.0
Transmission Feeders....			3.59	3.59	

Note: The above fractional values were used rather than the nearest whole number in order not to penalize any particular system for the particular values of load which were taken to represent the ten years' growth.

Table IX gives the number of transformer banks, number of distribution feeders, etc., which were used as a basis for the calculations.

A. C. Versus D. C. Distribution. It is to be expected that certain difficulties will be encountered in making the change from d-c. to a-c. service in New Orleans, and one of the chief questions that has been raised in this connection concerns the difficulty of obtaining space underneath the streets for the location of transformer manholes. It is intended in the adopted system, in so far as practical, to locate the transformers in vaults on the customer's premises, thus reducing the cost and at the same time placing the transformers near the load to be served, as only large buildings, of course, will be selected for this arrangement. Unfortunately, however, there will be comparatively few locations in New Orleans where this type of construction can be used, due to the small number of buildings which have basements. A great deal of discussion has been devoted to the matter of transformer manholes in congested districts, and it will undoubtedly be difficult in some cases to find clear space sufficiently large for the purpose underneath the street. However, no fear is entertained as to the possibility of ultimately obtaining space for all the necessary manholes by resorting to various combinations of design. Fig. 3 shows roughly the dimensions of the proposed typical transformer manhole which were used for the calculations. These dimensions are very liberal, and undoubtedly the actual manholes as installed will be somewhat smaller.

The theoretically ideal location for a transformer manhole is at a street intersection, due to the possibility of feeding into the mains in four directions. However, the actual location in average cases will probably be near the intersection but removed several feet back from the corner so as to avoid the multiplicity of subsurface structures. In some cases it may be necessary to excavate to a sufficient depth to bring the ceiling below certain types of subsurface structures, and in a few cases it may possibly be necessary to construct three small manholes instead of one, each manhole housing one of the three transformers. It is very doubtful, however, whether it will be necessary in any ordinary case to use this particular construction.

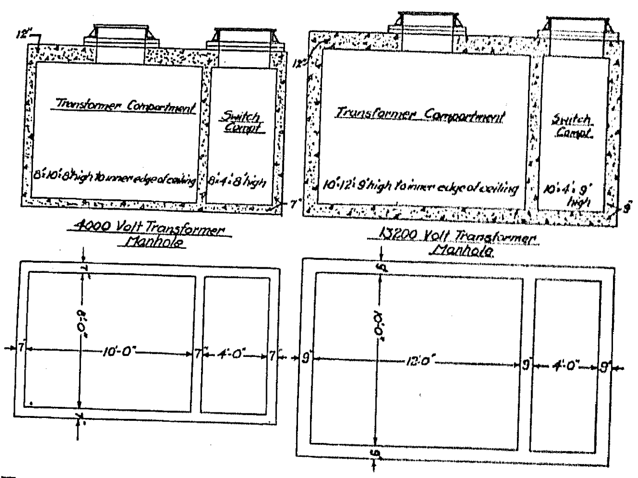

FIG. 3—TYPICAL TRANSFORMER MANHOLES FOR 4000-VOLT AND 13,200-VOLT DISTRIBUTION, SHOWING DIMENSIONS USED IN ESTIMATING THE COST OF CONSTRUCTION

Certain applications of power have heretofore been considered as inherently requiring d-c. service. One of the principal cases of this kind in connection with service to business districts is that of high-speed elevators. That is, there has heretofore been a real difficulty in obtaining satisfactory high-speed elevators designed for a-c. service. A great deal of progress has been made in a-c. elevator design in recent years, however, and satisfactory a-c. equipment is now available in speeds equal to the highest speeds now used in d-c. equipment. Probably the most commonly used type of a-c. high-speed equipment is that utilizing variable voltage control. This type of equipment consists of individual motor-generator sets for each elevator supplying variable voltage d-c. to the elevator motors. The simplicity of control and economy of operation of this type of equipment are now fairly well known. There are also medium high-speed installations in service supply-

ing a-c. directly to the elevator motor that have been successful.

It may be stated in general that a-c. equipment can now be supplied for practically all the needs of modern business centers and no difficulty is expected in lining up new business to conform to the new type of service. Existing lighting services in a large number of cases can be transferred directly from the d-c. system to the new a-c. mains. Existing d-c. services which involves large amounts of motor load need not be transferred to the a-c. system at once. It is intended to gradually reduce this type of load and ultimately eliminate it by extending the process over a period of years sufficient to allow for 100 per cent depreciation of existing equipment. That is, it is expected that in the process of years of growth d-c. motor customers can be made to gradually disappear coincidently with the depreciation of existing d-c. motors and equipment. To facilitate this process, the present underground d-c. system will be completely paralleled by the new a-c. system, and the transfer of service connections, aside from changes on the customer's premises, will be merely a matter of cutting and splicing.

A certain amount of actual change over of customer's equipment will, of course, be desirable from time to time, and the expense of doing this must be borne by the company. This will apply particularly to the sections which are now served overhead. Fortunately, however, the motor load in these sections is small.

13,200-Volt Distribution. A central station company on the west coast has for a number of years been operating an 11,000-volt grounded "Y" underground distribution system, the characteristics of which are briefly as follows:

For single-phase service standard 6600-volt subway-type transformers are used between line and neutral. For 3-phase service single units are connected in "Y" on the high-tension side with neutral omitted, this being the same practise as the standard on the 4000-volt system. Paper insulated 15,000-volt cable is used exclusively. A single-pole combined switch and fuse developed by the central station company is used for sectionalizing and protective purposes. A record of excellent service is claimed for this system, notwithstanding the fact that the higher voltage may introduce a somewhat greater possibility of cable and transformer failure, and also that a high-voltage cable failure causes an interruption to comparatively large area. The economic advantage of the use of a higher voltage for systems such as that in New Orleans is immediately apparent. By using distribution transformers having primary suitable for 13,200 volts, the usual step-down transformer substation is eliminated, with the corresponding saving in investment, increase in efficiency and elimination of the usual operating charges for substation personnel. The reliability of service would presumably be somewhat impaired by the use of the higher voltage on a straight radial distribution system. However, by the use of the interconnected secondary network this problem is solved and the chief objection to the higher voltage is eliminated.

The system adopted for New Orleans contemplates the use of 3-conductor, 13,200-volt feeders to operate at about 150 amperes per leg, the conductor size being No. 4/0 a. w. g. Three single-phase regulators located in the generating station will be used for each feeder, these regulators being wound on the primary side for full delta voltage and having a capacity of 150-amperes line current. The size of feeders selected is a compromise between good economy and reliability. Considering the value of the total load for the underground district, it did not seem desirable to concentrate a greater amount of power in single units than that corresponding to this size of feeder.

It will be noted by referring to Fig. 1 that no primary fuses or disconnecting switches whatever will be used. These devices are considered unnecessary in connection with the interconnected secondary network. The failure of a distribution transformer will, therefore, have the same status as a primary cable failure, and will mean the disconnection from the system of an entire primary feeder unit. This, however, should not involve interruption to service. The question has been raised as to whether internal distribution transformer short circuit between turns or on the low-voltage side might not draw such a small current as to fail to open the generating station switch. No difficulty from this source is expected since experience has shown that minor transformer short circuits very rapidly develop into short circuits of sufficient magnitude to operate the station protective equipment.

The distribution transformers will be connected delta-Y as shown in Fig. 1, and the primaries will therefore be wound for 13,200 volts. These transformers will all be single-phase of the subway type and will have 10 per cent internal reactance for purposes of load distribution in the secondary network.

It was originally proposed to use a 3-phase 4-wire system for the primary with grounded neutral, designing the distribution transformers for 7630 primary and connecting them "Y-Y" but the relative merits of this plan as against the "Delta-Y" connection are somewhat open to question. In view of certain disadvantages of the grounded neutral system, such as the necessity of maintaining a neutral connection between the generating station and distribution transformers, the necessity of permanently grounding the generating station 13,200-volts bus, etc., the "Delta-Y" connection was selected.

Interconnected A-C. Low Voltage Network System. The low voltage a-c. network system proposed for New Orleans is similar to the system which has been in operation in New York for a number of months. This system makes use of automatic network switches which insure reliability of service and also provide several features of economy. This particular system is de-

scribed in another paper and it is not within the scope of this paper to go into details. However, a brief description will be given.

The secondary mains of a given territory are interconnected to form a network similar to that of the familiar d-c. low-voltage system. This network is fed by a comparatively large number of distribution transformers. These transformers are divided into several groups, each group being served by the distributors of an individual high-voltage feeder and the transformers of each group being located at points distributed throughout the territory served by the network. In the secondary leads of each distribution transformer bank is inserted one of the network switches mentioned above. In the case of the transformer or primary cable failure the automatic switches of all transformers connected to the primary unit in question will open and this whole unit, including the feeder, distributors and the transformers, will be disconnected from the system, leaving the service throughout the secondary network intact, since the other primary feeders and transformers which serve the network will not be affected. This operation is accomplished in much the same manner that a transmission feeder is disconnected from a substation bus in case of short circuit. The reliability of service is, therefore, practically equivalent to that of the substation itself, or in the case of the 13,200-volt system, equivalent to that of the generating station bus. In case one or more of the network switches should fail to open, these switches will be disconnected from the system by fuses of somewhat higher capacity than that of usual practise. After the trouble is cleared and voltage is restored to the faulty feeder, the automatic switches will reclose, reconnecting the transformers to the system. If the cables should become crossed in repairing the fault, the switches will remain open until the proper relations are restored by reconnecting the cables. The switches will also remain open until the voltage in the transformer secondaries is somewhat above that of the network, so that the flow of energy will be from the transformers into the network after the switches are closed.

By opening the feeder switches in the substation (or generating station in case of the 13,200-volt distribution) the automatic switches can be caused to open, thereby eliminating the iron losses of some of the transformers during light-load periods. As the load comes on, the automatic switches can be caused to reclose by closing the substation or generating station switch.

This system has the advantage over other systems which lack the automatic reclosing feature, in that it provides increased efficiency due to the reduction of iron losses during light load periods. This saving, however, is comparatively small in this case, due partly to the high-load factor in the New Orleans underground district, the load factor for the year 1922 being approximately 44 per cent at the d-c. substation.

However, there are a good many advantages in the ability to open and close the network switches at will by manipulation in the generating station or substation and in the ability to quickly reclose these switches after having them open. In view of this and also in view of the fact that the cost of the full automatic switch is very nearly the same as that of present types of switches or other devices which are automatic on short circuit only, the type having the automatic reclosing features was selected for the New Orleans system.

Aside from the saving in iron losses mentioned above, and aside from the features of reliability of service, the use of an interconnected low-voltage network of the type selected for New Orleans provides certain inherent economies. Chief of these is the possibility of reducing installed transformer capacity by taking advantage of diversity factor. Another large item of saving lies in the possibility of eliminating primary protective devices. In the case of the 13,200-volt system this is of great importance, since there are no such devices for this voltage and for underground service available on the market. As mentioned previously, the distribution transformers in the New Orleans system will be so located in relation to the primary feeders serving them that the transformers corresponding to any one primary feeder will be scattered throughout the district served by the network. In addition to this, the transformers will have 10 per cent internal reactance. As a result, it is to be expected that the total load of the district will be very evenly divided between the various transformer banks, both under conditions when all high-tension feeders are in service and when one or more of these feeders is out of service. The high reactance will have a tendency to cause larger variations in voltage on the secondary mains than would otherwise be expected, but since the secondary mains themselves will be of comparatively large size, the effect of the transformer reactance on voltage fluctuations should be confined mainly to the changes in the entire load of the network rather than to local load fluctuations. That is, local fluctuations of load will be distributed between a number of transformer banks and the effects will not be as great as might be supposed from consideration of the increased reactance alone without relation to the impedance constants of the entire system.

3-Phase 4-Wire Secondary Service. Considerable attention has been given lately to ways and means of combining a-c. lighting and power service so as to supply both from the same transformer banks and secondary mains. This matter has assumed added importance in connection with the development of secondary a-c. networks, since two complete sets of secondary mains are required for network systems, if power and lighting are served separately.

One of the systems which has proved to be most promising in filling the requirements for a combined power and lighting service, and the one which was selected for New Orleans is the 3-phase 4-wire Y-connected system, the lighting loads being connected be-

tween each outside wire and neutral and 3-phase power loads being served from the three outside wires. In this system it is impossible to maintain both the lighting voltage and the power voltage of the secondary mains standard. A number of different voltage combinations has been proposed in order to compromise between a lighting voltage higher than standard and a power voltage lower than standard. The voltages selected for the New Orleans system are 115 volts (at the lamp socket) between each outside wire and neutral, giving 200 volts between outside wires. This selection was made in order to provide standard voltage for the most important service involving the largest number of customers—namely, lighting; and to allow any penalty to fall on the service involving the least number of customers and pieces of apparatus—namely, power. In order to insure satisfactory service for the motor load in connection with this non-standard voltage, there are several possibilities which may be utilized.

First, it is expected that possibly 90 per cent of all standard motors which are operated on this system will perform in a satisfactory manner. Reduced voltage has the same effect as increasing the percentage loading of the motor or conversely decreasing the nominal load rating. Since the majority of all motors in operation throughout the country are being operated at loads well below nameplate rating, the reduction in voltage should have generally a beneficial effect on the system in serving to increase the power factor.

Second, where cases are encountered in which standard motors will not operate at the lower voltage, the situation can be remedied by the use of small auto transformers, stepping up the voltage to the proper amount.

Third, as the system expands and is better understood by the customers, it should be possible to purchase motors designed for the lower voltage. In the majority of cases this will mean only slight changes in the winding, all other parts of the motor remaining standard.

The question of metering a system of this kind is important but presents no insurmountable difficulties. Since 3-wire lighting services in such a system will require polyphase meters, it will be desirable to require the installation of 2-wire services for all small lighting loads. A move in this direction has already been made in connection with the present tendency to use 10 ampere 2-wire meters instead of 5-ampere 3-wire meters. Where power is served at a different rate than lighting, two meters are necessary and these can be standard meters. Where power and lighting are served under the same rate, the usual two-element meter designed for 3-phase 4-wire service can be used.

The question of flickering of lights caused by the starting of motors has frequently been raised in connection with proposals for combined power and lighting systems. However, practical experience has shown that systems of this kind can be operated without difficulty, if properly designed. A 3-phase 4-wire secondary network has been in operation in Memphis for a number of years and it is largely the experience gained from the operating of this system that has furnished a basis for predictions of performance of the system described in this paper. In the Memphis system standard 220-volt motors have been found to operate satisfactorily in the majority of cases at 200 volts. The metering has been taken care of satisfactorily and flickering of lights has been found to be of negligible proportions if the proper design is used.

Reliability of Service. In laying out the protective system of a distribution network of the type adopted for New Orleans, the secondary mains must necessarily be considered as the starting point. The chief consideration which was followed in this case was that of building up a solid and extensive network which will be capable of burning off low-voltage short circuits, and which will, in general, by virtue of its very magnitude, be enabled to maintain service regardless of all ordinary low-voltage failures.

In carrying out this principle, it is proposed to tie the secondary mains into a solid network, and eliminate sectionalizing fuses. This is in accordance with standard practise in certain large d-c. systems, and has proven its effectiveness during many years of operation.

As an additional precaution, however, against failure due to short circuit of the secondary mains, it is proposed to separate the secondary network into two or more sections, connected by manually-operated switches so that in case of extreme emergency the entire network can be divided into a small number of units. In this connection, voltage wires will also be provided running from some convenient point in each of the sections to a convenient central point, where the voltage conditions can be watched. By this method serious and continued trouble, due to low-voltage short circuits can be located quickly by observing the voltages in the various portions of the network, and the section in trouble can be quickly disconnected from the remainder of the system.

Primary short circuits will, of course, be cleared from the system by the network switches and the station switch, all other protective devices, except high-capacity fuses at the network switch terminals, being eliminated.

The simplicity of the system should, therefore, in itself constitute a reasonable amount of insurance against failure. That is, the fact that multiplicity of apparatus such as substation rotating apparatus, transformers, numerous circuit breakers, etc., is avoided, should greatly reduce the number of apparatus failures. Furthermore, in considering the network switches themselves in connection with the reliability of the system as a whole, particular note should be made of the fact that full reliance is placed in no one switch and that the failure of one or more switches to function will not necessarily mean service interruption, for in this case the secondary fuses backing up a faulty switch or switches will be blown and will eliminate the faulty

apparatus from the system. Reliance is, therefore, placed in numbers rather than in individual pieces of apparatus and it is this feature, together with extreme simplicity, that should recommend the system from the standpoint of continuity of service.

It was contemplated in laying out the system that sufficient primary feeder and transformer capacity will be provided to carry the maximum yearly load with one feeder and its corresponding transformers out of service, and without loading any unit above normal capacity under this condition. This is, of course, in accordance with conservative design and corresponds with the usual practise as to transmission feeders under conditions where continuity of service is of primary importance.

In making the calculations, reliability of service was also carefully considered in connection with the radial systems and these were made as nearly comparable with the network systems as was practicable. For this purpose, a certain number of automatic double-throw primary switches were included for large customers and the radial systems were laid out for quick sectionalizing for eliminating trouble by the familiar cut and try method by which service is restored to the circuit, one portion at a time after an outage has occurred.

Part II

Methods of Calculation

Load Characteristics. The characteristics of the present d-c. load can for convenience be divided into three classes of data:

1. Geographical Distribution
2. Yearly growth
3. Hourly variations

Power-factor and diversity characteristics of the future a-c. load are treated under a separate heading.

In order to obtain the geographical distribution of the total load for the underground district, data collected in connection with a former survey of the system was used. These data were received in the form of a map showing the total kw-hr. reading of meters in each block in the underground district divided by the number of days over which these readings were taken. These data were studied so as to obtain, for purposes of calculation, a small number of districts in which the average load would be approximately the same for each block in the district. Fig. 4 shows this subdivision into three districts and the total existing load in each district is indicated. These figures were obtained by calculation from the kw-hr. data by applying the proportion of daily kw-hr. in each district to the present peak load for the whole district.

In determining the yearly growth and the corresponding load distribution for ten years hence, a number of factors had to be considered. Data showing the previous peaks of the two d-c. systems were available. However, these data were not of a great deal of value in determining the growth for the coming ten-year period. The reason for this is that records of the exact boundaries of territories served by either of the two d-c. systems were not available for past years. Probably, the most definite indication of the amount of growth which can be expected was given by the growth of the yearly peak of the generating station. This, of course, indicates in a general way the growth of the whole city. Therefore, the latter data were given particular weight in estimating future growth. By combining those various classes of data and using a certain amount of judgment as to future growth, the peak load to be served by the new apparatus for the whole district at the end of the ten-year period was estimated to be approximately 14,625 kw.

The matter of determining the geographical distribution of this load was even more difficult. However, by studying the existing distribution and the general trend of expansion, a reasonably accurate estimate was obtained. There is a very definite

Fig. 4—Map of the Underground District of New Orleans, Showing the Distribution of the Present D-C. Load

trend of growth toward Section III and away from the French Quarter. This is due in part to the development of the better class of residential districts in that direction and in part to the campaign against modernizing the French Quarter which is being continually carried on. Taking these various factors into consideration, it was thought that the sections designated as II and III in Fig. 4 could be combined to form a single district which will have a load, to be taken by new equipment, about equally distributed over the whole area at the end of ten years. This division of territory was therefore made for the calculations, as shown on the previous Fig. 2 and described in the preceding part of this paper.

In order to provide an accurate method of calculating losses of each of the four proposed systems, a set of data was worked out which gives the number of hours

per year, during which the actual load is equal in amount to given fractions of the yearly peak load. The method of obtaining these data were as follows: Typical curves were selected for each month of the year 1922. Three daily curves were included for each month, one for a typical Sunday, one for a typical Wednesday and one for Saturday. For these various days, the curves of all the substations in the underground district were combined in order to obtain the total load of the district. Then for all the daily curves, the number of hours during which the load was a certain fraction of the yearly peak was counted. These figures were then multiplied by the total number of days in the month representing that particular type of curve. That is, the figures for the Sunday curves were multiplied by the number of Sundays in the month. Figures for the Saturday curves were multiplied by the number of Saturdays in the month, and the figures for the Wednesday curves were multiplied by the number of all days in the month other than Saturdays and Sundays. The total figures obtained represent very nearly the number of hours during which each fraction of the peak load existed for the whole year. As a matter of general interest, these data have been included in this report in the form of a curve. (See Fig. 5). For convenience, the peak load is divided into eighths, and the various points of the curves at one eighth, two eighths, three eighths, etc., represent the number of hours during which these particular fractions of the peak load represented the actual load during the year. It is understood, of course, that the points designated as one eighth, two eighths, three eighths, etc., do not represent an exact fraction of the peak load but rather a band of loads covering all loads up to 1/16 of the peak load above and down to 1/16 of the peak load below the horizontal line on the load curve which represents the particular fraction of the load designated.

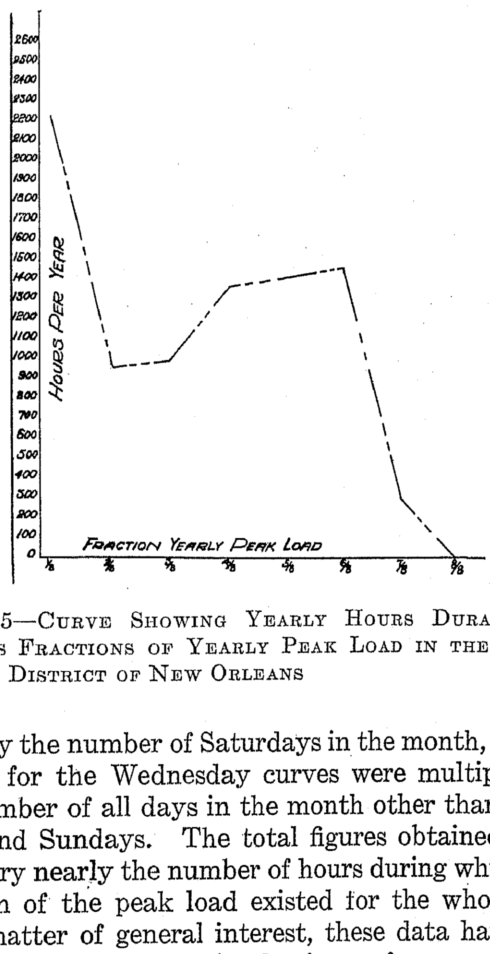

Fig. 5—Curve Showing Yearly Hours Duration of Various Fractions of Yearly Peak Load in the Underground District of New Orleans

Losses. To facilitate the calculation of yearly losses, factors were worked out from the load duration data, which factors could be used as multipliers of the peak losses to obtain the annual losses in kilowatt-hours. These factors may be called loss factors and may be expressed as the equivalent number of hours per year during which the peak losses should exist in order to produce yearly losses equal in amount to the actual losses. The factors for the copper losses of the various parts of the radial systems were obtained by taking the summation of the products of the squares of the various fractions of peak load times the corresponding number of hours per year, as shown on the duration curves. In the radial systems the various annual core losses were, of course, obtained by multiplying the particular core loss in kilowatts by the total number of hours in a year. In the network system the derivation of the duration factors was somewhat more complicated. It was necessary in this case to assume a certain schedule for cutting circuits out of service, based on the load duration curves. The amount of copper in service at different times in accordance with such a schedule was then taken into account. The loss factor for core loss in this case is less than that for the radial systems, while the loss factor for copper loss is more.

The actual loss factors which were obtained in the above manner are as follows:

Type of Losses	System and Apparatus	Loss Factor
Copper	Transformers and Regulators of Network System	2422
"	Secondary Mains of Network System	3022
"	Transformers, Regulators and Secondary Mains of Radial System	2207
Iron	Transformers and Regulators of Network System	6346
"	Transformers and Regulators of Radial System	8760

In calculating losses in secondary mains, an arbitrary symmetrical spacing of transformers was first assumed and the losses calculated for this case. The losses for the desired transformer spacing were then calculated by proportion under the assumption that these losses vary inversely as the square of the number of transformer banks (or d-c. feeders) keeping the size of the banks constant. This relation depends upon placing all transformer banks at street intersections, and may not strictly apply where they are placed indiscriminately.

It is interesting to note in this connection that for a given secondary network and given capacity of trans-

former banks or d-c. feeders, the losses of secondary mains are independent of the amount of load which is supplied to the district. In other words, applying this to the specific problem in hand, the d-c. mains could carry the total load of the district at the end of the ten-year period with no increase of losses in the mains over those existing at the present time, provided that the same sizes of d-c. feeders were used and that they were loaded with the same values of current with respect to their capacity, as at present. This assumes a uniform distribution of load throughout the district. This fact was considered in calculating the losses of the d-c. system.

Investment. The investment figures were for the most part based on actual prices of apparatus and material, plus the cost of installation. Full allowance was made for such incidental items as construction equipment, engineering, interest during construction, etc. In the case of substations, however, the estimates were based on data covering existing stations and those now under construction. Data covering the investment in substations of companies other than the Public Service Inc. were also studied.

Power Factor and Transformer Demand Factor. Due to the fact that the entire service of the underground district of New Orleans is now d-c., it was very difficult to obtain any definite idea of the power-factors and transformer demand factors which would exist in the new a-c. system, without making a very complete and laborious survey of the connected load in the district. In order to avoid the necessity of such a survey, it was thought to be sufficient to use as the basis of any estimate, figures of diversity and power-factor which could be obtained from existing a-c. systems in similar districts of other cities. For this purpose data were obtained from several sources and these together with known characteristics of the New Orleans system, were used to arrive at the estimated factors. In addition to this, a number of typical load curves of building services for the New Orleans underground district were obtained by actual test and these data were also studied.

The actual factors that were used are as follows:

Average power factor at the customers' services .... 85 per cent

Ratio of station peak load to connected transformer capacity for the radial systems .... 60 per cent

Ratio of station peak load to connected transformer capacity for the network systems .... 83 per cent

Energy Cost. Energy cost plays a very important part in any economic study of various systems of electrical distribution. It is therefore of considerable importance that the proper method be used in determining the energy cost. This is a subject that offers an exceedingly large number of possibilities of refinement. Therefore, an enormous amount of time might be spent in carrying out calculations of energy cost to the last degree of refinement. This might be time well spent, if the basic figures of energy costs were exact and unvarying. On the other hand, it is, of course, useless to employ a very high degree of refinement in the calculations, if there is a possibility of large variations in the basic cost figures. Furthermore, in the systems which have been considered in this paper, the variations in efficiency are, in general, opposite to the variations in investment. That is, the systems involving the least investment have the greatest efficiencies. Therefore, inaccuracies in the methods of calculating energy costs would affect to some extent the total amounts of the economy figures, but would not, generally speaking, affect the final conclusions as to the most economical system.

Nevertheless, for the New Orleans calculations, in order to obtain figures of energy cost having an accuracy which would be as little open to question as possible, considerable time was devoted to a study of the basic principles underlying energy costs, and to the actual calculations of the costs of losses in the proposed systems.

In working out the costs for the losses in the New Orleans systems, the following points were observed:

(1) Subdivision of unit cost into a demand charge and a kilowatt-hour charge.

(2) Subdivision of the demand charge between the various classes of apparatus through which the losses pass.

(3) Inclusion in the demand charge of a charge for wattless kilovolt-amperes produced by the a-c. distribution apparatus.

The demand charge was taken to represent fixed charges on investment in the increment (necessary to supply the losses) in the capacity of the various types of apparatus through which the losses must pass. In addition to these fixed charges on investment, certain portions of the operating expense of the generating station were included in the demand charge.

The output or energy charges consist solely of the remaining operating charges of the generating station. The subdivision of generating station operating charges between energy and demand charges was taken as follows:

	Demand Per Cent	Energy Kw-hr. Per Cent
Superintendence and Wages....	90	10
Fuel..........................	10	90
Water.........................	25	75
Lubricants....................	25	75
Station Supplies..............	100	..

This is admittedly an arbitrary subdivision.

Fixed charges were assumed to be 14 per cent of investment in each case, this percentage being divided as follows:

Interest	6.25 per cent
Taxes	3.10 per cent
Depreciation	4.15 per cent
Insurance	0.50 per cent
	14.00 per cent

The demand charges, other than those of the generating station, were based on actual investment in apparatus as calculated for the various systems, this being reduced to figures of unit investment per kilovolt ampere peak load. These charges were, therefore, different for the different systems. The charges for generating station investment were based on existing investment reduced to the unit value per kw. peak load.

There was a definite reason for basing the generating station demand charges upon kilowatts rather than kilovolt-amperes. This was the fact that there is very little variation of generating station investment per kilowatt with varying power-factor of the load. The steam end of the station is, of course, unaffected by power-factor, and the generating units are affected very little. The cost of switching equipment is mainly dependent upon short-circuit rupturing capacity and is, therefore, little affected by the load power-factor.

In view of this, the demand charges for losses in various parts of the system were divided into two items one for the generating station based on kilowatt of the losses, and the other for the remainder of the system, between the generating station and the location of the losses, based on kilovolt-ampere increase. The calculation of kilovolt-ampere increase through the various types of equipment was done vectorially, starting with 85 per cent power-factor at the customer's load.

Operating charges for the substations were omitted from the loss charges as being too small to materially affect the results.

It is, of course, understood that the generating station demand charges should not be applied against the underground system peak losses, unless the latter peak is coincident with the generating station peak. Such is approximately the case, however, under the load conditions which exist in New Orleans.

Network Switch Maintenance

For the majority of apparatus the value of 14 per cent for fixed charges was taken to include an ample amount for maintenance. However, in order that no question might be raised as to this item for the automatic switches, due to their somewhat complicated construction, an amount was added to cover maintenance of these switches for each of the two network systems in addition to the usual 14 per cent charge on investment.

Conclusion

Data have been presented, showing that considerable saving can be effected both in investment and in operating charges during a 10-year period of growth by introducing a special type of a-c. system, paralleling the present d-c. system in the underground district of a particular large city. The a-c. system selected in this case consists of 13,200-volt feeders, feeding directly into distribution transformers which in turn serve an interconnected low-voltage 3-phase 4-wire system through automatic network switches. This system is one of several which were investigated and it is the most economical under the particular conditions encountered of all those considered.

The practicability of the proposed system has been thoroughly investigated, and while certain difficulties in establishing such a system are recognized and experience may bring about some modifications of detail, methods of overcoming the outstanding difficulties are available in all cases.

Special consideration has been given to reliability of service, and the selected system contains features which provide a high degree of reliability, comparable with that of the best of modern d-c. systems, if stand-by storage battery equipment be eliminated from consideration.

Discussion

UNDERGROUND ALTERNATING-CURRENT NETWORK DISTRIBUTION FOR CENTRAL STATION SYSTEMS

(Kehoe)

GENERAL LIGHT AND POWER SUPPLY OF CHICAGO

(Armbrust and Jackson)

A STUDY OF UNDERGROUND DISTRIBUTION SYSTEMS FOR THE CITY OF NEW ORLEANS

(Bullard)

Chicago, Ill., June 26, 1924

E. R. Thomas: I would like to discuss a few things on the flicker problem which came up in Mr. Kehoe's paper. In Fig. 6 of his paper, there is a plot of some data that were collected on the flicker of incandescent lamps. This subject of lamp flicker dates back to the old problem of 25 versus 60 cycles, or what minimum frequency can be used for lighting. In the study of that subject we are indebted primarily, I believe, to Messrs. Kennelly and Whiting for their thorough research on critical frequency, which was made with a specially arranged Bunsen photometer.[1]

Fig. 1 herewith shows the results of their data and was primarily intended as discussion of frequency in regard to flicker. Now, we are probably more interested in the so-called dip or wink, that is if we are going to put both power and light on the same set of mains, what will the increments of starting currents do to our light?

In connection with this, Messrs. Kennelly and Whiting have obtained some data of various ranges of flicker and plotted this against light intensities. These are shown by the curves, *D*, *E*, *F*, and *G*, that is 44, 33, 7.5 and 3.5 per cent flicker in light intensities.

Dr. H. E. Ives at the Bureau of Standards obtained some interesting data on flicker.[2] He used a rather unique method in studying voltage dip. This consisted in employing an alternator whose voltage and frequency could be varied, and superimposing

1. The Frequency of Flicker at which Variation of Illumination Vanish, Kennelly and Whiting, *Trans.* N. E. L. A., 1907, pp. 327.

2. Allowable Amplitudes and Frequencies of Voltage Fluctuation in Incandescent Lamp Works, H. E. Ives, *Trans.* llumination Engineering Society, 1909, pp. 709.

this a-c. voltage on a d-c. voltage. The proportion of a-c. voltage to d-c. voltage was varied to give a range from pure d-c. voltage to pure a-c. voltage.

Figure 2 is a replot on semi-log coordinates of Dr. Ives' data on 25-watt tungsten lamps. You will notice that it gives a rather straight-line plot through the points. To this I have added a plot of the data collected by Mr. Kehoe, which appears in the lower left-hand corner. I believe that the reversal of

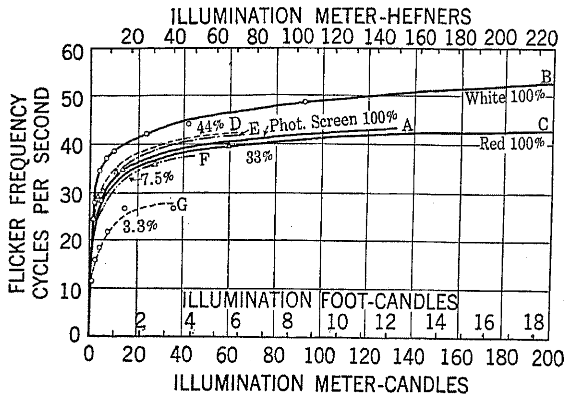

Fig. 1—Curve of Frequencies at which Flickering in Different Intensities of Illumination, Appeared to Vanish

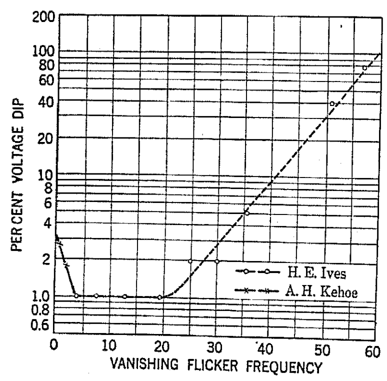

Fig. 2—Voltage Variation which Causes Flicker Phenomena 25 Watt Tungsten Lamp

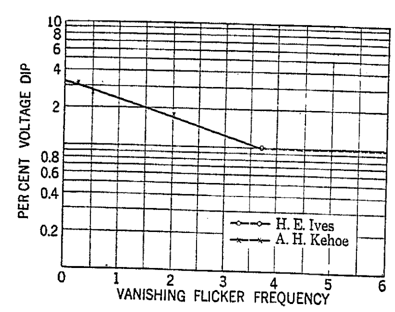

Fig. 3—Voltage Variations which Cause Flicker Phenomena 25 Watt Tungsten Lamp

these curves may probably be explained as depending on the physical reactions on the pupil of the eye attempting to adapt itself to a varying intensity of light.

Figure 3 is merely a repetition of Fig. 2 showing some of Mr. Kehoe's data plotted to a larger scale which bears out the same fundamental laws laid down by Messrs. Kennelly and Whiting. Some of the points brought out were:

The smallest range of flicker which could be recognized with certainty was about 1.4 per cent variation in illumination. This would correspond to about 0.5 per cent variation in voltage, on an ordinary Mazda lamp, and is somewhat lower than any point which we were able to observe.

Another point of interest from their data is that the most sensitive flicker frequency for small ranges of flicker is in the neighborhood of 2½ cycles. Our data shows this occurring at about 3½ cycles.

Messrs. Kennelly and Whiting have stated that this flicker frequency ceases to be objectionable at less than 7.5 per cent. Their figures are all given in terms of illumination, while ours are in per cent of voltage fluctuation. The 7.5 per cent change in illumination corresponds to about 2.4 per cent voltage variation on an ordinary Mazda lamp, thus checking our research fairly closely.

J. E. B. Stuart, Jr.: The remarks I want to make concern a continuation of some of the arcing data taken in connection with Mr. Kehoe's paper.

All of the data presented in the paper were taken with the idea of establishing a critical-point curve, or something like that, but we soon decided that the results were too inconsistent for plotting curves of any accuracy, so after the paper was handed in we did a lot of test work, where it was known that the arc would persist. We didn't try to fix the persisting point accurately but just ran through a number of tests where we were either sure of getting a good arc or none at all, and thus obtained roughly upper and lower limits. I may say that as far as our results showed, the plot of the voltage and current seems to be a hyperbolic function, but we have not done enough work to make sure of it.

All of the tests taken in the beginning were made with the arc from conductor to sheath, which is the condition usually met, especially where a single-conductor cable is used. We noticed a very peculiar action after a while. The lead sheath burned back much faster than either the conductor or the insulation and eventually this action tended to extinguish the arc, so we tried a few tests with copper-to-copper arcs. I won't describe the hook-up. It showed plainly that it is a much more persistent effect and much more dangerous when an arc is once started. The burning back is uniform. The arc is very uniform. The oscillograms show it too.

In all we tested about two-hundred samples, and took over seventy oscillograms. I have picked out several of them as they are rather interesting and they are reproduced in the accompanying illustration.

F. C. Hanker: Mr. Kehoe's paper presented some interesting data on distribution systems, and it has been very reassuring as to the reliability of the network. There is one point in connection with the so-called universal system described, particularly in the voltages that may be selected. There has been considerable work on standardization of utilization voltages, as it is called, in which the voltage at the lamp or utilization device has been standardized at 115 volts with recognized departures at 110 and 120. That standardization was satisfactory under past conditions as affecting motors and control as higher voltages were even multiples of the lamp voltage.

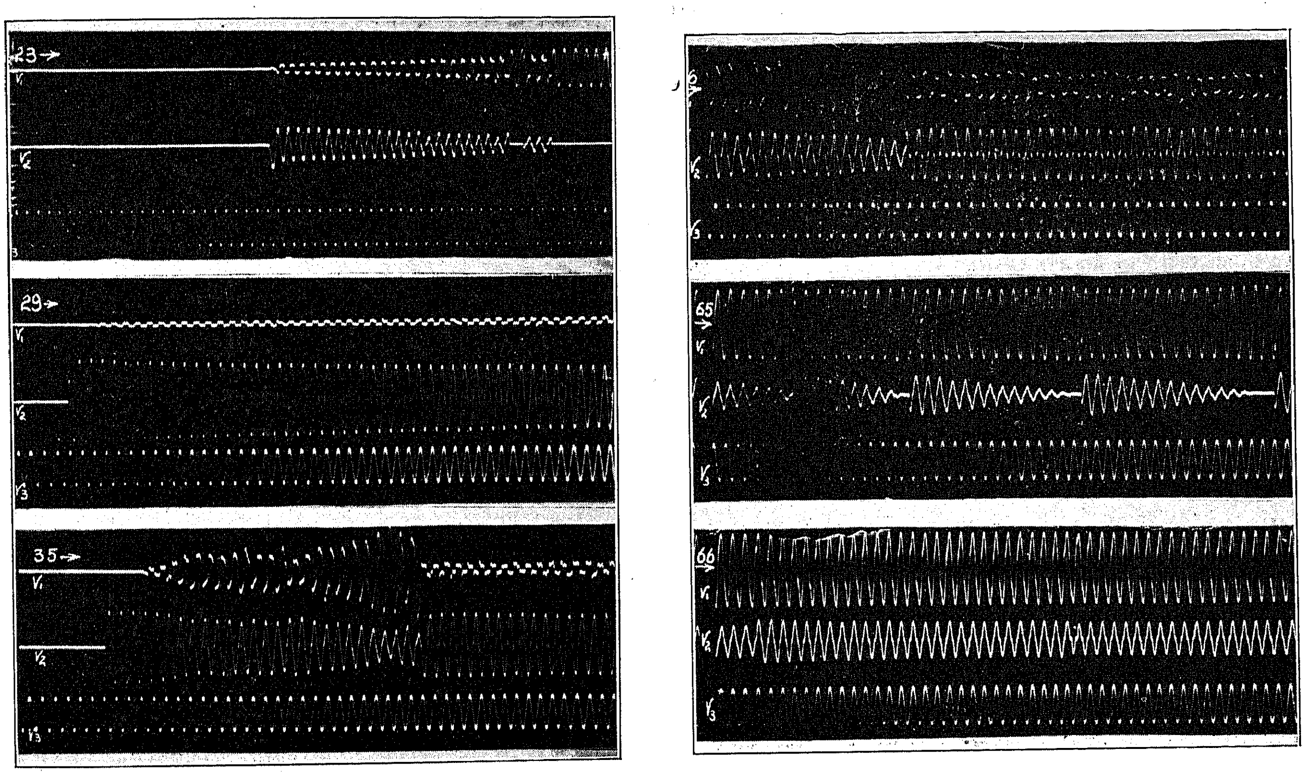
With the three-phase, four-wire system, which is apparently the one most generally considered on the network, we have a factor which causes trouble on the motor and the control voltage in case the two lower voltages of the utilization device on single-phase is adopted. If you take the 110-volt standard the three-phase potential will be 190 volts, which is considerably less than the tolerance allowable on standard motors at say 220 volts or the control of the same voltage range or multiple. The 115-volt standard corresponds to 198 volts and the 120-volt to 208 volts, which is more nearly the standard of the control and motor devices.

The other difficulty is in connection with the single-phase utilization devices. In case you adopt 220 volts or slightly

higher, it would be necessary to go to at least 125 volts, line to neutral to secure 220 volts on the delta.

Any development or system that is adopted should take into consideration the total cost to the industry, because if you take an odd voltage, such as would result in the using of 110 volts or 115 volts in a number of cases, there will be the additional expense of development and the possibility of trouble with existing devices. There probably would not be that difficulty where you come to systems that have conditions like New York, or some of the larger systems, where it is necessary that they maintain very close voltage regulation. If the system is generally used that condition would not always exist and we will have voltage drops that will bring us much below the guaranteed stove and that class, are designed so that they have quite a wide voltage variation and still are satisfactory. Others, like the electric iron, waffle iron, and devices of that general type require rather a close voltage regulation, and at the present time it is necessary that we have two standards to meet the range that we encounter in different parts of the country.

The lamp situation prior to the present standardization, I think, is sufficient warning to see the necessity for careful standardization and careful study of the voltages that will be used on the network system. Undoubtedly there is no question as to the economy from the distribution system itself. But when you take into consideration the other factors, it is quite necessary that considerable thought be given to voltage standardization.



Arcing Tests on Lead-Covered Cable

These oscillograms show the voltage and current in arcs from sheath to copper of single-conductor cables. The conductor and the sheath were short-circuited by copper wire (or, in case of Film No. 23, by a nail driven through the sheath). Sixty-cycle Voltage was then applied between sheath and conductor. The voltage across the arc is shown by V_1. The current through the arc is shown by V_2. V_3 shows the 60-cycle timing voltage. Further details on the respective tests are given in the following:

Film No. 23—4/0 cable, 6/32 in. rubber. Nail driven in the center of cable. Voltage (440 volts) applied at one end of copper and sheath. Maximum current, 11,000 amperes. Voltage wave increases gradually and current wave decreases gradually until the arc breaks.

Film No. 29—4/0 cable, 6/32 in. rubber. Arc started at center with three strands of No. 18 copper. Voltage (1600 volts) applied at both ends. Maximum current 555 amperes. The arc held twelve seconds. The duration of the arc at this voltage is not consistent. In this test the dying out of current and the consequential building up of voltage are clearly shown.

Film No. 35—500,000 cir. mil conductor, 20/32 in. paper. Arc started with two strands of No. 32 copper at one end. Voltage (2750 volts) applied at other end. Maximum current, 294 amperes. A rather unstable condition, which is characteristic of a number of the arcs, is shown, but this arc held for twelve seconds.

Films Nos. 6, 65, and 66—Three stages of an arc on 4/0, 6/32 in. rubber cable. The arc was started with two strands of No. 32 copper, at one end. Voltage (2750 volts) was applied at the other end. Maximum current, 635 amperes. The arc held until the switch was opened at the end of two and one-half minutes. Film No. 6 shows the sputtering effect which is characteristic of sheath to copper arcs. They go out sometimes, remain out a few cycles and then reappear. Film No. 65 was taken a minute after the start of the arc. The arc appears to go out but then revives again. Film No. 66 was taken two minutes after the start and the arc is still persisting strongly.

satisfactory operating condition on the standard equipment.

Before there is a too general use of the new system, if it is generally adopted, there should be some agreement as to the voltages to be adopted in order to minimize as much as possible the additional expense that may be involved in the development of the new equipment for the different conditions.

There are a great number of utilization devices in service now, and a great deal of difficulty caused in shifting from one town to another, or, in a number of cases, from one part of the city to another, in that the utilization devices are not generally applicable to the wide voltage range. Some devices, such as the toaster

A. H. Sweetnam: In connection with Mr. Kehoe's paper there has been considerable comment outside the meeting regarding the relative current demand of a standard three-phase motor wound for, we will say 220 volts, when operated at 220 volts and at some lower voltage, such as 208 or 199 volts, supplied by a low-tension network.

It follows, naturally, that a motor wound for 220 volts and operated at a lower voltage, other conditions being the same, will draw less excitation and greater load current. Tests which I have had made on several small three-phase squirrel-cage motors indicate an appreciable improvement in power-factor

when operated below rated voltage, but at the expense of lowered efficiency from approximately one-fourth to full load. I do not know that this condition will prevail with motors having characteristics differing from those tested, but it would appear to me that this question should be very carefully determined before giving consideration to the adoption of such a network scheme. The commercial aspect seems to have a great deal of bearing since, under the conditions stated, customers supplied from a network would be paying a premium by reason of the lowered efficiency of the equipment.

R. A. Paine: I think Mr. Kehoe has taken a big step in advance in enabling central-station companies who have been burdened with a rather expensive d-c. system in order to maintain the highest reliability of service, to decrease this expense, and I want to agree with one of the comments that Mr. Bullard made, *i. e.*, if you leave out the storage battery, I think we have a fair promise of getting as reliable service from the a-c. system as from the d-c. system.

In connection with the arcing tests made by Mr. Kehoe, I think they are fundamentally sound and in agreement with theory. I think this is due to two reasons. One is that in the a-c. system, of course, the voltage goes through a zero point, and the other is that if you take a circuit and use d-c. on that circuit and then also use a-c. on the same circuit, you have, in addition to the resistance when you use a-c., reactance which will tend to lower the voltage across the gap and, therefore, tend to extinguish the arc. One of the serious questions that has confronted most distribution engineers is: Is the a-c. 220-volt system going to be self-clearing as our d-c. systems always have been?

With radial a-c. systems at the present time we have something less than 0.1 per cent interruptions, and any device which will take care of that 0.1 per cent interruption must be very strong. I do not believe that we have as yet had enough experience to tell what devices will be suitable for manhole use, as I believe all of Mr. Kehoe's installations are made in vaults inside of buildings and from that point supply the outside underground system.

As to the matter of the operation of 220-volt motors on say 200 volts or 208 volts, I believe that the gain in power factor of operating these 220-volt motors at somewhat reduced voltage will in a large degree offset any loss of efficiency, as most motor installations are considerably overmotored.

There is one thing, though, that must be done. We must *maintain* at the customer's service the somewhat reduced voltage. We can not have any long shoestring secondary.

Mr. Kehoe discussed the question of high-reactance transformers. It is absolutely essential in a network, using different sized transformers, that the reactance of the present distribution transformer be increased over its present 3 or 4 per cent, and it would seem somewhere between 7 and 10 per cent is the proper figure.

However, if any company wishes to try an experimental network, we have recently made some studies which would indicate that if you use an identical size of transformer throughout your network system, let us say you adopt a 50, 75 or 100 kv-a. as your standard, using all of one size, you can operate a network satisfactorily. Of course, that would be only a transient condition, because you can not operate continually a growing network with only one size of transformer.

E. P. Peck: Mr. Kehoe's paper, I think, brings out the first solution of what now appears to be the coming method of supplying a-c. underground load. The handicap that the a-c. system had for years was that it could not stand on the same footing with the d-c. system in reliability.

The United Company was, to my best knowledge, the first to put the a-c. subway system on a very reliable basis. The system that they described, as well as the systems described in the next two papers, appealed to me very much, because they have done a thing which has been done time and time again in history in a number of lines. They have simplified the mechanism. Almost any development starts out with a complicated mechanism, which gets more complicated by adding devices to take care of different troubles that come up. Finally some one comes out with a very simple thing that either does not have all the troubles or else takes care of them in a very simple way. This applies, I think, particularly to the system described by Mr. Bullard for New Orleans.

One of the questions that occurred to me in connection with the New Orleans system particularly, although it applies also to the system proposed for Chicago, if I understand it correctly, in which you have high-voltage feeders, 11,000, 12,000, or 13,200 volts supplying high-reactance transformers directly and from there into a network, is: What will the regulation be all over that network? This applies also to Mr. Kehoe's paper where the voltage is lower. The 10 per cent reactance transformer has quite a high drop, particularly where it carries motor load. The primary voltage will undoubtedly be well sustained, but how will the secondary voltage behave under all conditions of starting motors and other load variations?

The self-protection feature which is referred to in Mr. Kehoe's paper is, as far as I can recall, the first analysis of a thing that a good many have recognized in a general way. Personally, I will have to admit that I was very much surprised to find that arcs were self-extinguishing on voltages as high as this paper shows, particularly with quite high currents. However, there is still a question as to just what will happen in case of the high concentrations of energy that will occur on these large systems, also a question as to what will happen in terminal boxes, at lugs and things of that kind.

H. W. Smith: These papers contain a valuable contribution to the art of electrical distribution. During the past five or ten years, there has been intensive development in the field of large generating stations, high-voltage transmission, and the use of automatic switching equipment for substations. The best talent in the industry has been employed on these problems with the result that tremendous strides have been made. There is, however, a growing realization of the fact that the total investment in the distribution system is greater than in generating and substations, and that great economies can be obtained by applying the same grade of engineering talent to study the problems of distribution.

In many large cities, the Edison three-wire system has been the accepted standard for distribution in the underground section. The Edison system, backed up as it generally is with large storage-battery reserve, has proved extremely reliable. However, the cost of distribution is much greater than for alternating current, and there is a general tendency in most cities towards the restriction of the Edison d-c. load, and in some cases studies have been made towards replacement of the Edison d-c. by an a-c. system.

In studying the a-c. distribution system with a view to making it more reliable, a very valuable contribution has been made by Mr. Kehoe, and his paper clearly indicates the lines under which he has been working.

In considering this subject, I wish to call attention to some valuable papers which have been written on this subject. At the 14st Convention of the Association of Edison Illuminating Companies in October 1922, Mr. W. C. Eglin, Vice President and Chief Engineer of the Philadelphia Electric Company, presented a paper on the "Future Development of Distribution Systems." This paper deals with the general economics of the distribution problem, and recommends a three-phase, four-wire, secondary distribution system. It is pointed out that the ideal system for general distribution at lighting voltage must comply with several requirements:

(1) It must be polyphase to permit the operation of motors.

(2) It must be a symmetrical polyphase system.

(3) The voltages available must be suitable for both light and power requirements.

(4) One conductor must be a neutral which can be grounded in such a way as to limit the voltage of all other conductors to ground to a value below 150 volts.

A three-phase, four-wire system is recommended, the only drawback being its adaptation to the present normal voltages of lighting and power apparatus.

In studying the general system, the economics of the whole industry should be considered, and any system which covers special apparatus should, if possible, be restricted. If it is necessary to carry two lines of motors or appliances, it will place a burden on the industry as a whole.

The use of a three-phase, four-wire secondary system with grounded neutral will require changes in standard control equipment as three overload relays will be necessary to give complete protection. Also in the case of low voltages, certain changes may be necessary in the design of holding coils of contactors.

The distribution system should be laid out so that the standard squirrel-cage motors can be used as far as possible with standard control equipment.

The automatic network switch mentioned in these two papers will be built in the following sizes—250, 500, 800 and 1200 amperes.

It will be of great advantage to the industry if in the development of the a-c. network, the requirements can be met with as standard apparatus as possible. In other parts of the world, there are three-phase, four-wire systems, 200-350, 220-380 and 240-415 volts, and it is to be hoped that this condition will not obtain here.

Another contribution to this subject was made in a paper by Mr. M. T. Crawford, entitled "Alternating Current Underground Distribution" presented at the 41st Convention of the Association of Edison Illuminating Companies, 1922. This system which is used in Seattle, parallels all distribution transformers on the secondary mains with primary connections on alternate feeders and with oil circuit breakers installed in the secondary of each transformer, which are equipped with power directional relays operative on a reversal of power flow equal to or greater than 150 per cent of the transformer capacity. These switches are not automatically reclosing.

H. A. Stanley: I want to speak more particularly about Mr. Bullard's paper. He has a fine paper and is starting out to accomplish a very desirable end, but I would like to indicate two or three points where I think he may perhaps get into trouble; two or three difficulties, perhaps, inherent in the proposed system.

If you distribute lighting and power from the same set of mains, you must provide regulating capacity for the total power load as well as the lighting load, which introduces somewhat of an economic waste. I think I foresee possible difficulties in rate making. Rates are ordinarily differentiated in regard to investment, but you have here the same investment for both power and lighting and you have only the load factor differential left to take into account in making a power rate below the lighting schedule.

Mr. Sweetnam has noted a point in reference to power-factor —improved power factor of the motor load benefiting the central station but the customer paying for it. Speaking from the viewpoint of a smaller company, and this perhaps would not apply to a large company; it seems to me the lower voltage on the motors is going to lead to a further difficulty. It would be difficult for the smaller company to maintain (already too low) constant voltage. Two hundred volts at no load leaves no leeway for voltage fluctuations with load. The comment of the motor manufacturers on this point should be of interest. If you are starting from zero and building a new company and your customer has not become accustomed to good voltage, that is one thing, but the customer who has become accustomed to it will not take readily to the lower voltage.

It seems to me the system lends itself somewhat to the theft of current and more than ordinary precautions will have to be taken in metering.

Now, there may be a few possible difficulties in apparatus details. It strikes me that the network protective device does not lend itself readily to manhole installation, at least in the present state of the art; there are some major difficulties to be overcome in perfecting the device for that purpose.

Another point I think is important if I correctly interpret Mr. Bullard's paper. To work on a 13,000-volt feeder, it obviously must be dead. The theory appears to be to operate the feeder switch at the substation and the automatic devices will function at the far end of the feeder. On a feeder of this size there will be from ten to twenty-five network switches. How are you going to protect the cable splicer? On the usual theory of disconnecting switches it would be necessary to have two breaks in series at each possible point where the cable could be energized. I should hardly suppose you could depend on the network switch for protection of human life. Are disconnecting switches in the program and will you send a man around to open them at twenty or thirty-points before doing maintenance work?

W. L. Abbott: I remember conventions thirty years ago where the lion and the lamb of a-c. and d-c. did not concert so harmoniously as they have in this meeting. It was conceded as a great victory for the a-c. school when d-c. systems were fed from a-c. generators in transmission lines.

With that combination of the two, it was thought the ideal system had been evolved, but now take a glance at the situation here in the Loop in Chicago, where Mr. Armbrust pointed out we have now a load of 75,000 kw. per square mile, and are contemplating a load of 200,000 kw. within twenty years, and, of course, it won't stop at the end of twenty years.

How are we going to distribute that load? In fact, how are we going to transform it? Substations are not altogether desirable, and space for substations is not readily available, and it is a growing problem to find locations where these substations may be placed sufficiently near together in such a congested territory as the Chicago Loop district.

Then, there is the other problem of distributing this power through the streets. If you could see a cross-section of the downtown streets of Chicago, you would wonder where the next main is going to get in at all. The street is full from the surface ten feet down. True, more space could be made available if all of these underground structures could be taken out and rearranged, but they are crisscrossed and with huge manholes and sewer openings which have just about reached the limit of capacity. Then, again, the heat evolved by these d-c. distribution lines is very considerable, and any greater congestion of those lines is going to be a serious matter.

We will have to get more power and have more power distributed in the Loop than we have now. It can not be done much longer by adding more copper in our distribution. It will have to be done at higher voltage, and the last transformation must be made in the building which is to be served.

That is the problem which is approaching.

R. B. Mateer (by letter): In many of our cities accepted primary distribution voltages are 2400 and 4000, while transmission potentials over cables linking generating and distributing substation range from 6000 to 13,200 volts, and any step forward which will limit the investment in or eliminate the use of distributing substation is commendable.

It is suggested, however, that in all interconnected network the transformers should be of a uniform or standard size and as far as possible, evenly spaced. Such practice will not only be a step forward in our efforts at standardization, but will materially assist in uniform loading of the step-down equipment.

A. H. Kehoe: The discussions have indicated the importance of keeping standard equipment throughout the entire electrical supply system, including the utilization devices. The adoption of three-phase, four-wire combined light and power services

having a reduced voltage for motor operation, is sometimes considered as making it necessary to adopt an additional line of motors having a lower voltage rating than is at present the standard. On a large number of electrical supply systems, motors are operating at reduced voltage due to the low power factor current supplied through small sizes of isolated transformers. The adoption of a three-phase, four-wire supply is for the purpose of supplying lighting service from combined mains, and there is no reason to use this system, except at locations where satisfactory lighting service can be obtained. Therefore, polyphase voltage when used for motors will not be below the amount now regularly found in practise.

I doubt if for typical motors the average loading condition makes for lower efficiency. Generally there is an improvement in efficiency due to the reduced voltage, up to about three-quarters load on the motor, which is probably above the average loading of motors. Because of the large number of motors now operating at reduced voltage, I doubt if the efficiency will be changed by the adoption of three-phase, four-wire systems.

Regulation due to transformer reactance is accomplished with automatic regulators in each supply feeder. The division of current is so nearly uniform that the regulation between any two points in the network depends upon the drop in the secondary mains, as the automatic regulating equipment will maintain a constant voltage at the low-voltage supply points to the mains.

It is important in designing a reliable network to omit any type of equipment in which faults may develop which will not clear themselves. The concentration of current at any point where trouble can occur is usually well below the values indicated in my paper, and there should be no necessity of exceeding these to meet any conditions which are likely to arise in the next few years.

In presenting distribution-system designs, uniform and standard connections of network cables and locations for distribution transformers are assumed. In actual service however, it is inevitable in many locations to have concentrated loads which are as large as the entire remaining load in the immediate vicinity. In such cases the center of distribution of the particular district is not at the existing intersections of the mains, but is at the particular concentrated load. The economical design will then not allow the adoption of a single size of distribution transformer and a standard transformer location throughout the entire system. This condition results in the network of street mains being of smaller capacity than would otherwise be the case to supply load. There results a lack of uniformity and standardization of equipment which however does not make it any more difficult to obtain uniform loading of distribution transformers, if indicated design is used.

Concerning protection of cable splicers, in many districts one non-automatic break is considered sufficient, and two breaks in series have been used with one—an automatic oil circuit breaker. With these network units open, and the high-voltage supply grounded, it is impossible to have the switch function automatically as its closing energy is obtained from the supply side of the switch. If one of these switches is closed manually with the high-voltage cable grounded in the immediate vicinity of workmen, the condition will be similar to closing a knife disconnecting switch on a grounded feeder, except that the fuse protection at the network switch will clear the backfeed.

W. R. Bullard: The question of the selection of service voltage of the three-phase four-wire system, so as to satisfy as nearly as possible existing voltage standards, is one that has received a lot of attention by various engineers. One of the schemes which was given some consideration for use in New Orleans would utilize 400 volts as the delta voltage giving 230 volts between each line and neutral. In this case autotransformers would be connected between line and neutral at lighting services in order to obtain a neutral for the usual three-wire 115/230-volt system. Existing motors, which are connected delta, could be reconnected *Y* and operated without further change on the 400-volt system. This proposal has the advantage of a saving in copper of the low-voltage mains due to the higher voltage. However, in this case it was found that the cost of the autotransformers and losses therein would more than offset any saving in losses and cost of the secondary mains.

In this connection, I would refer to a point which was brought out in my paper; namely, that once the size of the secondary mains and the corresponding capacity of distribution transformer installations is established, these secondary mains will continue to serve the load indefinitely with practically the same copper losses, regardless of what the growth of load may be. Low-voltage mains therefore continue in a more or less fixed physical state after they are once installed. On the other hand the connected capacity of autotransformers in a 400-volt system would continue to grow with the growth of load and their cost would some day out-strip the cost of the low-voltage mains, regardless of any economy which might be secured by the use of a higher voltage system at the start. Furthermore, I believe it has been brought out in Mr. Kehoe's paper that the 400-volt system would not be able to burn off short circuits with the same facility that the 200-volt system will.

It is somewhat unfortunate for the three-phase four-wire system that the present standards for lighting and power voltage are just what they are, but in selecting the voltages to use on this system it would seem that an out-and-out compromise effecting both types of service would have some serious disadvantages. The use of 120 volts for lighting, for instance, would give a somewhat higher voltage for power than the use of 115 volts, but the resulting voltage would still be non-standard for motors and the lighting voltage in this case would not be the preferred standard. Time alone will tell just what the trend of standardization will be. However, in the meantime we have selected what seemed to us to be the most desirable arrangement in view of the present standards.

I might also mention that while we expect to supply the customers at the start with 115/200 volts, we are buying transformers rated at 120 volts. This will reduce the duty on regulators at heavy loads and will enable a change to 120 volts to be made without difficulty if it is ever found to be desirable.

In regard to Mr. Stanley's point concerning the difficulty of adjusting rates of power and lighting service to meet the combined power and lighting system, I feel that the rates should be treated as secondary to the economics of the problem rather than modify the economics by using a more costly system in order to satisfy existing rates. Furthermore, common facilities for the power and lighting loads are usually provided in the generating station and are also provided from that point at least to some point in the substation. It is therefore rather difficult to see why the same principle should not be extended to the remainder of the distribution system as far as rates are concerned.

Referring to Mr. Stanley's point concerning the additional cost of regulator capacity to regulate the power load, I feel that the case must be an exceptional one indeed where it can be shown to be more economical to provide separate facilities and regulate only the lighting load. If the reference is to station regulators, this type of equipment represents a small part of the cost of the whole system and any saving of regulator capacity will, I believe, at least for New Orleans, be much more than offset by the additional cost for duplicate primary cables which would be necessary to serve unregulated power loads.

I failed to mention in my paper the method of protection to workmen which we expect to use in case work is to be done on primary cables or on transformers. The procedure in this case will be first,—to kill the primary feeder by opening the switch at the generating station and

Second,—to ground and short circuit the primary cables in the generating station and also at one or two points external to the station, points being selected for this purpose which will offer most effective protection, and permanent facilities for grounding and short circuiting being provided at these points.

Equivalent Single-Phase Networks
for Calculating Short-Circuit Currents Due to Grounds on Three-Phase Star Grounded Systems

BY ROY A. SHETZLINE
Associate, A. I. E. E.
Department of Development and Research, American Tel. and Tel. Company, New York, N. Y.

Review of the Subject.—*This paper presents a method for calculating the steady state value of the short-circuit current in a fault to ground on a power system operated with grounded neutral, and the distribution of this current throughout the system. Constant impedances and electromotive forces in the system, and electrically short lines, are assumed, and line capacitance is neglected.*

If, at the time the fault to ground occurs, the distribution of the load current in the system is known, the total current in any portion of the system under the short circuit condition may be calculated by means of this method. By "total current" is meant here the sum of that part of the fault current which appears in the branch considered, and the normal current in the branch due to the loads. The latter current, of course, does not appear in the fault.

Formulas and equivalent circuits for the usual three-phase transformer and generator connections used in practise, are given. The use of such circuits permits the calculation of the fault current and its distribution in the power system from an equivalent single-phase network. Since currents in a three-phase network under balanced conditions may also be calculated from a single-phase network, it is accordingly possible to calculate, entirely on a single-phase two-wire basis, the total current in any branch of a star grounded network for a ground on any phase.

The setting up of equivalent two-wire single-phase networks similar to those for the three-phase case is not generally possible where the number of phases exceeds three.

The value of the method lies in its enabling one to calculate on a single-phase two-wire basis the short circuit current (steady state) due to a ground on a three-phase grounded neutral system, as regards both magnitude and distribution and taking into account all system loads. In the usual approximate method of making short-circuit calculations, a single-phase-to-neutral network is substituted for the actual network. While this method involves less labor than that proposed in the paper, the results obtained by it are inexact, the effect of non-grounded loads being usually ignored. The method of the paper involves much less work than that required by three-phase calculations giving equal accuracy.

An illustrative example is given.

INTRODUCTION

THE determination of the magnitude and distribution of currents in power lines under short-circuit conditions[1] is of large interest to all engineers engaged in power transmission problems. It is of interest also to telephone engineers, who are concerned with the inductive effects of these currents. It was from the latter standpoint that the studies on which this paper is based were undertaken. The results, however, are submitted here largely on account of their more general interest and utility.

Calculations of the magnitude and distribution of the fault or residual current, due to a ground on a non-grounded power system, are not difficult according to the methods worked out in Technical Report No. 52 of the Joint Committee on Inductive Interference of California.[2] The calculations are much more complex and difficult in the case of star-grounded power systems as in the case considered in this paper. Approximate calculations can, of course, be made by the well-known "equivalent single-phase to neutral" method. However, where substantial loads, either concentrated or distributed along the line, are located at points not remote from the position of the fault, the neglect of the residual current in the sound phases through these loads may lead to considerable errors in estimates of induced voltages. To the power engineer interested in accurate relay settings the additional accuracy of the proposed method may be of importance.

Considering a three-phase system for example, it is, of course, possible to take the loads into account by working out the currents on a three-phase basis. This is a laborious proceeding and the time involved is likely to be prohibitive if the network is at all complicated. By taking account of the symmetry, with respect to the faulty phase, presented by a normally balanced three-phase system, and by making use of a fictitious generator[3] in the fault in the place of all sources of e. m. f. in the power network, it is possible to simplify the calculation and to replace the three-phase network with a single-phase two-wire network that takes account of all loads. The method of doing this is described below.

In the case of a system of more than three phases it is, of course, still possible to replace all electromotive forces in the network by one at the fault. While this reduces the calculations to a single-phase basis, it is not generally possible to complete the simplification by replacing the network by a two-wire network.

Methods in common use for the approximate calculation of these fault currents are based on what amounts to an assumption of steady-state conditions. The same assumption underlies the methods to be discussed

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

3. The possibility of using a fictitious generator in connection with problems similar to that under discussion here is referred to by L. P. Ferris (TRANS. A. I. E. E., Vol. XLI, p. 90, 1922), in a discussion of a paper by Conwell and Evans.

in this paper. The determination of transient short-circuit currents is, of course, desirable. While methods have been devised for determining low-frequency transients by measurements in a model of the actual network under study,[4] it seems unlikely that the general calculation of transients can be simplified to such a point as to be of practical value to the operating engineer. Allowance is often made for the fact that maximum instantaneous values may be larger than the sustained values by the use of the so-called transient impedances. This can likewise be done in the application of the methods described in this paper.

An essential feature of the method here described is the reduction of the number of metallic conductors in the circuit to two. With a three-phase system, this can always be done in the case of a single fault to ground, assuming the system symmetrical. With certain other types of fault, this reduction cannot be readily effected, but some simplification is still usually possible by the replacement of the system electromotive forces by single electromotive forces at the fault or faults.

The magnitude and distribution of the short-circuit currents are the principal factors of interest in the power system, so far as induction into telephone circuits under abnormal conditions on a grounded neutral power system is concerned. The potential differences between any two points in the network may also be of interest in certain cases, however, and these may be readily determined by the method under discussion.

The following two well-known network theorems are the basis of the method to be described:

(a) Superposition Theorem: In any network with an arbitrary distribution of n e. m. fs. in its branches the current in any branch is the sum of the n currents which would be produced in this branch by the n electromotive forces taken separately in their respective positions in the network. (In applying this theorem, it is evident that instead of considering all the e. m. fs. separately they may be combined into groups in any desired way, subject, of course, to the condition that in the net result each shall have been used once and only once).

(b) In any network of impedances having an arbitrary distribution of e. m. fs. in its branches, the current in any branch is equal to the negative of the voltage across an open circuit in the branch, divided by the impedance of the network looking into this open circuit with all e. m. fs. removed.

Theorems (a) and (b) are true only providing there are no unilateral impedances in the networks.

The proof of theorem (b) follows at once from theorem (a). Referring to Fig. 1, the current I in the branch 1, 2 is the same as would be produced in that branch jointly by two superposed systems of electromotive forces, *viz.*:

(1) The n existing e. m. fs. plus an e. m. f. V_0 in the branch 1, 2 of such magnitude and phase that the current due to the n other e. m. fs. is exactly cancelled in branch 1, 2.

(2) A single e. m. f. $-V_0$ in the branch 1, 2.

Evidently the e. m. f. referred to in (1) is numerically equal to the open circuit voltage of branch 1, 2. Z being, as indicated, the impedance looking into the network from terminals 1, 2, the current in branch 1, 2 in case (2) is $-V_0/Z$, and it must be also I, since the total current in branch 1, 2 in case (1) is zero.

In connection with the application of this theorem to be made presently, it should be pointed out that the "existing e. m. fs." assumed to be removed, include not only e. m. fs. due to prime movers, but also those maintained by mechanical loads, in virtue of which they normally receive energy from the electrical system. It will be apparent from this that the method under discussion automatically takes into account the momentary return under short-circuit conditions of energy to the system from machines which are normally receivers.

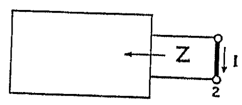

FIG. 1

METHOD OF CALCULATING SHORT-CIRCUIT CURRENT—THREE-PHASE SYSTEM

The following discussion describes by means of an example the manner in which the magnitude of the short circuit current through the fault may be calculated. Considering the network shown in Fig. 2, G is a star-connected generator; T, a bank of transformers connected in delta on the station side and star-grounded on the line side; S, a bank of (non-grounded) step-down transformers at the substation; and L is the substation load. The line has become accidentally grounded at E as shown. It is required to determine the short-circuit current to ground.

Let Z_g[5] = impedance of each generator winding

E_g = magnitude of induced generator voltage in each winding (Y-induced voltage)

Z_T = impedance of each transformer of bank T (low-tension basis)

U_T = ratio of transformation of each transformer of bank T

Z_s = impedance of each transformer of bank S (low-tension basis)

U_s = ratio of transformation of each transformer of bank S

Z_L[5] = impedance of each leg of the load

4. O. R. Schurig, JOURNAL A. I. E. E., October 1923, p. 1033.

5. This is the actual impedance, *i. e.*, the impedance in the absence of induced e. m. fs. representing the delivery of energy to or from sources external to the electrical system.

z'' = self impedance per mile of transmission line circuit composed of the two ungrounded conductors in parallel and the third conductor as a return.

z' = self impedance per mile of transmission line circuit composed of the two ungrounded conductors in parallel and earth return

z = self impedance per mile of transmission line circuit composed of the grounded conductor and earth return.

l = distance in miles from T to E

a = distance in miles from power house to substation.

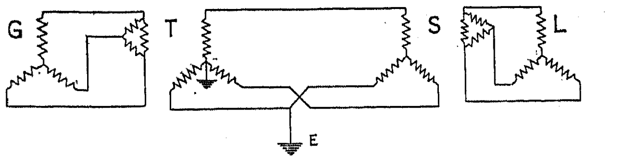

Fig. 2

The short-circuit current to ground may be obtained by the use of theorem (b), whose application to this case is illustrated in Fig. 3. In this figure, V_0 is the open circuit voltage at the fault, *i. e.*, the voltage to neutral of the system. The short-circuit current is $I + I_1$, I being the current in the faulty conductor directly to the neutral ground at T, and I_1 the current reaching the same point over a parallel path, E to S and the ungrounded conductors to T.

Applying Kirchhoff's voltage equation around the path taken by current I, and neglecting for the present the mutual impedance between the line circuits whose self-impedances are designated, z, z',

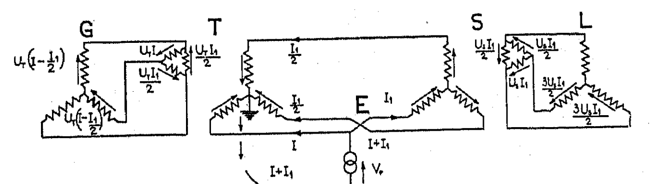

Fig. 3

$$V_0 - l z I - [\,(U_T I)\, Z_T + 2 Z_g\, U_T (I - I_1/2)\,]\, U_T = 0$$

or $$[l z + U_T^2 (Z_T + 2 Z_g)\,]\, I - U_T^2 Z_g I_1 = V_0 \qquad (1)$$

Similarly around the path taken by the current I_1

$$V_0 - (a - l)\, z'' I_1 - \left[\, 2 Z_L \left(\frac{3\, U_s}{2} \right) I_1 + Z_s U_s I_1 \right] U_s - \left[\, Z_L \left(\frac{3\, U_s}{2} \right) I_1 + Z_s U_s I_1/2 \right] U_s - l z' I_1 - [\, - Z_g U_T (I - I_1/2) + Z_T (U_T I_1/2)\,]\, U_T = 0$$

or $$- (U_T^2 Z_g)\, I + [\,(a - l)\, z'' + l z' + (3/2)\, U_s^2 (3 Z_L + Z_s) + (U_T^2/2)\,(Z_T + Z_g)\,]\, I_1 = V_0 \quad (2)$$

From (1) and (2)

$$I/I_1 = \frac{(a - l)\, z'' + l z' + (3/2)\, U_s^2 (3 Z_L + Z_s) + (U_T^2/2)\,(Z_T + 3 Z_g)}{l z + U_T^2 (Z_T + 3 Z_g)} \qquad (3)$$

From equation (1) and (2) $I + I_1$ may be obtained.

When the mutual impedance, which may be denoted by z_m, between the circuits whose self-impedances are designated z and z', is taken into account, equations (1) and (2) become

$$[l z + U_T^2 (Z_T + 2 Z_g)\,]\, I - [\,(U_T^2 Z_g - l z_m)\,]\, I_1 = V_0 \qquad (4)$$

$$(- U_T^2 Z_g + l z_m)\, I + [\,(a - l)\, z'' + l z'^{\,2} + (3/2)\, U_s^2 (3 Z_L + Z_s) + (U_T^2/2)\,(Z_T + Z_g)\,]\, I_1 = V_0 \qquad (5)$$

In calculations of short-circuit currents z_m is frequently disregarded. In some cases rather large errors may result from disregarding it, and where accuracy is desired, it should be included unless it can be shown that its effect is unimportant.

Distribution of Currents

The magnitude of the short-circuit current *through the fault* may thus be obtained as outlined above. It

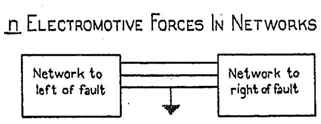

Fig. 4

is usually necessary, however, to determine the current *in some specified branch* of the network other than the fault itself. The *total* current in any branch may be considered as made up of two currents, namely, the portion of the fault current in the branch, and the normal current due to the system loads. The latter current, of course, does not appear in the fault. These currents may be determined as follows: Figs. 4, 5 and 6 represent the power network under three conditions, namely: (1) the actual network (Fig. 4) with the fault as shown; (2) the actual network after removing all sources of e. m. f. (but not the impedances of the windings in which they are generated), and with the fictitious generator of voltage V_0 in the fault (Fig. 5); and, (3) the actual network (Fig. 6) with the fictitious generator. By the superposition theorem, the difference of the currents in any branch for the conditions exhibited by Figs. 5 and 6 gives the current for the condition of Fig. 4 and this is the desired result, namely, the total current in that branch under the conditions of fault. The current in the branch due to the arrangement of Fig. 5 is (aside from a 180-deg. phase displacement) the portion of the *fault current*

in the branch, and may be calculated by means of the formulas given in the preceding section. Since V_0 is equal to the open circuit voltage at the fault, the currents obtained with Fig. 6 are those in the power network with the fault removed, *i. e.*, the load currents. Consequently, the total current in any branch of the network is obtained by means of the method of analysis above outlined.

Although theorems (a) and (b) have thus far been applied to a particular network, it is apparent that they may be applied in a similar manner to other types of network as well. The treatment of a large number of three-phase network elements commonly found in high-tension transmission systems by this method is given in the next two sections.

In most cases of inductive interference with communication circuits, due to grounds on star-grounded power systems, the fault or residual currents are many times more important as regards inductive effects than the normal-load currents (which do not appear in the fault). Consequently it is sufficiently accurate

n Electromotive Forces In Networks Removed

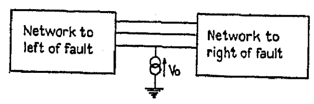

Fig. 5

n Electromotive Forces In Networks

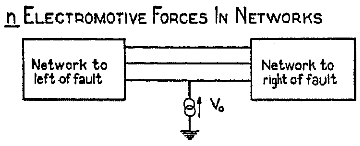

Fig. 6

in such cases to consider only the magnitude and distribution of the fault current. In such cases it is necessary to consider merely the network typified by Fig. 5.

Equivalent Two Terminal Networks for Three-Phase Systems

The preceding discussion has shown how to replace the three-phase system with a single-phase system. In applying the results, it is convenient to have equivalent two-terminal impedances to replace the three-terminal impedances presented by power apparatus at generating and substations.

Returning to the arrangement shown in Figs. 2 and 3, and assuming symmetry in the three phases, it is evident that the two sound conductors may be replaced by a single conductor as $F\,D$ in Fig. 7. To determine equivalent two-terminal impedances for the generating and substations for use with the resulting two-wire system, we may further assume impedances Z, Y and X with mutual impedance M between Z and Y, as indicated in Fig. 7. These impedances are then to be determined in terms of the impedances of the generator, load and transformers. The impedances of the branches, $A\,B$ and $E\,F$, Fig. 7, will evidently be z and z' ohms per mile and that of $B\,C$, with $D\,E$ as return, z'' ohms per (loop) mile, by the preceding work. (These ignore mutual impedance between the circuits whose self-impedances are z and z'. If this cannot be ignored, it is necessary to assume a mutual impedance z_m between $A\,B$ and $F\,E$.) Then

$$V_0 = l\,z\,I + Y\,I - M\,I_1$$

$$V_0 = [\,(a - l)\,z'' + X + l\,z' + Z]\,I_1 - M\,I$$

By comparison with the equations (1) and (2)

$$X = (3/2)\,U_s^2\,(Z_s + 3\,Z_L)$$

$$Y = U_T^2\,(Z_T + 2\,Z_g)$$

$$Z = (U_T^2/2)\,(Z_T + Z_g)$$

$M = U_T^2\,Z_g$, and represents the voltage *drop* from G to F per ampere from A to G or the voltage drop from G to A per ampere from F to G

By similar processes, the equivalent networks for the various transformer connections exhibited in the diagrams of Figs. A and B may be obtained.

In these diagrams the symbols U, U' and U'' refer to transformer ratios from line side to station side and the impedances Z_T, Z_g, Z_T', Z_g', etc. to transformer

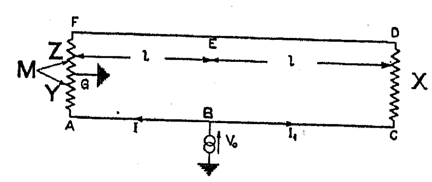

Fig. 7

or machine winding impedances on the station-side voltage basis. Diagrams 13 to 18 inclusive deal with 3-winding transformers.[6] It is to be noted that in the diagrams for the open delta (19 and 20) and Scott (21, 22 and 23) connections the accidental ground is assumed to exist on the phase, with respect to which the other two phases are symmetrical. Diagrams 24 and 25 illustrate combinations of some of the network elements with line circuits.

The scheme of reduction of the three-phase system to a single-phase system which has been described, assumes electrical symmetry, not only in apparatus but also in lines. In practical cases, dissymmetry in lines when untransposed is probably the only dissymmetry which it might be necessary to consider and even here, it is probable that if mean self and mutual impedances are used, the error from assuming symmetry would be small.

Systems of More than Three Phases

The setting up of equivalent two-wire single-phase network elements similar to those shown in the diagrams of Figs. A and B is not generally possible where the number of phases exceeds three. Where only

(B)
In networks involving mutuals the voltage drop in any winding due to current in another is in the direction of the current producing the drop. For example in diagram (7), an ampere from B to D produces a drop of 3 U²Zg volts in winding A G in direction A to G and a rise of 3/2 U² Zg volts in winding CG in direction C to G. In accordance with this convention, it will be noted in diagram (25) that the equivalent network is the same as that in (7) providing the "tie transformers" between the two voltage systems have zero impedance.
per Unit Length
TIE TRANSFORMERS

Fig. B

three phases are involved, the two sound phases are symmetrical with respect to the faulty phase (assuming, of course, equality in line and apparatus constants for the three phases). With four or more phases, however, except in very special cases, the three or more sound phases do not form a system having complete symmetry with respect to the faulty phase, and they therefore cannot be combined with the faulty phase, by formulas of general validity, to form a single-phase two-wire network.

ILLUSTRATIVE EXAMPLE

The network of Fig. 8 consists of 44-kv. and 110-kv. lines interconnected at three places, fed by four generating stations and supplying one large load. The kilovolt-ampere capacities of all machines and transformers, the connections of the transformers, and the lengths of the several transmission circuits, with sizes of conductors, are indicated in the figure. The method developed above will be applied to the calculation of the residual current in the various branches of this network due to a ground on one phase of the 44-kv. line at a point 28 mi. to the right of station B.

The equivalent single-phase two-wire network is shown in Fig. 9. Diagrams 1, 3, 5, 24 and 25, of Figs. A and B are used to obtain the equivalent networks. For the condition assumed, grounded apparatus on the 110-kv. lines behaves as though ungrounded.

In determining the impedances of the various branches, the resistance components have, for simplicity been neglected. The percentage reactances of all transformers and generators or loads have been taken at 5 and 10 per cent respectively. The reactances

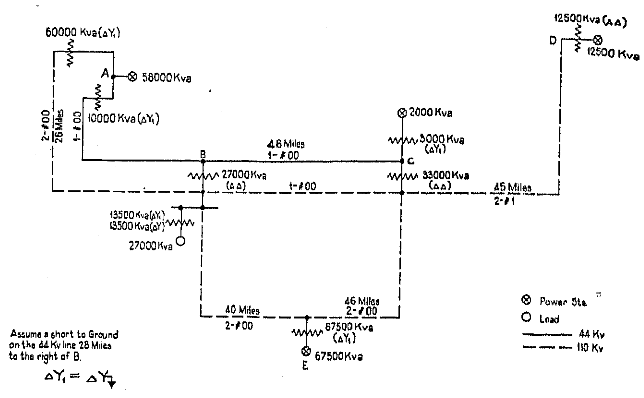

FIG. 8

in ohms of the machines and transformers are found from the percentage reactances and kilovolt-ampere capacities in the usual way, and the numerical values of the impedances of the various equivalent networks may then be found at once. Thus, for the case of generating station A, using the notation of diagram 25, Fig. B,

$$Z_o = (10/100.)\frac{V^2}{1000 \text{ kv-a.}}$$

$$(U')^2 Z_o = (10/100).\frac{V^2\left[\dfrac{44{,}000}{\sqrt{3}\,(\sqrt{3}\,V)}\right]^2}{1000\,(58{,}000/3)} = 1.11$$

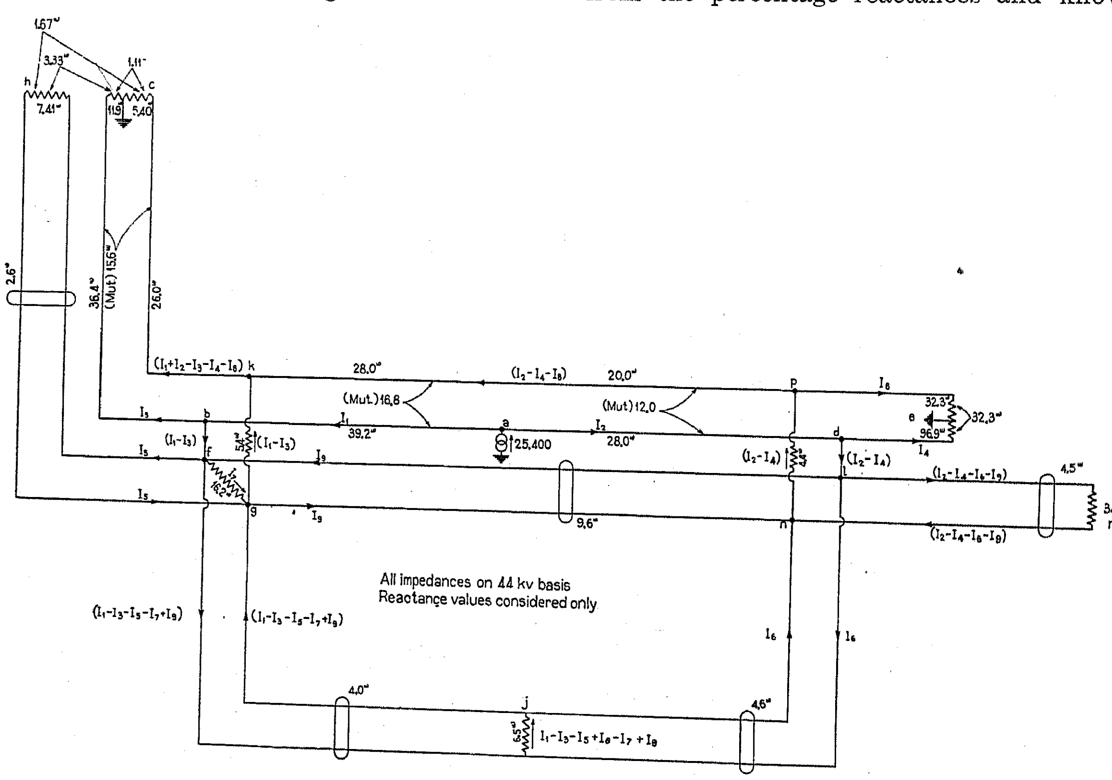

FIG. 9

and similarly

$$(U')^2 Z_T' = \frac{5\,V^2 \left[\dfrac{44{,}000}{\sqrt{3}\,V} \right]^2}{100\,(1000)\,(10{,}000/3)} = 9.68,$$

$(U')^2 Z_T'' = 9.68/6 = 1.61;$

Consequently

$$\frac{(U')^2}{2}\,(Z_T' + Z_o) = 5.40;\ (3/2)\,(U')^2 Z_o = 1.67$$

$$(U')^2\,(Z_T' + 2\,Z_o) = 11.9;\ 3\,(U')^2 Z_o = 3.33$$

$$(3/2)\,(U')^2\,(Z_T'' + 3\,Z_o) = 7.41;\ (U')^2 Z_o = 1.11$$

The equivalent impedances of the other generating and load networks may be similarly determined and are given in Fig. 9. In all cases they are on a 44-kv. basis.

As regards the transmission lines, the reactances of circuits composed of one and two (similar) wires with ground return are given approximately by the following formulas:

$$x = 0.00465\,f \log_{10} \frac{2\,h}{r} \text{ ohms/mile (one wire)}$$

$$x = 0.00233\,f \log_{10} \frac{(2\,h)^2}{r\,D} \text{ ohms/mile (two wires)}$$

where f is the frequency in cycles per second, r is the radius of, and D the distance between, the wires, and h is the depth of the equivalent ground plane.[7]

Substituting $f = 60$, $r = 0.182$ inches (00 wire), $D = 8$ ft. and $h = 500$ ft., it is found that

Reactance of one wire with earth return equals 1.4 ohms per mile.

Reactance of two wires (8 ft. spacing) with earth return equals 1.0 ohms per mile.

Also, the reactance of a metallic circuit composed of one wire as one side and two wires in parallel as the other is about 1.2 ohms per mile; and of a circuit composed of two wires as one side and four wires as the other, about 0.6 ohms per mile.

The mutual impedance z_m between two circuits having the ground as a common side and one and two wires respectively as the other sides may be computed from the formula

$$z_m = 0.00465\,f \log_{10} \left(\frac{2\,h}{D} \right) \text{ ohms/mile}$$

where f is the frequency in cycles per second, h is the depth of the equivalent ground plane and D is the distance between the wires of the two circuits. From this, using the same values for f, h and D as before

$$z_m = 0.6 \text{ ohms/mile}$$

The impedances (neglecting resistances) of the various transmission line circuits resulting from these figures are given in Fig. 9 (all on a 44-kv. basis).

The remainder of the work consists in solving the network for the currents whose magnitudes are desired, using Kirchhoff's laws. For the case under discussion, the currents (for notation refer to Fig. 9) are found to be

$I_1 = 395$ $I_4 = 222$ $I_7 = 105$

$I_2 = 557$ $I_5 = 177$ $I_8 = 380$

$I_3 = 149$ $I_6 = 198$ $I_9 = 75$

These, of course, do not include the normal load currents.

It is interesting to note the difference in the calculated residual currents as determined by the single-phase-to-neutral method and by the method given in this paper. The results based on the same line and apparatus impedances for the two methods are as follows:

Section	Ground Currents	
	Single-Phase-to-Neutral Method	Method given in this Paper
Fault to Station B	290	350
Station B to Station A	290	350
Fault to Station C	203	602

The large difference in the two currents designated "Fault to Station C" is due to the fact that the impedances between points designated d and e and p and e (Fig. 9) are relatively large, while those from p to n and in the 110-kv. network are small. Consequently, current finds a relatively easy path from d through the 110-kv. network to the two sound phases of the 44 kv. circuit thence to the ground at C, which path is ignored in the single-phase-to-neutral method. The difference in the other currents is only 21 per cent as based on the values obtained by the single-phase-to-neutral method.

In conclusion, I wish to express my appreciation of many valuable suggestions received from H. M. Trueblood. I am also indebted to C. M. Hebbert for checking the mathematical deductions.

7. For four wires with ground return $x = 0.00058\,f \log_{10} \dfrac{(2\,h)^8}{12\,r^2\,D^6}$ ohms/mile. See Technical Report No. 64 in "Inductive Interference." (*California Railroad Commission*, 1919), pp. 653, 654. Also see page 171 where curves and formulas showing the inductance of circuits with ground return are given.

Discussion

H. M. Trueblood: The question of the degree of precision worth while in estimating short-circuit currents in power networks presents itself as of immediate importance as soon as consideration of the problem of the inductive effects of these currents in exposed communication circuits is undertaken; for it is necessary only to glance over a single-line diagram of a large modern power system to realize that an exact calculation of the distribution of residual current due to an arbitrarily located fault to ground will be a lengthy, difficult and expensive proceeding.

Certain factors tend toward the conclusion that a comparatively low order of precision is all that can be justified. Among these are the matter of the impedance of the fault itself, and the uncertainty introduced into the calculated induction due to

lack of knowledge of the distribution of current in the earth. As to the first of these, it is usually essential to know what maximum effects may be expected. From this point of view, the impedance of the fault may be neglected, because on practically any system faults to ground can occur having impedances negligible compared to the other impedances involved.

Regarding the distribution of current in the earth, it is known from tests that this is very different in different localities. Where there is no information on this point, a large uncertainty is introduced into the calculated induction for parallels of moderate or wide separations, although the uncertainty regarding the magnitude of the short-circuit current itself due to this cause is of a much smaller order, probably never over 15 per cent. However, I do not think this uncertainty is of much importance as an argument for limiting an otherwise desirable precision in estimates of short-circuit current. In important cases, the effect of the distribution of the earth current can always be determined by tests, and it is reasonable to expect that as time goes on, general information regarding this important factor in different localities will be collected. Cases occur, of course, in which estimates of induction of a rather rough character suffice, as when it is known that the induced voltages will be small. However, in cases in which the induced voltages will be large, even where they are well beyond tolerable magnitudes, fairly precise estimates are usually necessary, since it is generally desirable to determine what reductions in the magnitude of the

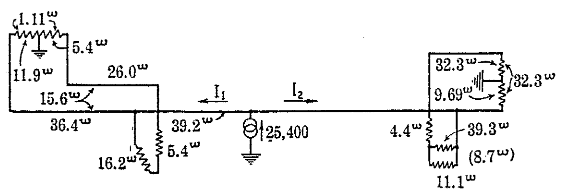

FIG. 1

residual current might be effected by possible changes in the power system.

From such considerations as these, it has seemed desirable to some of us who have been studying the problem of low-frequency induction in telephone circuits, to have a method of estimating power-system short-circuit currents, accurate, let us say, to 10 or 15 per cent., and capable of application to fairly complicated networks. Fortunately for us, the problem is one of so much importance in the operation of power systems that it has received a great deal of attention from power engineers, and our work upon it has benefited greatly from a study of the valuable and ingenious methods of attack which have been devised by these engineers and which are referred to in Mr. Shetzline's paper.

While the time and labor for a rigorous solution are greatly reduced by the methods suggested by Mr. Shetzline (he has stated, for instance, that only about 10 hours' work was necessary to obtain the solution of the illustrative example given in his paper), the amount of computation necessary would, nevertheless, in some cases still be excessive. Two general possibilities for bringing the labor involved in such cases within bounds have received attention. The first of these involves a judicious simplification of the network, and this usually means also a combination of the method of the paper and the "equivalent single-phase" method, an eye being kept throughout the work on the matter of what short circuit locations are important, what currents it is necessary to know accurately and what currents are unimportant. These questions, of course, are directly related to the location of exposures.

In the accompanying diagrams and in the tabulated numerical results, Mr. Shetzline's illustrative example is carried further, in order to illustrate the application of this process of simplification. It is assumed that only two currents are desired—those to the right (I_2) and the left (I_1) of the fault. Fig. 1 herewith is the simplified network, derived from Fig. 9 of Mr. Shetzline's paper by consolidating the 6.5-ohm generating station and the 4.6-ohm line to the right of it into the single 11.1-ohm impedance shown

	I_1	I_2
Exact Method................	350	602
Method of Fig. 1..............	355	575
Method of Fig. 2..............	290	203

at the right in Fig. 1, and by suppressing certain branches of the network completely. In a process of this sort, one is guided by a consideration of the relative magnitudes of the self and mutual impedances, and their positions in the network with reference

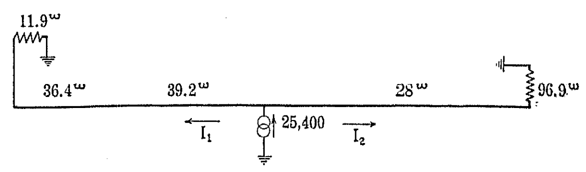

FIG. 2

to the branch carrying the desired current. Fig. 2 illustrates the "equivalent single-phase method." As the table shows, the simplified method gives results within 4 or 5 per cent of the correct values, whereas the single-phase method gives one result which is only about one-third of the correct value. The work involved in applying the method of Fig. 1 is only a little greater than that of the single-phase method.

The solution just discussed is satisfactory for the purpose of

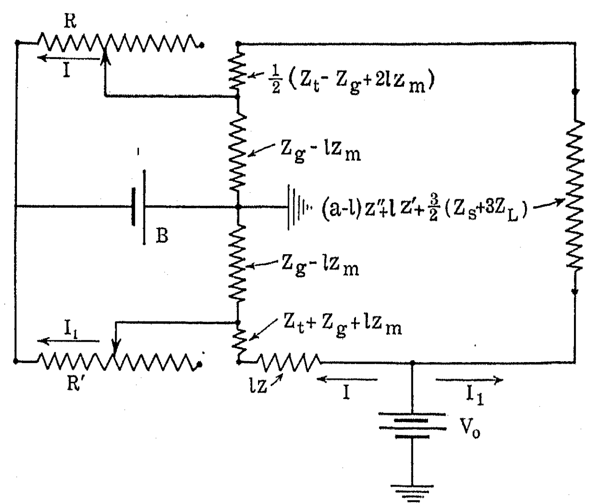

FIG. 3

determining the currents I_1 and I_2, which alone we have supposed to be of interest in this case. It would not, however, be adequate to the demands of an engineer whose job it is to determine relay settings for the system. This brings me to the second possibility, which is that of reproducing in miniature the equivalent network of the system worked out according to Mr. Shetzline's paper, and obtaining a desired current distribution by direct readings on ammeters. This scheme, of course, suggests itself at once to any one acquainted with the use of calculating tables by power companies and with the papers by power engineers on this subject. The difficulties in setting up a miniature network, using direct current (and thus assuming a common phase angle for all impedances), are encountered in connection with the mutual impedances which it is necessary to

use at certain places in Mr. Shetzline's equivalent networks. Aside from this, the network is, of course, simpler than the three-wire network, since it has only two wires. I am not prepared to say that in all cases it will be found possible to represent the mutual impedances correctly, although so far in our consideration of the question, we have found no cases in which it could not be done.

The adjoining Figs. 3 and 4 illustrate arrangements for representing the mutual impedance M of Fig. 7 of Mr. Shetzline's paper. The transformer ratio is taken as unity, for simplicity. The resistance R and R' in Fig. 3 are adjusted until the two currents marked I are equal, and until the two currents marked I_1 are equal. The battery B may have any suitable voltage. When this adjustment has been made, and the other impedances have the indicated values, the d-c. miniature network correctly reproduces the network of Mr. Shetzline's Figures 2 and 3, of course, under the assumption that all impedances have a common

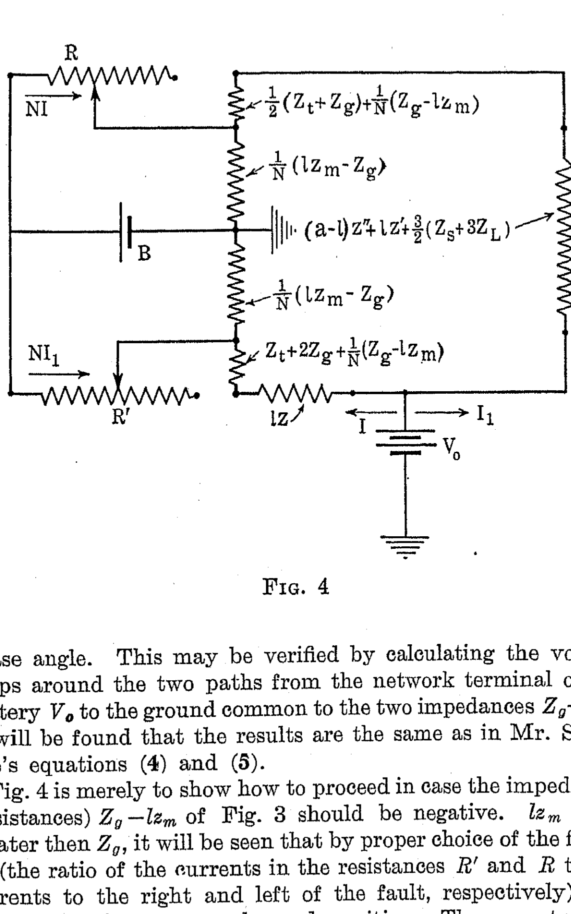

FIG. 4

phase angle. This may be verified by calculating the voltage drops around the two paths from the network terminal of the battery V_0 to the ground common to the two impedances $Z_g - lz_m$. It will be found that the results are the same as in Mr. Shetzline's equations (4) and (5).

Fig. 4 is merely to show how to proceed in case the impedances (resistances) $Z_g - lz_m$ of Fig. 3 should be negative. lz_m being greater then Z_g, it will be seen that by proper choice of the factor N (the ratio of the currents in the resistances R' and R to the currents to the right and left of the fault, respectively), the remaining resistances may be made positive. The correctness of the construction may be verified as in the other case.

R. D. Evans (by letter): Mr. Shetzline in his paper has presented an ingenious solution of a complicated problem and without doubt his solution is essentially correct.

In reviewing the paper I do not find that different effective impedances of machines when carrying single-phase loads and when carrying the balanced polyphase loads have been assumed. However, the method presented in the paper is a general one and may readily be modified to meet this condition, it being necessary only to determine new values for machine impedances.

There appears to be a typographical error in connection with the illustrative example. One would expect that the 13,500-kv-a. transformer at Station B would supply a relatively large residual current. For this reason it would appear that the residual current flowing from Station B to Station A should be considerably less than the value of 350 amperes given in the last table.

It has been our practice to solve single-phase short-circuit problems by the use of "phase-sequence quantities." Our method is an application of the general method developed by C. L. Fortescue[2] for the solution of unbalanced-polyphase-circuit problems. This method has been developed particularly for the solution of the various power-circuit problems and possesses a number of advantages, some of which will be mentioned. The phase-sequence method of calculation may be arranged so that steps used in the solution of line-to-ground short circuits may also be used to solve the other types of short circuits, namely, the three-phase short circuit and the single-phase line-to-line short circuit. A further advantage of this method is in the ease of application to calculating boards, because the complications of inductive coupling between branches, mentioned during the discussion, are avoided. It is my intention to publish, in the near future, an article describing this method and when this has been done, the relative merits of the two methods for the calculation of the various problems may be determined. In closing, I wish to emphasize the great advantage which, in my opinion, resides in the phase-sequence method from the analytical point of view in giving adequate conceptions of unbalanced-circuit conditions.

R. A. Shetzline: Mr. Evans has correctly pointed out that the impedances designated Z_g and Z_L should be those for the proper current distribution in the machines, and also that this matter may be taken care of without difficulty and without impairment of the generality of the method.

Mr. Evans' reference to a typographical error is probably due to a misunderstanding regarding the line to which the 13,500-kv-a. transformers at station B are connected. From his statements, I presume that he believes them to be directly connected to the 44-kv. line. However, the transformers are metallically separated from the 44-kv. line by the 27,000-kv-a. bank of delta-delta transformers. Accordingly, the residual current in the section fault to station B will also be that in the section station B to station A.

Mr. Evans has stated that the phase-sequence method of calculation may be used to determine three-phase short-circuit and single-phase line-to-line short-circuit currents, in addition to single-phase line-to-ground short-circuit currents. Three-phase short-circuit currents are readily determined on a single-phase basis by well known methods and present no difficulties. As regards the calculation of single-phase line-to-line short-circuit currents, I wish to state that the substitution of equivalent networks and of a single fictitious generator is applicable to this case also, with corresponding results as regards simplicity of solution.

Standardization in Construction and Operation
as Applied to Light and Power Companies

M. L. SINDEBAND
Member, A. I. E. E.
Electrical Engineer, Amer. Gas & Electric Co., N. Y. City

Reveiw of the Subject.—*Standardization is a subject that is very much discussed. The advantages of standardization have long been realized by industrial and manufacturing companies. The electric light and power companies seems to be slow in adopting standards of construction and this article relates the experience of one company who tried it out.*

Definition and Object

A STANDARD is ordinarily defined as something which is set up as a unit of reference, something accepted as more or less perfect which is used for comparison of objects of the same kind.

Standardization is the adoption of a standard. In engineering however, this is not necessarily so. Here a certain object may be accomplished in a number of different but of equally good ways. The adoption of one of these or the limitation of the number to a selected few would be standardization in a true sense.

The objects sought by standardization in engineering are:

1. To provide a standard so that a given job can be carried out in a satisfactory and workmanlike manner.
2. To accomplish this in a minimum of time with a minimum of effort at a minimum cost.
3. To insure continuity of service either of the apparatus or structure in question itself or of the apparatus to which it is auxiliary, which service is a prime requisite in the art and business of generating and supplying electric light and power.

Accomplishment

For the past five years the electric light and power properties under the control of the American Gas and Electric Company have been following a system of standardized construction in the distribution and substation divisions and the beneficial results obtained have been so clearly marked that we have been encouraged to push the idea of standardization in other directions.

While the results of standardizing have been shown to be most satisfactory in both substation and distribution work, at the same time, the problems involved are of a different nature and they will, therefore, be discussed separately.

Distribution Work

The problem encountered was to try and sell standards of construction to a group of men from different parts of the country, who for years had been accustomed to do certain work in a certain fashion, each man having his own ideas and in most cases at variance with the ideas of the others. It also involved the problem of human engineering as well.

A preliminary set of standards was prepared and several meetings of all interested parties held. As a result of these meetings, a compromise series of construction drawings has been prepared, covering the various types of structures normally encountered in distribution work. These are complete including as they do a full bill of material. They have been

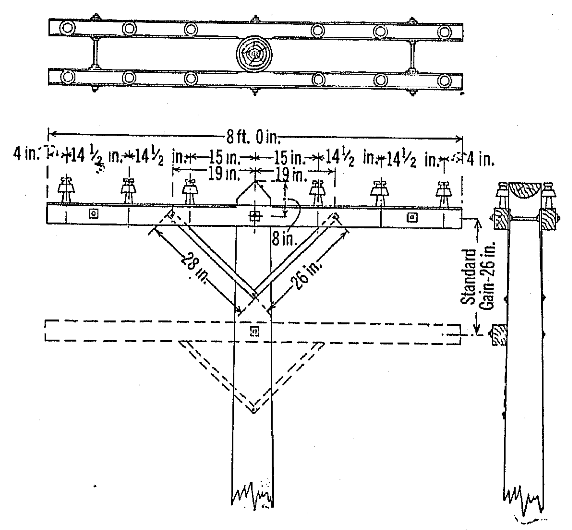

FIG. 1—STANDARD 4000-VOLT LINE CONSTRUCTION FOR SINGLE AND DOUBLE ARM

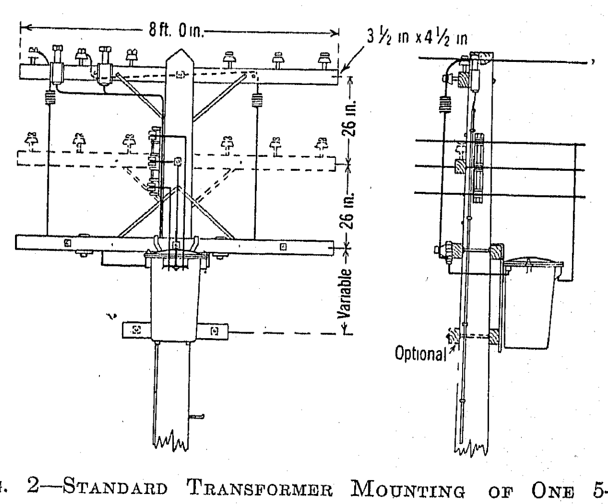

FIG. 2—STANDARD TRANSFORMER MOUNTING OF ONE 5-15 KV-A. UNIT

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

printed and are furnished to the distribution departments of the various properties who are expected to adhere to the construction shown in the standard drawings and to employ only approved line material. Figs. 1, 2, 3 and 4 are typical of such standards and the illustrations shown in Figs. 5, 6, 7, 8 and 9 are illustra-

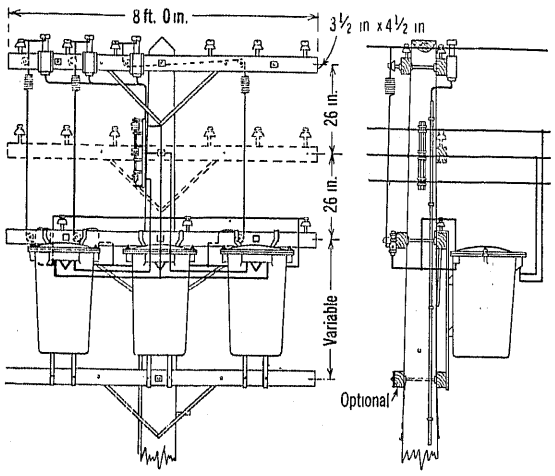

FIG. 3—STANDARD TRANSFORMER MOUNTING OF THREE UNITS 5-15 KV-A.

tive of the installations carried out in accordance with the above drawings.

It is quite evident from the illustrations cited that if the field is provided with a standard, that it can confidently be expected to produce a workmanlike job. Left

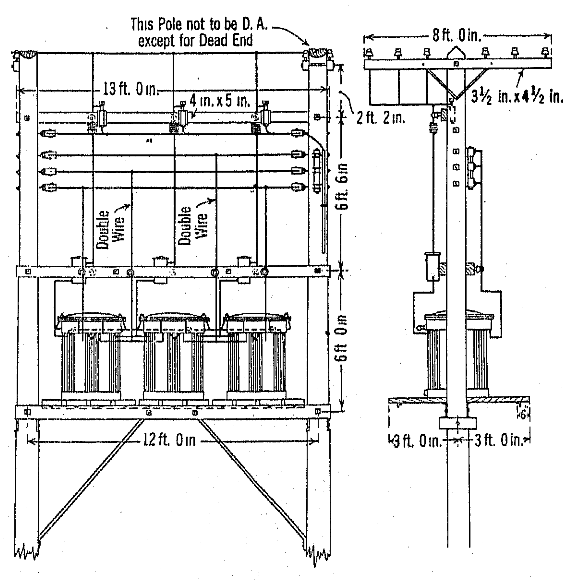

FIG. 4—STANDARD PLATFORM MOUNTING OF THREE TRANSFORMERS MAX. 3-75 KV-A. UNITS

however, to itself, the field is quite likely to produce something like Figs. 10, 11 and 12 which, while bad, are not by far the worst that could be shown.

This method of carrying out construction is far superior to the individualistic method. That it does introduce economies not available otherwise can be shown by the following:

1. It makes it possible to purchase the material involved more reasonably.

2. The material can be transferred from one district to another or from one storeroom to another and will naturally fit the corresponding job equally well in the new location.

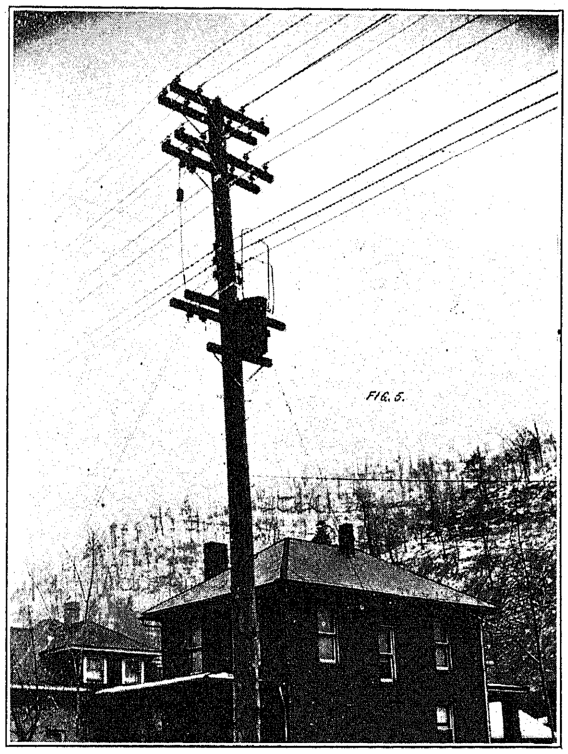

FIG. 5

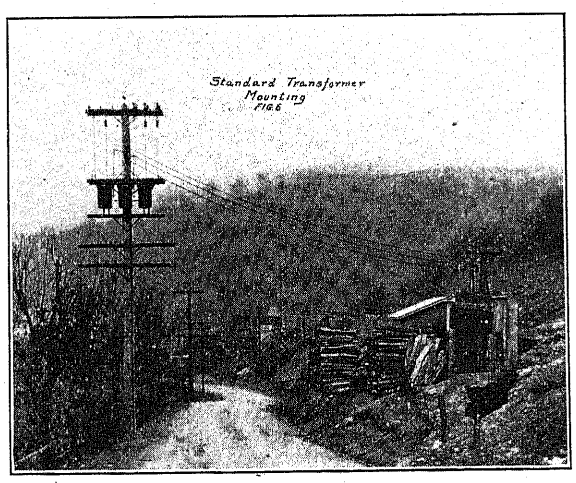

FIG. 6—STANDARD TRANSFORMER MOUNTING

3. The accumulation of obsolete material in the various storerooms is eliminated. If a standard is to be changed and a particular storeroom has an over-supply of a given item of material, it is rapidly distributed and used up without delaying materially the adoption of the new standard.

The above points can be elaborated, but it is not believed necessary; the main point is that the use of standardized form of construction makes it possible in

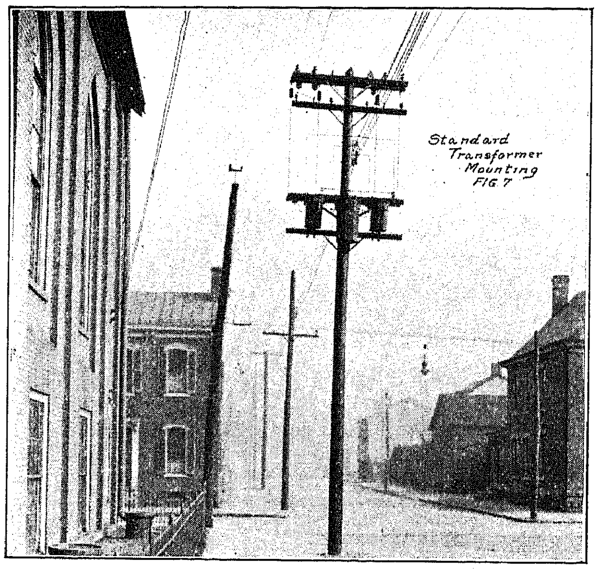

FIG. 7—STANDARD TRANSFORMER MOUNTING

the long run to do work cheaper than would be possible otherwise. Further, as has been shown, a more workmanlike job invariably results from the use of this form

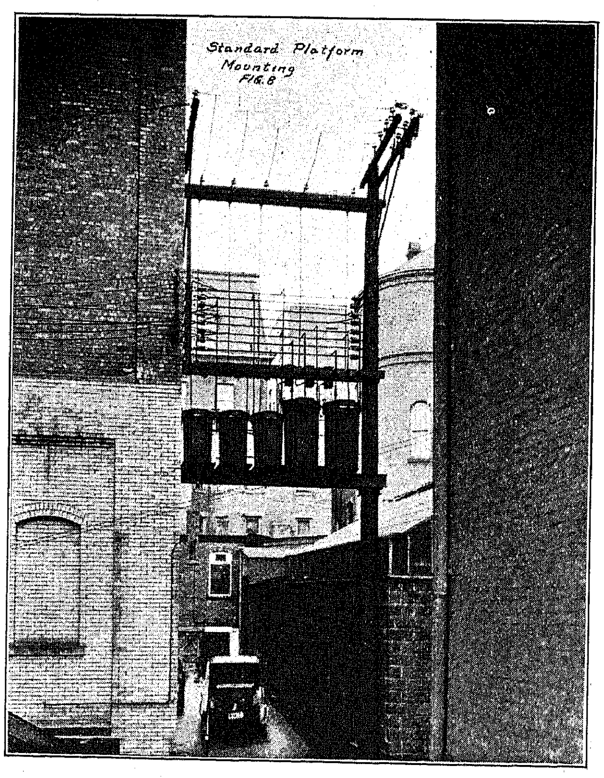

FIG. 8—STANDARD PLATFORM MOUNTING

of construction and a more workmanlike job will mean better service.

Standardized construction results in training a group of men at each property to do a certain type of work in exactly the same manner and employing the same material as at any other property of a given group. This is particularly valuable in case of unreasonable

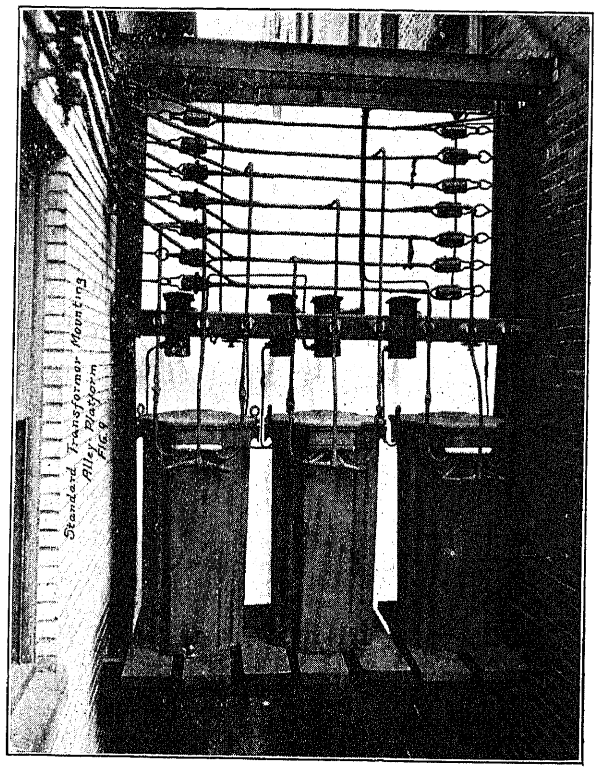

FIG. 9—STANDARD TRANSFORMER MOUNTING ALLEY PLATFORM

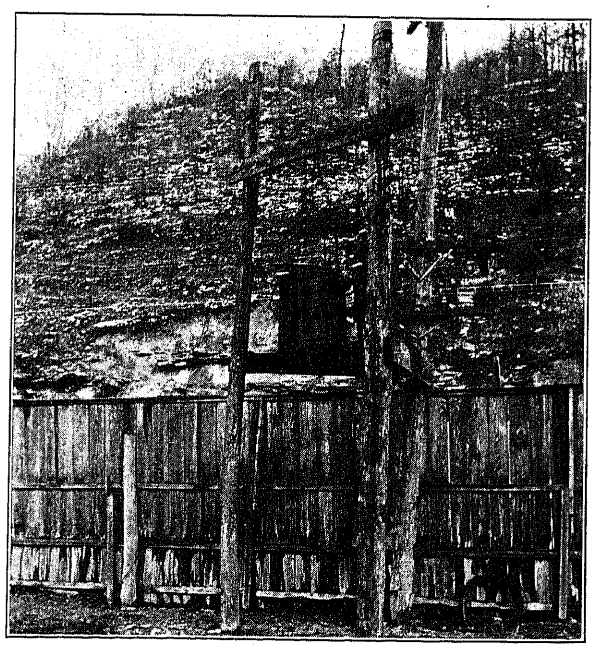

FIG. 10

labor demands. The ability in case of labor trouble to bring in a number of men from separate districts who are thoroughly familiar with the work and who can,

from the start, jump into the work and carry it along the same lines as customary elsewhere, not only makes it possible to render better service but also tends to produce a more reasonable attitude on the part of labor.

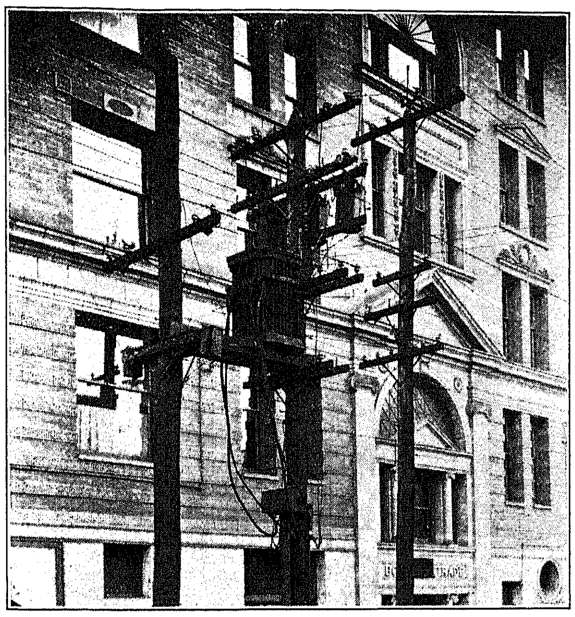

Fig. 11—Obsolete Construction

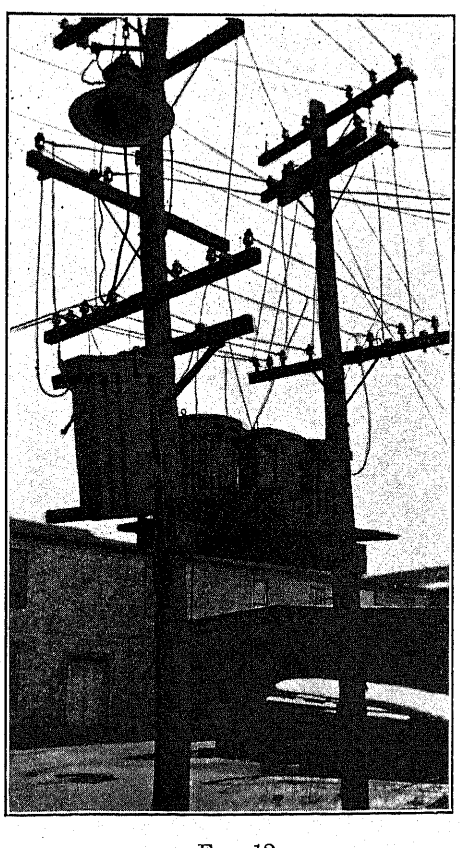

Fig. 12

Again, in the case of the holding company extending and taking over new properties where individualistic methods of construction have been going on, a problem frequently encountered is that of arresting the expansion of the existing system with an organization used to nothing else. The availability of a standardized system simplifies this problem considerably, as it makes it

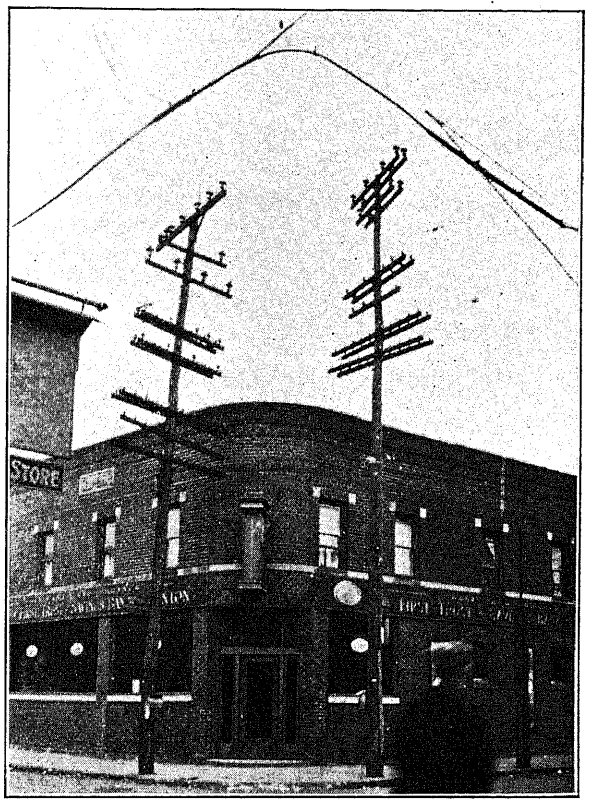

Fig. 13

Fig. 14

possible to select a few men from the older group, all accustomed to the one given method and to rebuild the new organization around these as nuclei.

There is still another benefit derived from the adop-

tion of standardized construction, which seems to us of great importance, and that is the question of appearances as affecting the relations between the utility and the municipality and more specifically the agitation for underground service. There is no doubt that in the past the question of appearance disturbed the distribution construction men very little. Especially true has this been in cities of moderate size population, say from 30 to 100,000. It was cheapest or it appeared cheapest to neglect appearances. But, with the growth of the city and the development of a civic pride, these formerly neglected eyesores, illustration of which is shown in Fig. 11 and again in Figs. 12, 13 and 14, are taken up and agitation for their removal is started.

With the example of the larger cities before them, the removal of overhead distribution and the substitution of underground is generally quickly enacted into an ordinance. The burden of establishing the unreasonableness of any such legislation falls on the utility, a burden that is doubly burdensome since it involves not only expensive litigation but results also in loss of public goodwill. A good deal of this can be forestalled, however, if the utility will set its house in order in time and standardization is a great accelerator toward that end.

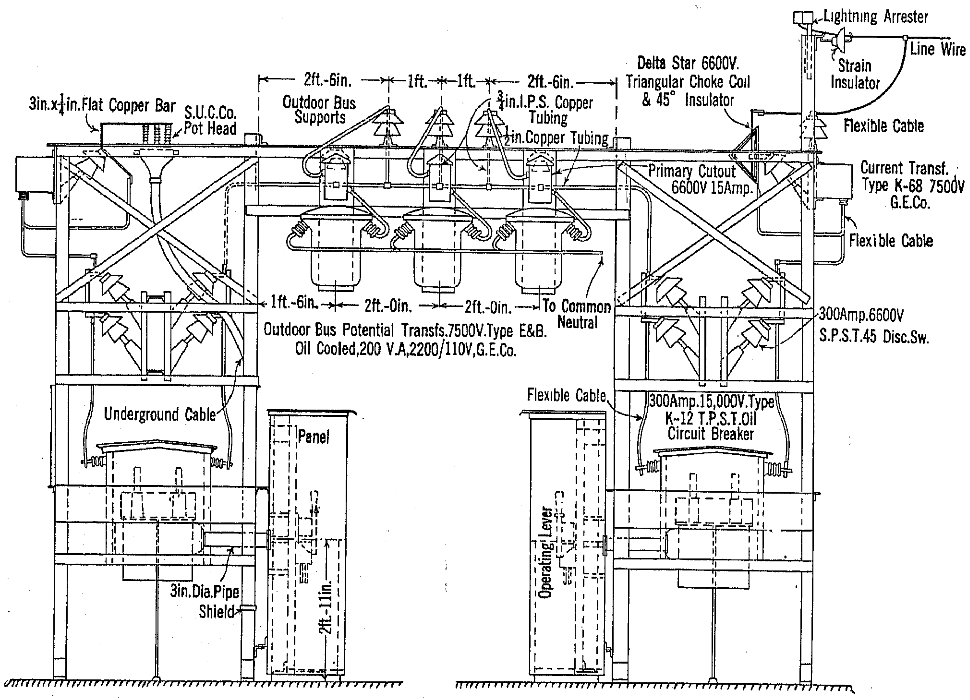

FIG. 15

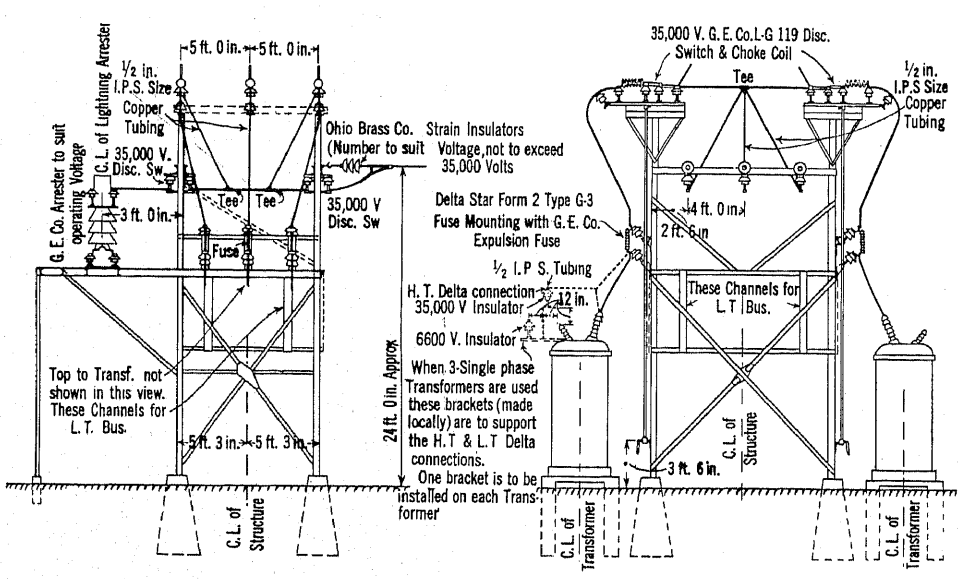

FIG. 16

Possibilities and Limits

Of the possibilities and limitations to standardization, as far as overhead distribution work is concerned, little need be said except that the logical limit here is the point where almost the entire field is covered. There is no reason why almost every type of construction problem encountered should not be covered by a standard, and in so far as it has been possible to anticipate them, they have actually been covered. New conditions and situations arise from time to time and as fast as a satisfactory solution is reached it is incorporated as a standard. The results achieved have been most satisfactory from every angle.

There is one pitfall in the path of standardization that we have tried to avoid and that is the danger of automatizing the various distribution departments and destroying their initiative. We believe successful care has been taken of this problem by bringing the various responsible heads of the distribution departments together each year for a period of 3 or 4 days and going over in open discussion all the standards; dissecting each one from a construction standpoint and from a standpoint of material entering into it. The result is not only a set of standards that is alive, and by alive is meant incorporating the best engineering ideas and the latest developments in the line of apparatus, but the maintenance of a critical attitude on the part of the field men toward the standards, an attitude of questioning the infallibility of any standards, no matter who the authors or how late their adoption. So much for distribution work.

The case of substations is somewhat different from that of distribution work, as the field men dealt with are perhaps of an entirely different type. In general, however, the objects sought are the same. To re-state them, however, they are:

1. To provide a standard so that a given job can be carried out in a satisfactory and workmanlike manner.

2. To accomplish this in a minimum of time with a minimum of effort and at a minimum cost.

3. To insure continuity of service either of the apparatus or structure in question or of the apparatus to which it is auxiliary. This service, is a prime requisite in the art and business of generating and supplying electric light and power.

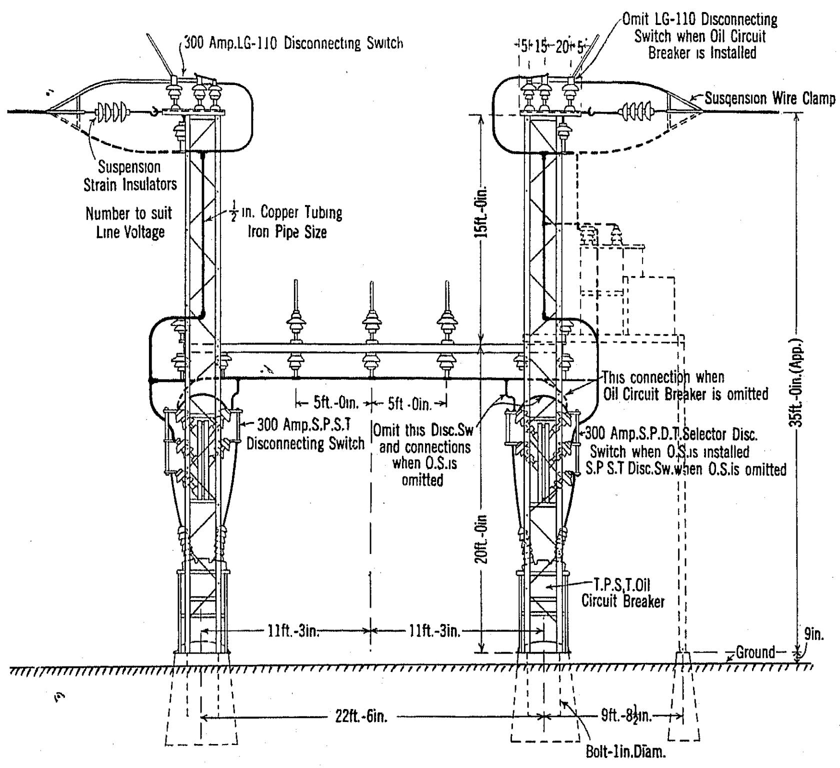

Fig. 17

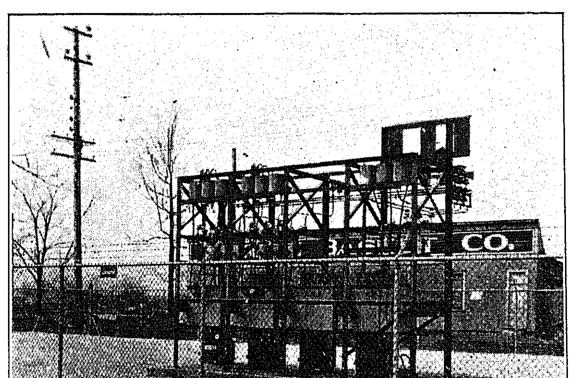

Fig. 18

That these results are possible of achievement by standardization in the case of substation work will be evident from the citations of things aaccomplished given below:

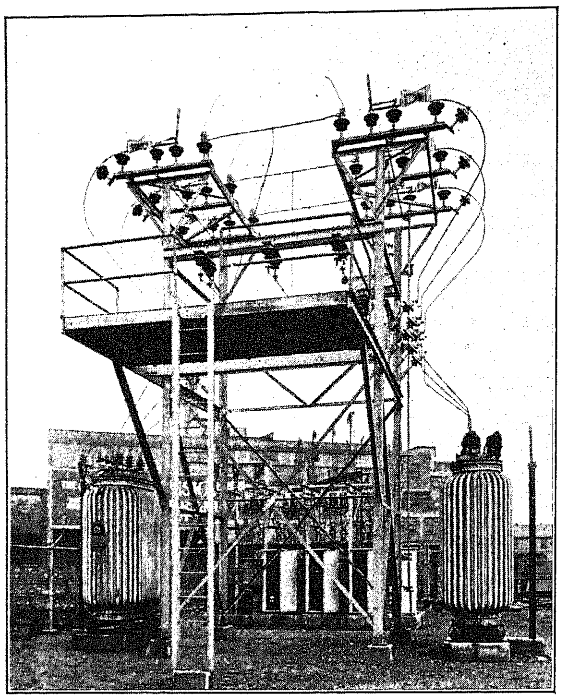

FIG. 19

SUBSTATIONS

As in the case of distribution work, a series of complete construction drawings has been prepared, covering a variety of substations ranging from 2300 volts up to 66,000 volts. Typical types of substations covered

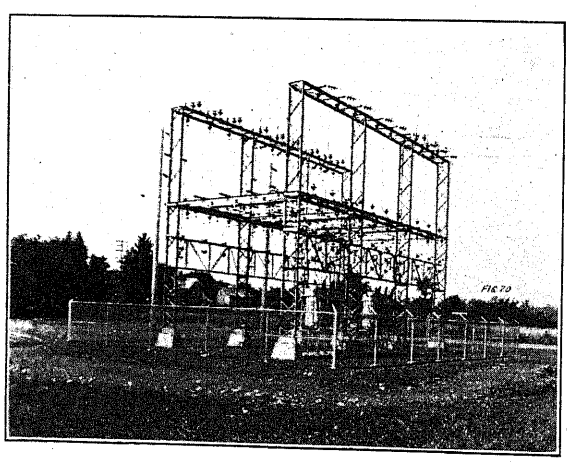

FIG. 20

are the tapoff transformer station, the sectionalizing station, the low-tension distribution station and the manifold combinations of these. Examples of these are shown in Figs. 15, 16 and 17 while Figs. 18, 19 and 20 illustrate installations made from the standards shown in Figs. 15, 16 and 17, respectively.

When a certain substation is found necessary and the field is in possession of a set of standard substations, it can easily pick a suitable one, and having the drawings before it, estimating is made comparatively simple. If later, estimates and requisitions are approved, the central engineering office need only check the selection of the standard and if that is concurred in, it is a matter of only a day or two before complete working drawings and bills of material are sent to the field. The fact that substations have previously been built from similar bills

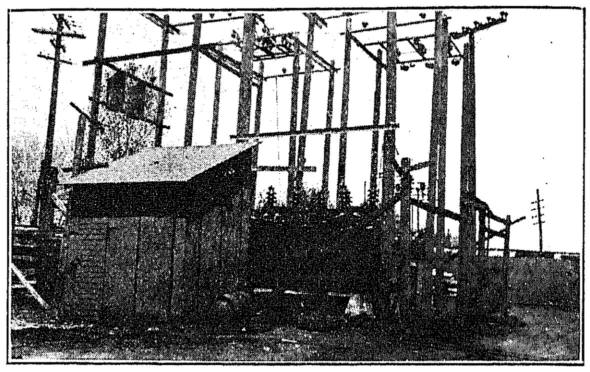

FIG. 21

of material insures the presence of all the necessary material on the ground when all that has been ordered has arrived and further insures the perfect assembly of material. This results, of course, in economical construction. Further, quantity buying of certain items of material results in saving from that direction, though the main saving is in the engineering expense and in the time involved in getting construction plans out to the field.

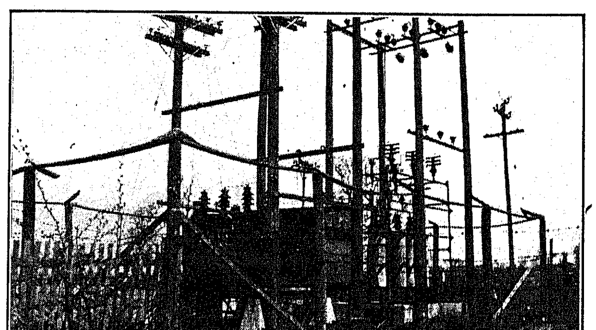

FIG. 22

It might be argued that the same results could be accomplished without standardization and this is perhaps true for the larger utilities but our experience with many of the moderate size ones has convinced us that if left to themselves, the results will almost always be deplorable. Thus Figs. 21 and 22 are examples of such substations that were in operation the early part of 1924. No elaborate arguments are necessary to prove that the construction shown in Fig. 19 is bound to

result in a much better grade of service than could be expected from a construction shown in Fig. 21.

Possibilities and Limits

In the case of substations as in the case of distribution work, the possibilities are again very great, that is, most substation installations can be taken care of by standards but the limitations are even greater. Unless care is exercised in the application of standards it is quite conceivable that all the economies will be more than counterbalanced by the unwarranted extra expenditures resulting from the misapplication of the standard. That, therefore, is a point that has to be watched by the organization responsible for the issuance of the standards. In other words, it is up to them to see that where a case demands special engineering treatment, that case receives it, but this particular limitation applies not only to standardization as regards the substations but to other forms of standardization as well. Summed up in another way, while standardization can eliminate a vast amount of routine drafting and engineering, it is a mistake to try and make it serve for engineering brains.

Reference has been made both in the case of distribution and substation work to the idea of insurance of continuity of service. This is attained in these two cases indirectly only and only through the fact that standardization invariably results in a more workmanlike installation. Continuity of service, however, cannot be obtained as a result merely of a workmanlike initial installation. A necessary adjunct to this is a never-ceasing system of maintenance and inspection of every piece of apparatus and equipment from the turbine to the distribution transformer. Our experience with standardization in other channels has led us to the conclusion that standardization could be applied to advantage in this work also. Accordingly, we have worked out a maintenance and inspection procedure for every piece of apparatus in the power link and this was made the same regardless of location of the pieces of apparatus in question. The frequency of inspection has been made different for different sizes and types of stations, thus giving weight to the importance of a particular station in maintaining service.

This system has only recently been worked out and will be put into effect within the next four weeks. It is impossible, therefore, to give any results of actual experience. It is expected, as a result of the installation of the system, to decrease the number of shut-downs of stations, substations and interconnecting lines; to maintain our equipment in better physical condition, and further, to know at all times what to expect as regards performance of the apparatus and equipment.

Summary

An attempt was made to show that standardization in construction, as applied to light and power companies, results in a better type of construction, and further, in the possibility and probability of more reliable service; that it results in definite economies in construction and engineering; that it requires continual alertness to preclude the possibility of misapplication of standards, and finally, that the idea can be developed further into maintenance and operation with equally beneficial results.

Discussion

E. P. Peck: In connection with Mr. Sindeband's paper, the plan, as a whole, is unquestionably right. The details will vary as time goes on. The main thing in a plan of that kind is to be sure that your standards are workable and that there are no unworkable theoretical ideas that some one happens to have put into them. I foresee that he is going to have a good deal of trouble with specialty salesmen. As soon as you standardize and decide to use one man's equipment, every manufacturer of specialties in the country will concentrate on you to have you change over and use his specialty.

Current-Limiting Reactor Characteristics

BY S. I. OESTERREICHER

Member, A. I. E. E.

Electrical Engineer, Metropolitan Device Corp., Brooklyn, N. Y.

Review of the Subject.—*To prevent in large generating and distribution systems the possible concentration of enormous amounts of electrical energies at certain critical points, makes the extensive use of the current-limiting reactor a necessity.*

Connected reactor installations of 30,000 to 50,000-kv-a. capacities are not unusual any more.

Aside from the many important issues involved in the generating system as a whole by the reactor equipment, the reactor itself became a very important factor.

After the paramount issue of short-circuit protection is disposed of, a number of minor features is to be considered in the reactor design.

The general characteristics of the various winding types, the circuit connections affecting the true reactance values, current distributions, throughout a multilayer reactor and conductor efficiencies are considered.

Creeping due to heating of the conductor is evaluated.

Attention is called to the fact, that the attraction or repulsion of the turns or layers within a reactor depends upon the layer or turn interconnections.

The mechanical forces upon the conductor during short-circuit stresses are investigated and an approximate expression is given for their calculation.

In view of the important functions performed by the air core type current-limiting reactors in large generating and distributing systems, it might be of interest, perhaps, to direct attention to a few of their inherent characteristics, as influenced by their designs and the usually encountered installations.

Current-limiting reactors are connected into the circuits of electric generating and distribution systems with one particular object in view. Namely, to relieve the system of the abnormal and dangerous stresses, caused by a number of operating disturbances. However, circuit disturbances are comparatively few and far apart and as a further coincidence, do not always reoccur upon the same circuits. Thus, it seems that while reactors are primarily installed to meet transients only, in reality they meet two distinctly unrelated operating conditions.

In view of this and the additional fact that single reactor installations of 30,000 kv-a. connected rated capacities are not unusual any more, it must be conceded that the reactor characteristics during normal operating conditions are also important, and well worth considering.

Types of Reactor Windings

An air core type current-limiting reactor is the simplest conceivable electrical apparatus. It consists of a number of convolutions of a copper conductor. The convolutions are held into a rigid predetermined interrelation by some suitable arrangement like clamps, braces, arms, etc.

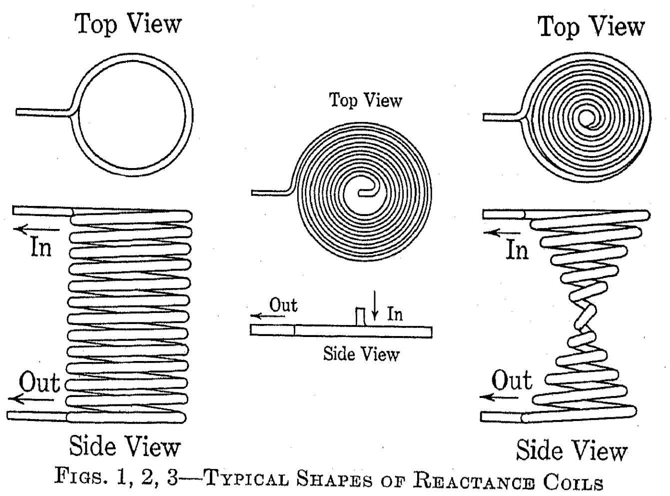
The inherent general characteristics of the reactor are somewhat influenced by the type of winding method used in its construction and after installation, by the relation and the circuit connection of the reactor in regard to other reactors placed in its immediate vicinity.

There are two principal types of winding shapes used in the design of current-limiting reactors, viz:

(1) Concentric multiple turns or concentric coaxial multiple turns. The turns might be connected either in series or in parallel, or both, in series—in parallel. This winding type is also called a drum winding. (Fig. 1).

(2) A spiral, wound either in single or multiple layers, connected also either in series or in parallel. This type of a winding is known as a disk or pancake type winding (Fig. 2).

As a modification of the concentric coaxial winding and for the sake of records only, the hour glass type winding is mentioned here and shown diagramatically in Fig. 3. Its use, however, is mostly restricted to



Figs. 1, 2, 3—Typical Shapes of Reactance Coils

lightning arrester choke coils. Due to difficulties in manufacture when designed for larger current ratings and the uneven stress distribution in different parts of the winding during short circuits, makes this a most undesirable winding form for current-limiting reactors.

The superiority of the disk winding over the drum winding is so overwhelming that for current-limiting reactors the first type is used almost exclusively. The summarized advantages are as follows:

1. For a given winding volume and turn spacing, a disk-wound coil will have a greater inductance value than a drum-wound coil.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

2. A disk-wound multilayer coil can be braced much more securely and conveniently than a drum-wound coil.

3. The voltage gradient between turns and layers and the electrostatic field distribution across the entire winding is much more uniform. This assumes that proper care has been taken for an even magnetic field distribution, by properly located conductor transpositions of a multilayer winding.

4. During short-circuit stresses, the magnetic field of a multilayer disk-winding attracts all the various layers toward the center layer. Thus, the predominant force is that of compression.

The only advantage of a drum winding is that if a reactor of adjustable inductance values has to be designed, it lends itself somewhat more convenient to sub-divisions and interconnections than a multilayer disk-winding.

The reactance x of an air core solenoid is given by the expression

$$X = a\,N^2\,Q\,10^{-6} \qquad (1)$$

where a = the radius of the solenoid,
N = number of turns, and
Q = a constant depending upon the frequency

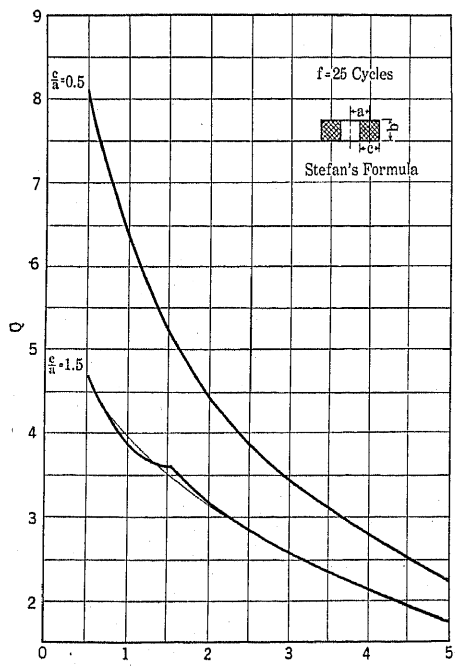


FIG. 4

f and the shape factor of the winding. The shape factor is determined by the relation of the length b and thickness c over the radius a of the coil.

The value of Q being primarily a function of the inductance of the winding, or still more general, the characteristic of the solenoid, is better expressed by

$$Q = 2\,\pi\,f\,L \quad \times \text{ constant} \qquad (2)$$

For L a great number of formulas have been derived and published. Those best adopted for the calculation of current-limiting reactors are the Stefan formula for multilayer disk coils and the Nagaoka formula for concentric coaxial multilayer coils. In both formulas auxiliary units determine the shape factor of the coil. A characteristic curve as to how the shape of the coil influences the value of Q is shown in Fig. 4. The curves are plotted from the Stefan formula.

In connection with the numerous available inductance formulas, it is, perhaps, proper here to mention the fact that most of the formulas were developed for the solution of a particular problem in view. However, all formulas assume an even current sheet throughout the entire winding area. This is an unobtainable condition in large air-spaced windings, the type of which is used almost exclusively in current-limiting reactors. It is therefore evident that a very painstaking exact calculation method is liable to be just as much in error as a simple one.

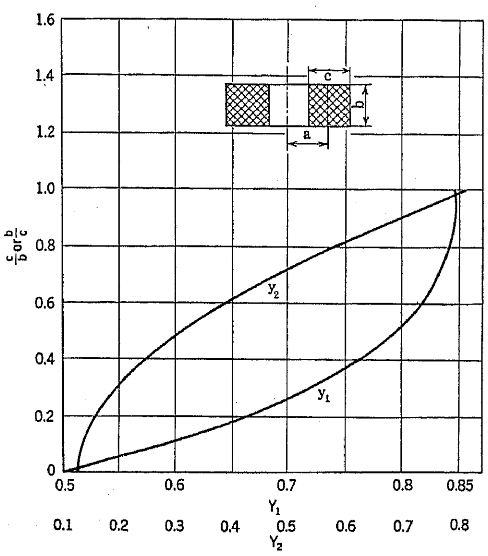

FIG. 5—VALUES OF y_1 AND y_2 CANNOT EXTEND BEYOND THE CURVES SHOWN BELOW
PLOTTED FROM TABLE ON PAGE 196
U. S. BUREAU STANDARDS BULLETIN
STEFAN'S FORMULA

For this reason, some of the simpler inductance formulas are much more desirable for everyday use than some of the more exact ones. In most of the formulas, using one or the other type of compiled auxiliary units, the expressions for the calculations of the auxiliary units are also given. Evidently for the purpose to enable the user to go beyond the already compiled tables. If such values are calculated beyond the tables, they should be used rather cautiously. For instance, if the y_1, and y_2 values of the Stefan formula are plotted against each other, it will be found that the formula will become unreliable for any computation beyond the intersection of the two curves, that is, beyond a certain shape factor, for which the Stefan formula was developed. (Fig. 5).

Inasmuch as part of the design of a reactor is to find

the shortest conductor length which has the desired inductance L, naturally the most efficient ratios of c. to .a and b. to .a were quickly evaluated and are usually stated as

$$a : b : c = 1.5 : 1.2 : 1.$$

However, it seems that undue importance is given to these most efficient ratios, especially as far as current-limiting reactors are concerned.

While it is true, of course, that the aim in the reactor design is also to have the relation of minimum conductor length and maximum inductance as close to the most efficient ratios as possible, this aim is usually offset by the fact that in many installations no space is available for such ideal coils. Another extenuating circumstance for the partial neglect of the theoretical ratios lies in the fact that during short-circuit stresses, it is of much greater importance to have a certain copper volume V in the coil, which is capable of withstanding the heating caused by the short-circuit currents for a certain specified time, than to have an ideal conductor length.

Furthermore, from equation (**1**), it is readily seen that the reactance x increases as a square function of the number of turns. Thus a small additional conductor length in the form of a few turns quickly offsets a certain variation in the coil dimension ratios.

In many previous papers about reactors, much stress has been laid upon small conductor area. No doubt, on account of the fact that with increasing conductor areas, the eddy current losses increase as a square function of the conductor diameter. The eddy current losses again, by increasing the effective resistance of the conductor, would considerably increase the total $I^2 R$ (a-c.) losses of the coil. For this reason, we often read not only about the most economical conductor length, but also about the most economical conductor area.

Due to such theoretical considerations in the past, a number of reactor failures occurred where the failures had to be attributed to the mechanical weakness of the conductor. The conductors ruptured on account of the intense vibrations caused by the magnetic field of the coil during short circuits. Thus, a compromise had to be made between electrical theory and mechanical strength. In this respect, the prevailing opinion at present is that the winding as a whole should have sufficient heat radiating area to safely conduct the heat losses of the conductor into the surrounding medium without any undue increase in the temperature rise of the reactor and within the prescribed limits of the materials used in the coil construction. However, the conductor should be strong enough to withstand any force, regardless of whether caused by thermal or magnetic origin or whether the eddy current losses increase or not.

To fulfill this condition in both directions and to enable the convenient winding of the conductor into a certain form, the total conductor area is subdivided into as few parts as absolutely essential for a conservative design. In many reactors the current rating is such that to provide an even heating of the entire conductor area, the conductor must be split up into more parts, otherwise the crowding of the current in certain parts of the winding will cause excessive temperature rises.

When such a split multiple conductor is wound into a certain winding space and at both ends connected in parallel, it is cut, of course, with an unequal magnetic field intensity. This is due to the fact that the various layers are placed into various magnetic planes of the

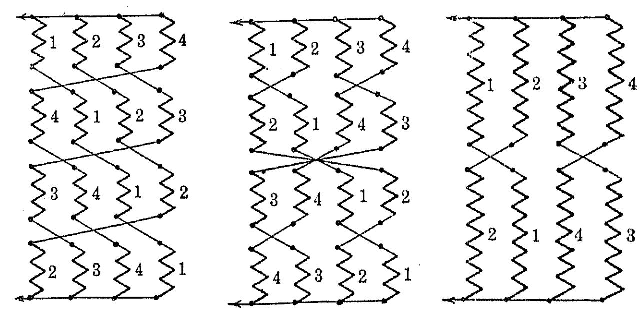

FIG. 6—FOR DISK WOUND TYPE, NUMBER OF TURNS IN ALL LAYERS EQUAL

FIG. 8—FOR CONCENTRIC COAXIAL TYPE, NUMBER OF TURNS IN EACH TWO SUCCESSIVE LAYERS EQUAL

SHOWING VARIOUS TRANSPOSITION METHODS IN MULTILAYER WINDINGS TO OBTAIN EQUAL CURRENT DISTRIBUTION THROUGHOUT EACH LAYER.

coil. To remedy this shortcoming of the arrangement, layer transpositions become necessary. In Figs. 6, 7 and 8 are shown diagramatically the most frequently used transposition methods. All the transpositions are so arranged that the turns in series of any one layer are carried through a uniform magnetic field throughout the coil.

Another advantage derived from these transpositions is in an electrostatic direction and is due to the reduction of the dielectric stresses in as many

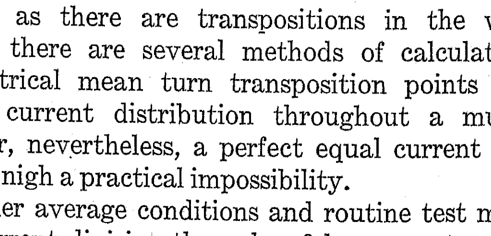

FIG. 9—CURRENT DISTRIBUTION THROUGH 9 MULTILAYER CURRENT-LIMITING REACTOR. TOTAL CURRENT 341 AMPERES. AVERAGE CURRENT 37.8 AMPERES = 100 PER CENT.

points as there are transpositions in the winding. While there are several methods of calculating the geometrical mean turn transposition points to give equal current distribution throughout a multilayer reactor, nevertheless, a perfect equal current division is well nigh a practical impossibility.

Under average conditions and routine test methods, the current division through a 9-layer reactor winding will be as indicated by the values in Fig. 9.

Inasmuch as every installed reactor is a cause of a certain voltage drop in its respective circuit, it seems paradoxical to speak about the most economical or the most efficient winding. However, as soon as the adding of artificial reactance into a generating system becomes a necessity, the resulting benefits usually offset certain inherent reactor disadvantages.

The apparent efficiency of a reactor is given by the expression:

$$\text{Efficiency} = 1 - \frac{I^2 R_{eff.}}{E I} \tag{3}$$

where I = full-load current in amperes, R_{eff} = the effective (a-c.) resistance and E = reactive volts across the reactor.

If maximum short-circuit protection would not be the main object in the reactor design, the most econom-

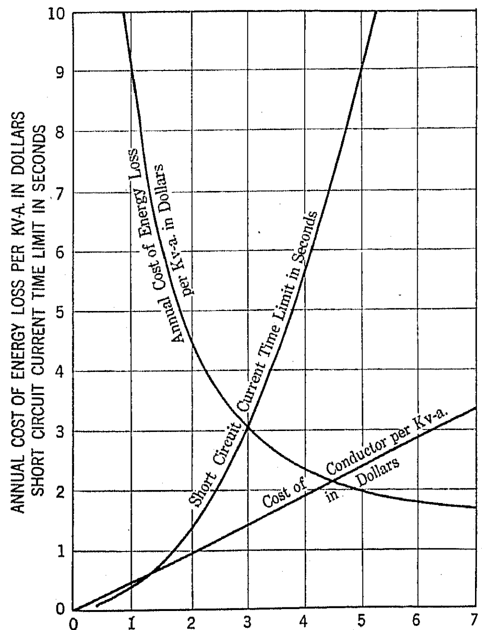

FIG. 10—TYPICAL RELATION OF CONDUCTOR COST, ECONOMY AND SHORT CIRCUIT TIME LIMIT DURATION OF REACTANCE COILS

ical conductor area would evidently follow Kelvin's law, which is given by

$$A = F I \sqrt{\frac{C e}{C c C a}} \tag{4}$$

Where A = cross section of conductor, I = square root of annual mean current squares.

F = a constant

$C e$ = cost of energy loss per kilowatt-hour in dollars

$C c$ = cost of copper per unit weight in dollars

$C a$ = annual charge in per cent on the conductor cost.

According to the units selected and the maximum temperature rise, the factor F in this equation has to be determined for the various types or makes of reactors.

A typical interrelation of economical copper volume, annual losses and short-circuit protection of a current-limiting reactor conductor is given in Fig. 10. The curves are based on a 65 deg. cent. temperature rise, 10 per cent annual charge upon the conductor and two cents per kw-hr. energy cost.

However, in many instances, especially upon 60-cycle reactors (2 to 3 per cent reactance) such interrelation cannot be followed.

To be able to offer a sufficient safety factor in the design of the reactor, it is best to neglect the heat radiation of the conductor during the short-circuit stress. That is, assume that no heat is lost through radiation in such short time interval as a short-circuit duration.

With such an assumption, the following relation exists between the conductor volume, short-circuit current, and effective (a-c.) resistance:

$I_{sc}^2 \times R_{eff.} \times t$ = gram calories $\times$ spec. heat of conductor $\times$ deg. cent. temperature rise.

Hence, the maximum short-circuit time limit in seconds for a reactor with a copper conductor, equals:

$$t = \frac{\text{Weight of copper in lb.} \times 180 \times \text{deg. cent. temperature rise}}{I_{sc}^2 \times R_{eff.}} \tag{5}$$

For the temperature rise during the short circuit, the temperature limitations of the respective materials used in the reactor construction have to be considered. Assuming that the normal continuous full-load temperature of a reactor reaches 65 deg. cent., assuming further, the ambient room temperature at 40 deg. cent., the various designs allow from 40 to 150 deg. cent. ultimate temperature rise during the short-circuit time lapse.

Inasmuch as the short-circuit time limit is usually a predetermined value, equation (5) can conveniently be converted to give the required cross sectional area of the conductor.

From (1) $x = a N^2 Q 10^{-6}$

The length l of the winding (in ft.)

$$1 = 0.524 \times a \times N \tag{6}$$

from which, the weight of the winding in lb.

$$W = 0.524 \times a \times N \times 0.32 \times \text{circ. mils} \times 10^{-3} \tag{7}$$

thus, area of conductor in circular mils

$$A = \frac{I_{sc}^2 \times R_{eff.} \times t \times 33.3}{a \times N \times x^\circ C \,\text{temperature rise}} \tag{8}$$

INFLUENCE OF MUTUAL INDUCTANCES BETWEEN REACTORS

In three-phase generating or distribution systems, a set of three neighboring reactors is usually connected into one generator, bus tie, station tie or feeder circuit. The three reactors may be installed either adjacent or super-imposed. In both arrangements the coils might be mounted with their axis either parallel or coaxial. As far as the consecutive phase rotation of the entire system is concerned, this also might be arranged in either a vertical or a horizontal plane. In both elec-

trical groupings, the three phases might consecutively rotate like 1-2-3——1-2-3———or the phases might be arranged 1-1-1———2-2-2———3-3-3——— These different arrangements and connections must necessarily influence the instantaneous magnetic flux directions between adjacent or superimposed reactors. Inasmuch as the instantaneous flux directions determine the average additive or subtractive values of the

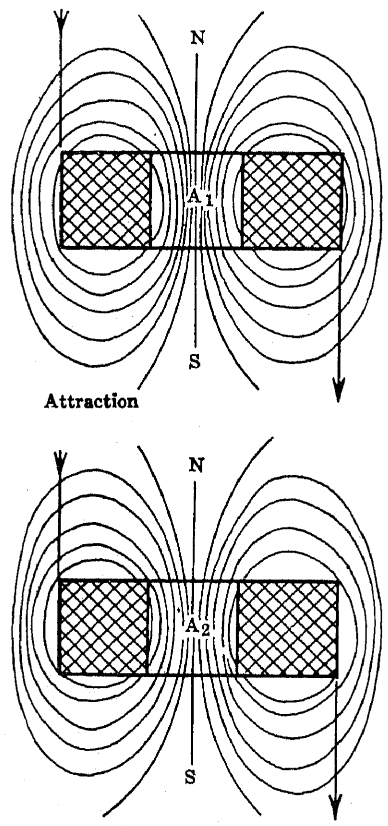

FIG. 11

mutual inductances between reactors, it follows, that the total inductance of each reactor will be influenced by the respective reactor arrangement.

For a simple illustration of the above, in Fig. 11, two windings have been superimposed in a coaxial relation. The current and winding directions are assumed to be in the same directions. The fluxes between reactors are attracting each other. The mutual inductances of the coils are additive. The total inductance L_t of coils A_1 and A_2 if connected in series equals:

$$L_t = L_{A1} + L_{A2} + 2_M \qquad (9)$$

Without changing any other features of this group, except turning the axis of these windings in a parallel relation (Fig. 12) the magnetic fluxes between the coils will now repeal each other. The mutual inductance (M) will be subtractive and L_t in this case is

$$L_t = L_{A1} + L_{A2} - 2_M \qquad (10)$$

Assuming that for a certain reactor intercenter spacing, the mutual inductance is only 3 per cent of that of the self inductance of any one coil; the fact that their axial arrangement is different is sufficient to reduce the total reactance of the circuit with as much as 12 per cent from the desired values.

Another important fact shown by Figs. 11 and 12 is that during short-circuit conditions, in the first case the coils must be braced against compression, whereas in the second case the same braces are subjected to tensile stresses.

While in principal the above claims hold true for any circuit, when applying the same to polyphase systems, due to the phase relations of the interlinked system, certain modifications have to be made.

Let three magnetic fluxes, 1, 2, 3, displaced by 120 deg. from each other, periodically vary in an interlinked system as shown in Fig. 13. The instantaneous polarities and their values through three air core solenoids 1-2-3 in C, are indicated at the zero instant of 1 and tabulated for one half period in Table I. Averaging the fluxes which attract each other between any two solenoids throughout the half cycle, the approximate average values of 1.05, 1.17 and 1.05 will be found to

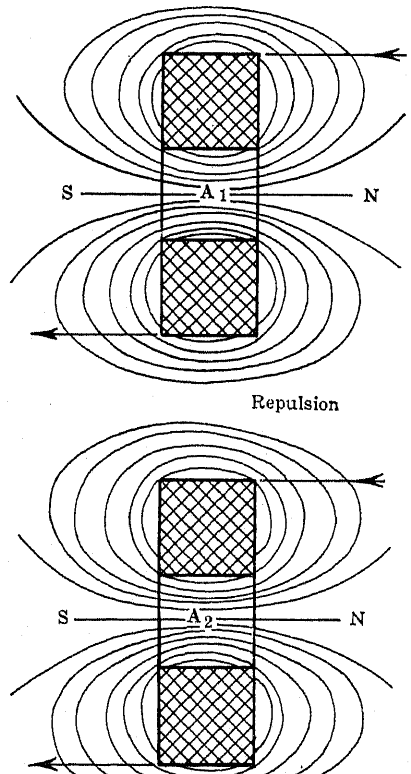

FIG. 12

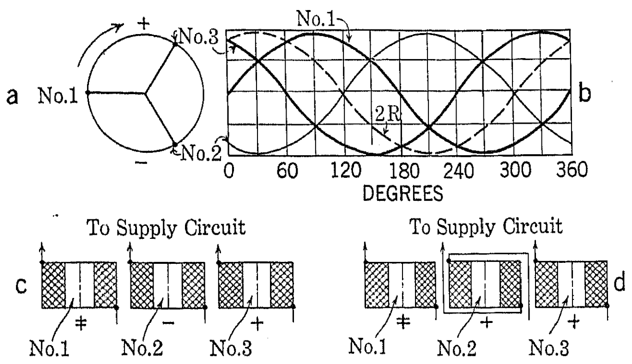
exist between coil 1 and 2, 2 and 3, 3 and 1. Reversing the connection in coil 2, as indicated in Fig. 13d, will also reverse the instantaneous magnetic polarity of this coil. To receive a clear conception as to the instantaneous relation of this 2 R magnetic polarity in regard to coil 1 and 3, the reversed polarity 2 R is plotted in its reversed direction between curves 1 and 3 as 2 R (Fig. 13b). If these reversed values are again tabu-

lated, it will be found, as shown in Table II, that the average values between coils 1 and 2 and 2 and 3 are only about one half the average values of Table I. The average values between coils 1 and 3 are the same in both cases.



INSTANTANEOUS POLARITY AT 0 DEG.

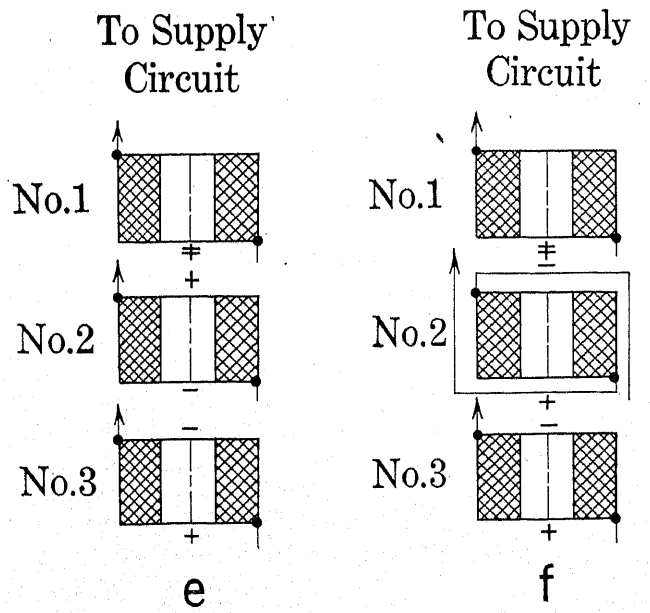

FIG. 13

Thus, by reversing the middle coil connection, or what amounts to the same, by reversing the middle coil winding direction of three coils supplied from a three phase circuit, the average mutual inductance effects between such coils are greatly reduced. Although the average mutual inductances between the two outside coils of either arrangement are the same, nevertheless, the usual double center spacing distance makes the effect less appreciable. The difference between coaxial and parallel axis mounted coils is only in the instan-

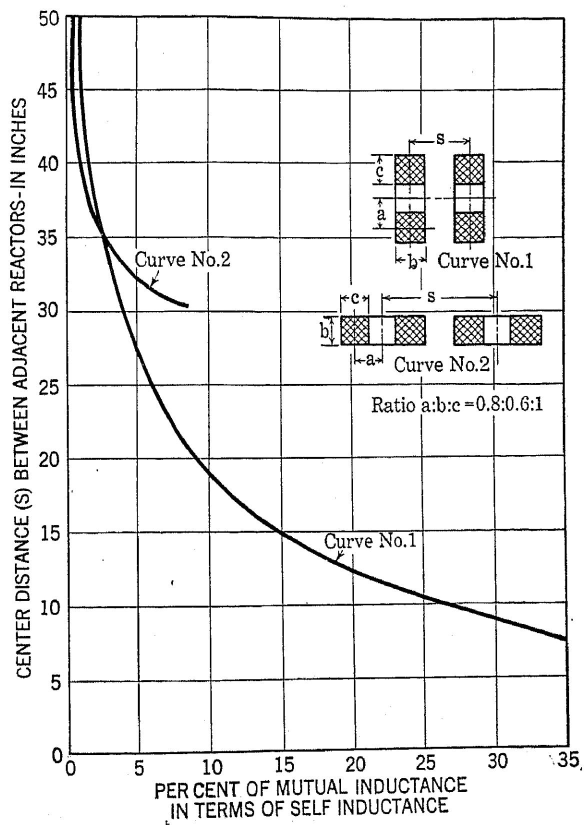

FIG. 14—VARIATION OF MUTUAL INDUCTANCE, IN TERMS OF SELF-INDUCTANCE, BETWEEN PARALLEL OR COAXIALLY MOUNTED CURRENT-LIMITING REACTORS

taneous polarities; the average values, however, remain the same for both arrangements.

An interesting point of such a connection reversal on the middle coils of a common three-phase group is that the sum of the three magnetic fluxes between the three windings is zero only at one point of a half cycle. Aside from this, the mutual inductances between two reactors is influenced partly by the shape factor and partly by the number of turns of each coil, both of which have usually the same numerical values for two coils connected into the same circuit. By far the greatest influence upon the mutual inductance is the spacing distance S between a set of coils.

Fig. 14 shows the characteristic relations of the

mutual inductances between adjacent coils of both principal mounting methods and throughout the usually encountered spacing ranges. The mutual inductance M for the different spacings is expressed in terms of the self-inductances of the respective coils. 100 per cent mutual inductance, corresponding to the total self-inductance L of the coil under consideration. The selected coil proportions are typical to the ones used in the designs of current-limiting feeder reactors, built to fit into the usually allotted power station compartments.

The preceding paragraphs may be summarized as follows:

(1) The type of winding used in a current-limiting reactor affects the electrical characteristics of the coil.

(2) The most economical conductor does not necessarily give the desired short-circuit protection.

(3) The copper volume of the reactor conductor should be selected, to give the desired short-circuit time limit protection regardless of economy to the design.

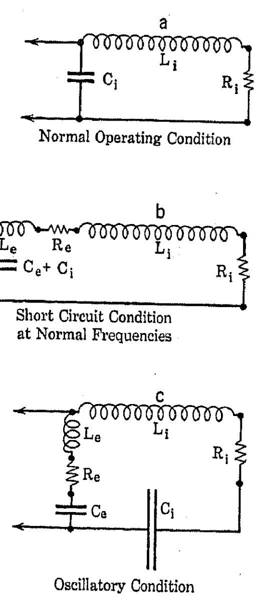

FIG. 15—EQUIVALENT CURRENT-LIMITING REACTOR CIRCUITS

(4) The influence of voltage drop between reactors, or the repelling or attracting forces may be controlled by proper intercenter spacings or by properly selected circuit connections.

While from the design standpoint or during normal operating conditions a reactance coil is comparatively a very simple apparatus, nevertheless, an equivalent electrical circuit of the same, has all the elements and combinations of the complex circuits. Some equivalent reactor circuits are given in Fig. 15. Fig. 15a shows the circuit in its simplest form and as it is usually assumed from the design standpoint. The circuit has an overwhelming amount of inductance L_i in series with an exceedingly small amount of resistance R_i, (usually of a value of about $1\frac{1}{2}$ to 4 per cent of X). Both inductance and resistance are shunted by a slight capacity C_i.

For normal conditions, the resistance as well as the capacity are usually neglected. During short circuits at normal frequencies, the external inductance L_e and external resistance R_e are in series with the internal inductance L_i and resistance R_i. Both the internal and external capacity $C_e + C_i$ shunt the circuit (Fig. 15b).

During normal frequencies, the external capacity

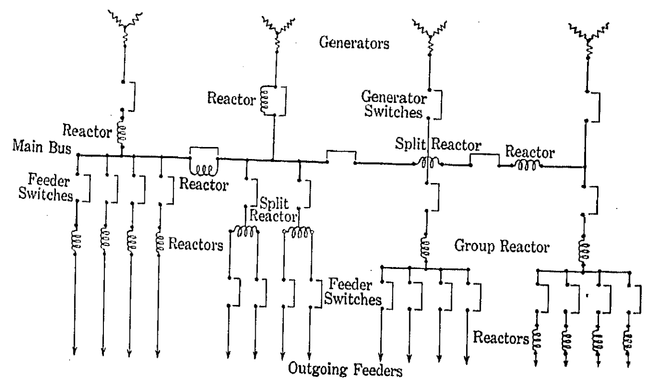

FIG. 16—ONE-LINE DIAGRAM OF VARIOUS GENERATOR, BUS AND FEEDER REACTOR CIRCUITS

of the circuit added to the internal capacity of the coil very seldom reaches the critical or oscillatory case. Under certain conditions, a reactor might oscillate upon itself. Such an oscillating circuit is equivalent to the one shown in Fig. 15c.

Certain distinctions are made between the various reactors, in relation to their particular location in a generating or distribution system. Thus we speak of

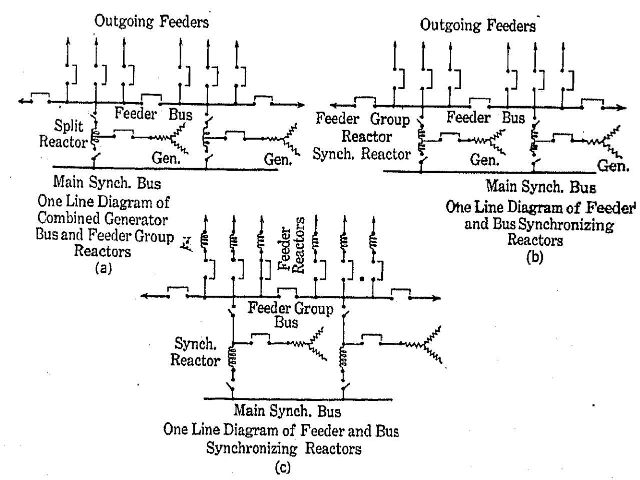

FIG. 17

generators, feeder, bus tie, station tie, synchronizing, equalizing reactors, etc., as the case might be. The refinement might be carried on still further, in the form of some of the various combinations of the above-named reactors, Figs. 16 and 17 indicate some of the most frequently used reactor connections. However, all these combinations affect only the numerical values of the reactors as to ratings, current-carrying capacities,

annual efficiencies, investment costs, short-circuit stresses, etc., and have nothing to do with the typical characteristics of the installations or that of the reactors.

Short Circuit Stresses

In three-phase systems a number of short circuits may occur, from which several may stress the reactor

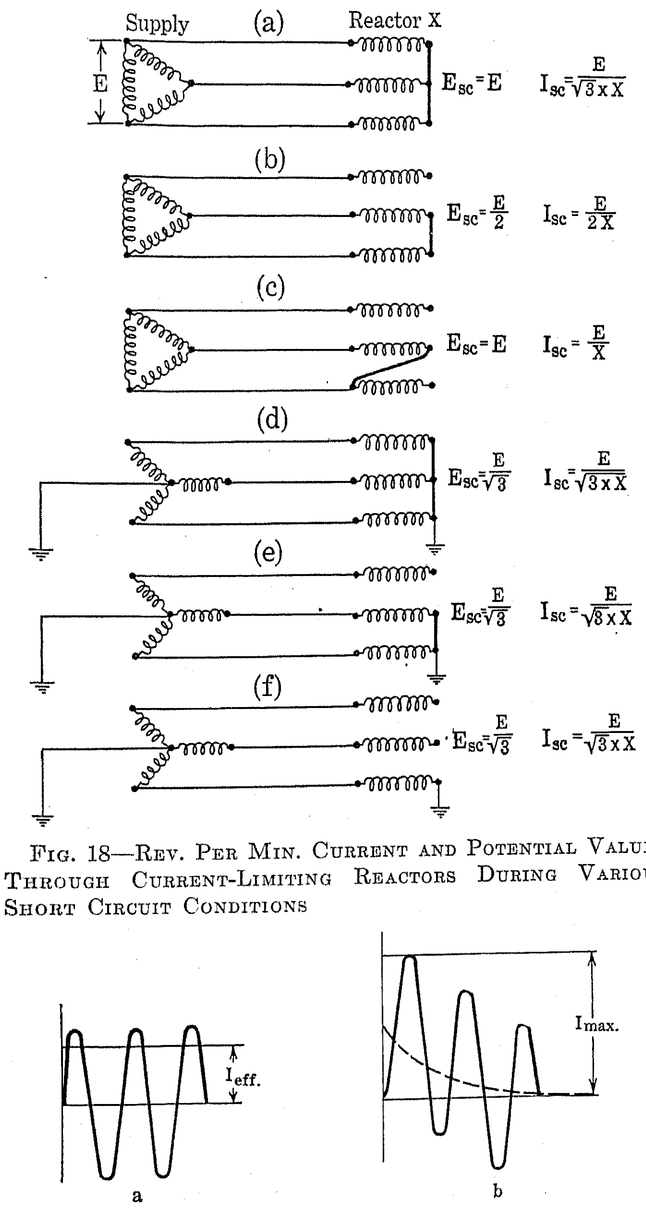

Fig. 18—Rev. Per Min. Current and Potential Values Through Current-Limiting Reactors During Various Short Circuit Conditions

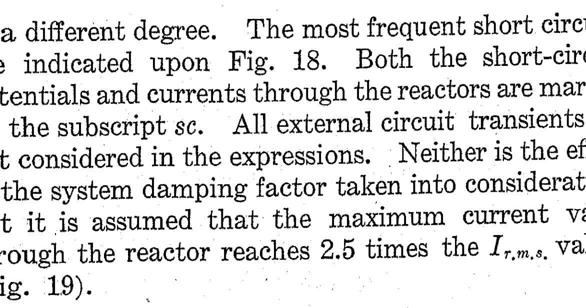

Fig. 19

to a different degree. The most frequent short circuits are indicated upon Fig. 18. Both the short-circuit potentials and currents through the reactors are marked by the subscript *sc*. All external circuit transients are not considered in the expressions. Neither is the effect of the system damping factor taken into consideration, but it is assumed that the maximum current value through the reactor reaches 2.5 times the $I_{r.m.s.}$ values (Fig. 19).

During short circuits there are three different stresses acting upon a reactor, namely:

(a) Thermal
(b) Mechanical (Electromagnetic)
(c) Electrical (Electrostatic)

The above three stresses may act simultaneously. Any one of these may be the predominating factor and thus affect the severity of the combined stresses upon the reactor.

(*a*) *Thermal Stresses.* Due to the inherent conductor resistance of the reactors, there is a heat generation in the coil, which forces the conductor continually to expand or to contract. This shape change takes place, of course, both in axial as well as in radial direction of the conductor cross section. During normal operation, this heat generation expressed in kilowatts is usually very small, hardly more than two to four per cent of the reactor rating. However, during short-circuit stresses, this heat generation increases as the squares of the current ratios increase. Expressing this as a function of the per cent of the coil reactance

$$W_{sc} = (2.5\, I\, 100/\%)^2\, R_{eff}. \tag{11}$$

where I = normal full load current (r. m. s.)

R_{eff} = resistance of the conductor just prior to the short circuit, (a-c. resistance).

Thus during a short circuit with five per cent reactance, the heat generation in a reactor will be about 400 times the normal $I^2 R$ value, with three per cent reactance 1110 times the normal value, etc. This heat generation causes the conductor to expand rapidly. Assuming that a reactor conductor at 15 deg. cent. has a length of 425 ft., and limiting the maximum ultimate short-circuit temperature to 150 deg. cent., the length of this conductor, according to the Stephan values, will be

$$l\,t = 425\left(\frac{1 + 135 \times 161}{10^7} + \frac{135^2 \times 403}{10}\right) = 426.24 \text{ ft.}$$

that is, during a two-second short-circuit time lapse, the conductor length increases about 14¾ in. Unless all conductor supporting arms yield evenly under such a sudden creeping stress, it might happen that between two adjacent supports or braces, there will be an accumulation of the linear expansion.

This seems to be a rather reasonable anticipation in time and is caused usually by the repeated heating and cooling of the conductor upon the supporting anchorages which loose their grip upon the conductor. Such a defect will cause considerable buckling of the conductor between two or more supports. The buckling alone, perhaps, would not be serious enough to endanger the proper functioning of the reactor, providing the conductor spacing is large enough or the insulation sufficient to prevent internal short circuits between layers or turns. However, such a buckled turn section is also under the influence of the magnetic attraction or repulsion of the layers and turns of its surrounding. The magnetic stress manifests itself during each half cycle

from zero to maximum in the form of a vehement vibration of the conductor. Furthermore, during the short-circuit time lapse, the conductor temperature increases rapidly. At or around 300 deg. cent. the strength of the copper decreases some 20 to 30 per cent. The elongation shrinks from 55 per cent at 0 deg. cent. to 40 per cent at 300 deg. cent. and the metal becomes brittle. Thus a condition will be easily created and a failure caused which has to be attributed to the combination of the thermal and magnetic stresses at a critical point in the reactor winding.

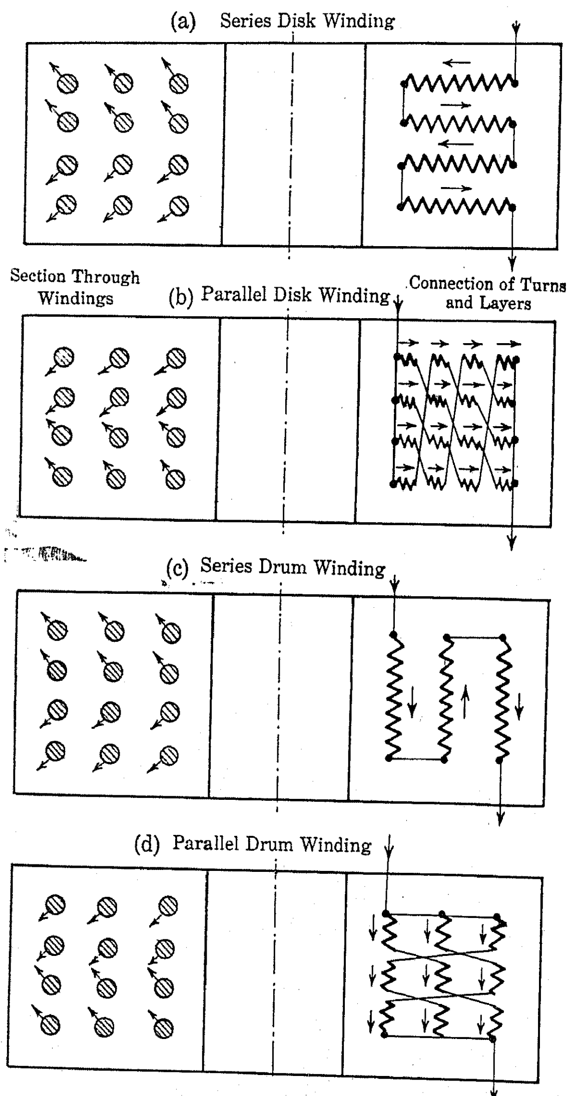

Fig. 20—Mechanical Forces Acting Upon a Reactor Conductor Due to the Main and Leakage Flux

(b) *Mechanical Stresses.* Under normal operating conditions the mechanical forces acting within a reactor winding are negligible. During short circuits, however, these forces increase to extremely high values. The internal forces act in a radial as well as axial direction of the winding. The radial forces are due to the tendency of each turn to place itself into the neutral flux zone, that is, farthest from its own magnetic center. The force subjects the conductor turn to a tensile stress. The axial forces within the reactor are due to the attraction or repulsion between the various layers, turns and the unsymmetrical end effects. Whether the forces are attractive or repulsive, depends upon the interconnections between turns or layers and upon the current distribution throughout the winding.

In Fig. 20, four different connection methods are shown with their force directions indicated by the arrows. There are several other possible connections for which the resultant forces may vary somewhat. Thus the winding supporting structure must be designed to suit in some cases tensile stresses which tend to disrupt the arrangement, whereas in other cases the predominant forces subject the housing to compression. An exact mathematical solution for the various reactor internal stresses is not available. Several approximations have been offered for the solution of the problem. Such a method derived from the combinations of several familiar expressions is offered below. The formula is based upon the assumption, that the entire inductance of the winding is concentrated in one center turn, having a as its mean diameter. The constant in the formula assumes a shape factor a: b: c: = 8: 6: 1 and if used within the Stefan formula, y_1, and y_2, constant ranges gives results about eight per cent high.

If x = total reactance of reactor in ohms
f = frequency
a = mean radius in inches
I = short-circuit current in amperes.

Then force F in lb. $= \dfrac{1.2 \times X}{f \times a} \times I^2$ (12)

Assuming an internal reactor connection method as per Fig. 20B, a maximum short-circuit current of 14,000 amperes and a current-limiting reactor of the following characteristics:

11 layers in parallel
61 turns in series
0.5 ohms reactance on 25 cycles.
11.5″ mean radius

Then F per layer $= \dfrac{1.2 \times 0.5}{25 \times 11.5} \times (14{,}000^2/11) = 3370$ lb.

If the maximum unsupported conductor length is 8 in. and the turn section modulus in a radial direction is 0.0013, then the tensile stress, per square inch for each turn section

$$= \frac{3370 \times 8}{0.0013 \times 61 \times 72.2} = 4692 \text{ lb.}$$

(c) *Electrical Stresses.* During normal frequencies the electrostatic stresses, due to the small internal capacity of the reactor, are negligible. If the frequency is considerably increased, it might happen that the air core reactor, which is an almost ideal inductance, becomes a pure condenser and discharges between turns and layers. The simplest case of this phenomena is a

single-layer series winding. In such a winding, each turn acts in regard to the next one as a condenser. The successive charges gradually increase toward the end turns. If anywhere in the arrangement the dielectric strength between turns varies, if the potential is high enough or the wave steep enough at that point, a discharge may occur.

In multilayer series or parallel windings the electrostatic field distribution is not so simple. In such a coil, besides each turn, each layer has also a charge in regard to its neighbor. Their values are different between different layers and between layers and ground. As in all high-frequency phenomena, the reactor is no exception in its inconsistent actions. Much research has to be done, before entirely reliable practical data will be available. In the meanwhile, such high-frequency oscillations like lightning should be deflected from a system before it can do damage anywhere. If a lightning arrester cannot do this, a reactor certainly will not do it.

Nevertheless a number of well understood conditions can be created within the reactor windings, by which the unequal electrostatic stresses are considerably reduced or equalized. Well selected transpositions lower considerably the critical points between layers. Dielectrics with even and permanent characteristics which are used between turns or layers, will invariably reduce the stresses. High-potential high-frequency tests, faithfully made, will always detect any weakness in the design or in the coil construction.

Discussion

For discussion of this paper see page 940.

Current-Limiting Reactors

Their Design, Installation and Operation

BY F. H. KIERSTEAD and H. O. STEPHENS
Associate, A. I. E. E. Associate, A. I. E. E.
Both of General Electric Co., Pittsfield, Mass.

Review of the Subject.—*The essential features in the design, installation and operation of current-limiting reactors are pointed out. The application of reactors to different circuits is not treated because a number of good papers dealing with this subject has been presented at Institute meetings.*

Design.—*A current-limiting reactor should have low reactance at low currents and high reactance at high currents. Such a reactor has been developed and is known as the "saturated core" reactor. It has not been used as yet for current-limiting protection to any extent. A reactor having an iron core and only an a-c. winding gives a drooping voltage-ampere characteristic and, therefore, is not suitable for current-limiting protection. Reactors with air cores have straight line volt-ampere characteristics and, therefore, are well adapted for this protection.*

Since the only function of current-limiting reactors is to limit the current during short circuits to safe values, they should be capable of performing this function when other apparatus is being destroyed, due to excessive current. For this reason, heat resisting materials should be used for holding and insulating the conductor of a reactor. A useful formula is given for determining short-circuit temperature rises.

A current-limiting reactor functions as such only when there are short circuits on the system. Short circuits are almost sure to be preceded or accompanied by voltage disturbances of abnormal value. Therefore, the insulation factor of safety in a reactor should be relatively high.

Reactors with shunting resistors give to the system in which they are placed, the protection from over-voltage that the resistors afford and are, therefore, to be recommended.

Reactors are subjected to internal magnetic forces due to the current in the reactor itself and to external magnetic force due to the field between adjacent reactors. A method is given for calculating the magnitude and direction of the internal forces. Tests show that the peak magnetic force should be used in calculating the strength of the conductor.

The direction of the external forces is discussed and reference is made to H. B. Dwight's formulas for calculating their magnitude. Tests show that the stresses on the members which support the reactor against the external forces depend in a decisive way upon the ratio of the mechanical frequency to the electrical frequency.

Installation.—*The installation of reactors is considered from the following view points.*

I. Arrangement.
II. Compartments.
III. Bracing and Securing in Place.
IV. Support of the Leads.
V. Ventilation.

Operation.—*In general, reactors require very little attention in service, but no effort should be spared to keep them free from foreign conducting material. Loose magnetic material such as nails, etc., are particularly dangerous because the magnetic field of the reactor during a short circuit will pick up nails at quite a distance from the reactor and draw them into the winding. Tests show that such foreign material lodged in the winding causes the reactor to instantly arc over during a short circuit.*

It is the purpose of this paper to point out the essential features in the design, installation and operation of current-limiting reactors. The application of reactors to different circuits is not treated, since a number of good papers dealing with this subject have been presented at Institute meetings.

Design

Under this heading the fundamental conditions in the design of reactors for satisfactory and reliable service will be considered. These conditions are as follows:

I —Straight Line Volt-Ampere Characteristics
II —Liberal Thermal Capacity
III—Insulation Strength Should be High Since a Reactor is a Protective Device
IV—High Mechanical Strength
V —Most Economical Losses

In order to show why these characteristics are essential, we have considered the design of reactors from each of these five points of view.

I—Straight Line Volt-Ampere Characteristics

High efficiency and good regulation require current-limiting reactors to have as low reactive drop as possible when normal current is flowing. Good short-circuit current control, on the other hand, demands the maximum reactive drop possible.

A reactor having low reactance at low currents and high reactance at high currents would meet these conditions. Such a reactor has been developed and is known as the "saturated core" reactor.[1] It has an a-c. and a d-c. winding on an iron core. Normally the d-c. ampere turns are so large compared with the a-c. that the core is saturated with a d-c. flux and the normal a-c. ampere turns have no appreciable effect in changing the core density. For this reason, the reactance at all currents up to normal rated current is negligible. At high currents the a-c. ampere turns begin to have an appreciable effect on the core density and the reactance of the reactor increases very rapidly. Such reactors, however, are in the developmental stage, and as yet have not been used for current-limiting protection to any extent.

A reactor having an iron magnetic circuit and only an a-c. winding gives a drooping volt-ampere character-

· *Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.*

1. See A. I. E. E. paper by Boyajian on "Theory of D-C. Excitation of Reactors and Regulators" and A. I. E. E. paper by Blake on "Application of Saturated Core Reactors and Regulators."

istic due to saturation of the iron and, therefore, is not suitable for current-limiting protection. For example, the magnetic flux in a 5 per cent reactor must increase 20 times normal at short circuit, if the flux wave is symmetrical, and 40 times if it is assymmetrical. The flux wave will be assymmetrical if the short circuit occurs when the voltage wave is passing through zero. If the flux density in the core was 500 lines per sq. cm. at normal current (a ridiculously low value), then at short circuit with assymmetrical current the flux density would have to increase to 20,000 lines per sq. cm. Therefore, the reactance in ohms introduced in the circuit by an iron core reactor would be very much lower at short-circuit current than at normal current and to limit the short-circuit current to a particular value would require a much greater reactance at normal current than a reactor having a straight line characteristic. For this reason, iron core reactors have not been used to any extent for short-circuit protection.

Reactors with air magnetic circuits have constant reactance for any current and for this reason are well adapted for current limiting protection.

II. Liberal Thermal Capacity

Since the only function of current-limiting reactors

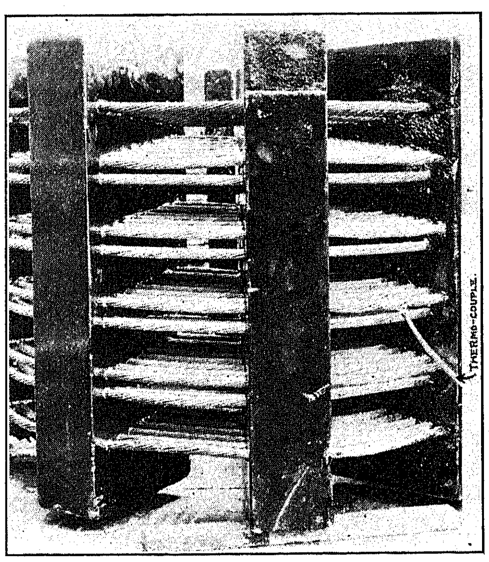

Fig. 1—Reactor after Having Been Subjected to a Temperature of 725 Deg. Cent. Resulting from Short Circuit.

is to limit the current during short circuits to safe values, they should be capable of satisfactorily performing this function when all the other apparatus in the circuit is being destroyed due to the excessive current. As long as the reactor is operative, the short circuit is limited to a single circuit, but if the reactor fails due to a prolonged short circuit, the whole station may become involved. Of course, it would be impracticable to build all reactors with sufficient thermal capacity to withstand a short circuit for an indefinite length of time and it is the duty of the operator to clear the circuit within a reasonable time. On the other hand every effort should be made to use heat-resisting material for supporting and insulating the conductor of the reactor. If this is done, the temperature of the conductor may be carried nearly to the melting point during short circuits without failure. Fig. 1 shows a reactor on which a short-circuit test was continued until the conductor reached a temperature of 725 deg. cent. The reactor was uninjured by this test and was fully

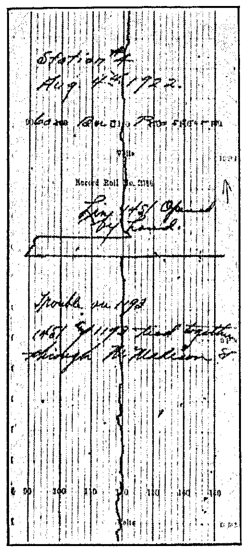

Fig. 2—Record of Bus Bar Voltage Showing 6-Min. Short Circuit

operative. This shows the value of heat-resisting supports.

A number of reports of long continued short circuits have been received. Among these reports is one from a large central station describing a six-minute short circuit on a 0.5-ohm reactor in a 12,000-volt feeder. Fig. 2 gives the record of the station bus voltage during this interval. The duration of the drop in voltage indicates the time during which the feeder was short-circuited. This reactor is still in service. Other reports simply give additional instances where the heat-resisting supports had enabled the reactor to function through a long continued short circuit. Actual experience with reactors in service for many years has proven beyond doubt that the supports which hold the conductor should be heat-resisting.

The size of the conductor to be used in a reactor may depend on the heating at normal load or during short circuit, or again it may be determined by the maximum permissible losses.

The temperature limits depend on the materials in contact with the conductor. With organic material there is always the danger of carbonization at the hot inaccessible spots during operation and during short circuits this danger becomes more imminent. Furthermore, there are usually no indications of such carboni-

zation until it has caused a failure. With inorganic material this danger does not exist and higher temperatures may be permitted.

In 1914 when the first cast-in-concrete reactors were being built, there was some doubt as to what should be the limiting temperatures. Tests indicated that very high temperatures would be safe but the conservative practise of 125 deg. cent. for the limiting temperature at normal current and 350 deg. cent. at short circuit was adopted. In determining short-circuit temperatures, it is assumed that the full voltage is maintained across the reactor and that all of the heat is stored in the conductor during the specified duration of the short circuit. Since that time there have been many indications that these reactors could be safely operated at higher temperatures and no indications that these temperatures are too high. However, these conservative limits are being maintained.

The following is a useful formula for determining the short-circuit temperature rise, assuming that all of the heat is stored in the conductor.

$$T = \frac{1}{\dfrac{92 \times A^2 \times 10^6}{K\,(1 + \theta \times .00427)\,t\,I^2} - \dfrac{1}{2\,(234.5 + \theta)}}$$

where,

T is the short-circuit temperature rise in degrees cent.
A is the cross section of conductor in sq. in.

K is the eddy current factor $= \dfrac{\text{Total copper losses}}{I^2 R}$

θ is the initial temperature
t is the time in seconds
I is the short-circuit current in amperes

The maximum anticipated time required to clear a short circuit should be given by the purchaser in his specifications, since he has the necessary data on the time settings of the relays which open the circuit. Where these data are not given, it is customary to design the reactor to stand full short-circuit current for at least three seconds.

III. Insulation Strength Should be High Since a Reactor is a Protective Device

A current-limiting reactor functions as such only when there are short circuits on the system. Short circuits are almost sure to be preceded or accompanied by voltage disturbances of abnormal value. Therefore, the insulation factor of safety in the reactor should be relatively high.

The reactor is a point of reflection for steep front waves and thus doubles any such wave that strikes it. It is, therefore, to be expected that nearly double line voltage will appear between the reactor and ground and across the reactor terminals during sudden changes in the system as when switching or during a disturbance such as a flashover of an insulator. Voltages of this order are an every-day occurrence. On more rare occasions voltages of more than double line voltage may be reflected from the reactor, as for instance, when there has been a disturbance which has resulted in a wave of more than line voltage being sent out toward the reactor. If, when this wave reaches the reactor its value is still more than line voltage, then it will be reflected with a value of more than double line voltage. Tests have proven that steep front impulses are rapidly damped out, so that unless such a disturbance happens near a reactor its wave will be considerably reduced before it reaches the reactor. This is especially true of underground cables since their insulation losses very rapidly damp out impulses. Therefore, it should be exceptional for voltage impulses higher than double line voltage to be reflected from reactors in underground cable systems.

On overhead lines lightning disturbances may cause impulse voltages on the lines as high as the line insulators or the lightning arresters will permit. Such disturbances may be reflected by the reactor at double their initial value. During such disturbances the voltage from the reactor to ground and across its terminals is liable to reach any value which the line insulators or the lightning arresters will permit.

Resonance between two circuits, one containing high electrostatic capacity and low inductance and the other containing low electrostatic capacity and high inductance, may cause high voltages to be built up not only across reactors but also from the line to ground. Authorities differ as to the magnitude of these voltages. In laboratory tests high voltages are obtainable. In tests on a large underground cable system 36 per cent over-voltage was observed with circuits considerably out of resonance. On account of operating conditions the investigation had to be discontinued before tests could be made with the circuits in resonance. This subject should be investigated more thoroughly because of its bearing on central station disturbances.

Operating experience with cast-in concrete reactors with liberal spacing and low voltage between adjacent layers and turns has indicated that voltages high enough to cause flash-over have not been obtained. On the other hand, a very high voltage is required to flash over these reactors. For instance, a reactor for a 13,200-volt circuit requires 60,000 volts to arc over the insulators to ground and 100,000 volts at high frequency to flash over the winding. In other words, this experience has simply indicated that voltages higher than the above have not been experienced.

Formerly, it was believed that some of the early failures of reactors were due to over-voltage, but later investigations using an especially constructed short-circuit testing generator proved conclusively that these failures were due to magnetic forces causing adjacent turns to touch. These tests practically eliminated any apprehension of reactor trouble due to excessive voltages.

The voltage concentration at the end turns and end layers in reactors due to steep front waves is very much

less than in transformers, because the series capacity (that is, the capacity between turns and layers) is so much greater than the capacity of the reactor to ground.[2] In tests on reactors with steep front waves 29 per cent of the voltage of the initial wave has been observed between the first and second layers of the reactor and 10 per cent between the first and second turns.[3]

The conclusions to be drawn from these investigations of the transient voltages that reactors may have to stand, is that these voltages may be as high as the weakest insulation or the lightning arrester setting will permit, and the reactor should have a reasonable factor of safety above these limits.

Reactors with shunting resistors give to the system in which they are placed the protection from over-voltage that the resistors afford and are, therefore, to be recommended. Shunting resistors also reduce the transient voltages on the reactor and conceivably it would be permissible to reduce the insulation of such reactors, but this practise has not been recommended.

The reasons for the use of resistors shunting reactors are two-fold. First, resistors protect a circuit by absorbing the energy which would cause high voltages. Such energy is always of higher frequency than the generated frequency and, therefore, piles up high voltages across reactors. If these reactors are shunted by resistors this voltage is applied to the resistors and the high frequency energy is absorbed. On the other hand, under normal conditions the voltage across the reactor, and therefore across the resistor, is very small and little energy is absorbed. A resistor shunting a reactor is, therefore, selective in its operation, absorbing a negligible amount of useful energy but absorbing a high percentage of destructive energy. Second, when reactors are placed in all the feeders from a central station, any disturbance originating in the station (as in switching) is prevented by the reactors from passing freely out in the lines where it may be dissipated, but if each reactor is shunted by a resistor, each furnishes a path for the escape of the disturbance into the feeders.

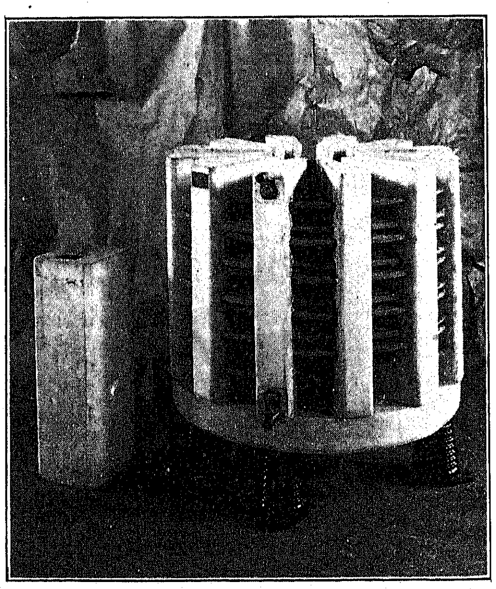

Fig. 3—Reactor with Resistor Removed

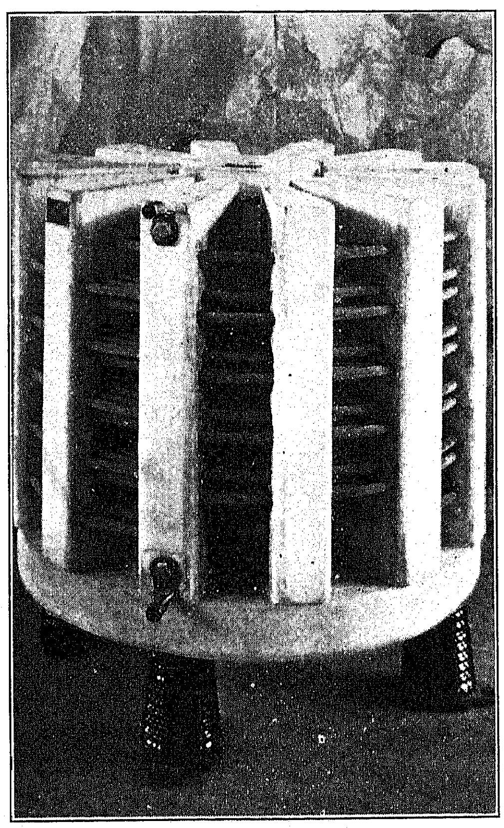

Fig. 4—Reactor with Resistor Assembled

The resistor is assembled in the center of the reactor so that no additional space is required. Fig. 3 shows a reactor and its resistor and Fig. 4 shows the same reactor with its resistor assembled.

IV. High Mechanical Strength

Reactors are subjected to magnetic forces due to the current in the reactor itself, which we will call internal forces, and to magnetic forces due to the field between adjacent reactors, which we will call external forces.

a. Internal Forces. The direction and relative magnitude of the internal forces are shown in Fig. 5. It will be noted that they are in a direction to place the supports for the conductor in compression and most of the turns of the conductor itself in tension.

In order to calculate the strength of a reactor to withstand these internal forces, it is necessary to determine the turn that is most liable to fail, which we will call the critical turn. The magnetic force on this turn

2. A paper by Blume and Boyajian entitled "Abnormal Voltages within Transformers" published in the A. I. E. E. Trans. 1919, page 577 gives the reasons.

3. See paper by Kierstead and Meeker entitled "Voltage Stresses in Reactors," A. I. E. E. Trans. 1920, page 1289.

and its ability to withstand this force should be calculated. The force on the critical turn is determined by summing up the forces of each individual turn upon it. This is most conveniently done by determining separately the arithmetical sum of the axial and radial forces and combining these results vectorially, which gives the resultant force on the critical turn both in magnitude and direction. Where the turns are all equally and symmetrically placed, this summation can be obtained by integration, but in the type of reactor shown in Fig. 5, this integration becomes too involved and it is more convenient to calculate the forces separately and record the results in curves and tabulations suitable for the particular type of reactor. The following formulas, derived from Maxwell's equation for the mutual inductances between circles, are convenient and accurate for calculating the axial and radial forces between two turns

$$P_1 = 4.5 \times 10^{-8} \times \frac{Z}{A} \times \frac{1}{\sqrt{(a+A)^2 + Z^2}} \times \left[\frac{a^2 + A^2 + Z^2}{(a-A)^2 + Z^2} E - F \right]$$

$$P_2 = 4.5 \times 10^{-8} \times \frac{1}{\sqrt{(a+A)^2 + Z^2}} \times \left[\frac{a^2 - A^2 - Z^2}{(a-A)^2 + Z^2} E + F \right]$$

where,

P_1 and P_2 are respectively the axial and radial forces in pounds per ampere per inch length of the conductor.

A is the radius of the larger circle in inches

a is the radius of the smaller circle in inches

Z is the distance between the planes of the circles in inches.

F and E are the complete elliptic integrals of the first and second kind, respectively, to modulus

$$k = \frac{2\sqrt{aA}}{\sqrt{(a+A)^2 + Z^2}}.$$

Their value may be obtained from Table XII and XIII in the Appendix of Bulletin of the Bureau of Standards, Vol. 8, No. 1 (Scientific Papers No. 169).

Referring to Fig. 5, it will be noted that the inner turns are subjected to the greatest forces. However, they are not the critical turns because the span of these turns between supports is much less than that of the outside turns, and the force is in such a direction as to place the conductor in tension. While the force on an outside turn is less, the greater span between supports, coupled with the fact that the direction of the force is such as to cause the turn to slacken, makes the turn much less capable of resisting it. If all the turns were symmetrically placed, the outside top and bottom turns would be the critical turns, but in the type of reactor shown in Fig. 5, due to the converging of the layers of turns, the outside turn in the second layer from the top and the second layer from the bottom are the critical turns. Fig. 6 shows the critical turn of a reactor just starting to bend under a short-circuit test to determine the effect of these forces.

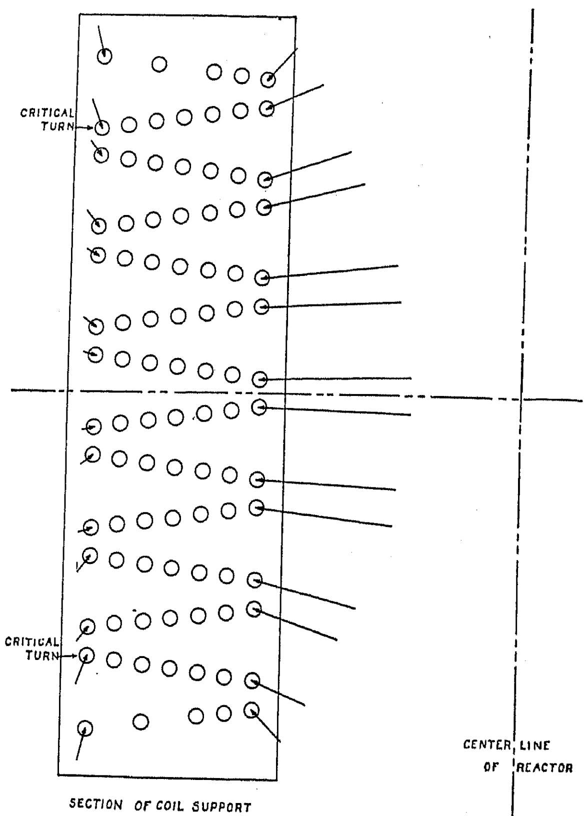

Fig. 5—Direction and Relative Magnitude of Internal Forces in a Reactor

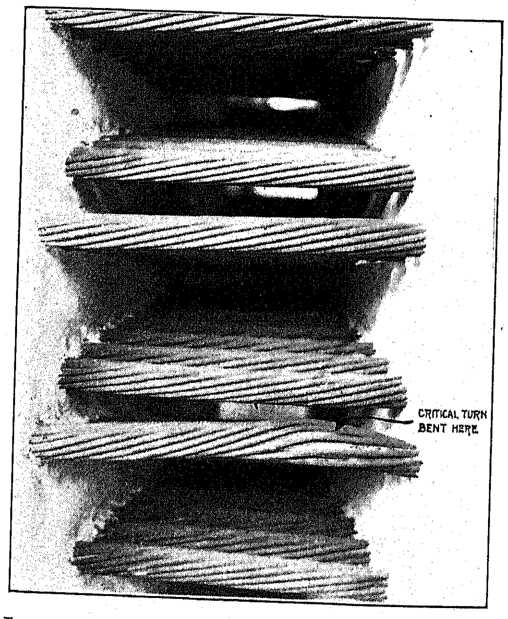

Fig. 6—Illustrating Bending of Critical Turn of Reactor by Magnetic Force during Short Circuit

Investigation of these forces has shown that the force on the critical turn in some ratings of reactors

may be as great as 300 lb. per inch of length of conductor. Such a reactor with a critical turn of 32 in. diameter would have a total force on the turn of 30,000 lb. When it is realized that this is only the force on one turn of a reactor, and at that, not the turn with the maximum force, an idea is obtained of the tremendous forces that reactor supports must withstand.

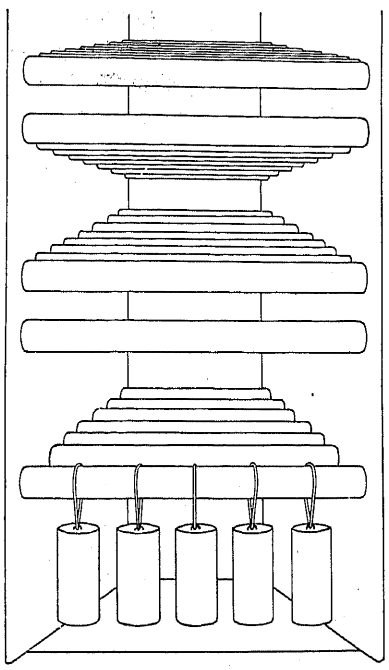

FIG. 7—METHOD OF APPLYING FORCE TO TEST STRENGTH OF TURNS

In order to measure the strength of the conductor to withstand magnetic forces, weights were applied to the conductor as shown in Fig. 7 and the deflection was measured for different weights.

With an accurate method of calculating the forces and with data for determining the strength of the turns,

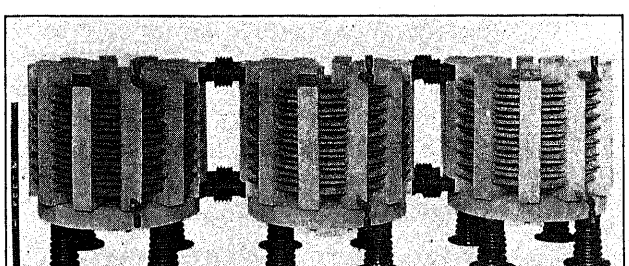

FIG. 8—SET OF THREE-PHASE REACTORS PLACED WITH AXES PARALLEL WITH BRACES BETWEEN PHASES

the ability of a reactor to withstand a steady magnetic force could be determined. It was necessary, however, to test reactors under short circuits up to destruction to determine their strength under the suddenly applied force of a short circuit. The results of these tests proved that the peak magnetic force and not the average should be used in calculating the strength of the conductors.

b. External Force. When reactors which are wound in the same direction are placed with their axes parallel as in Fig. 8, the magnetic forces will be attractive if the current in the one flows in the opposite direction to the current in the other, and repulsive if the currents are in the same direction. If they are mounted coaxially as in Fig. 9, the direction of the forces will be just the reverse. Therefore, the direction of the forces between similar reactors with their axes parallel will be attractive if the reactors are all connected symmetrically, and repulsive if the connection to the middle phase is reversed to that of the other phases. If the reactors are placed coaxially, the direction of the forces will be repulsive if symmetrically connected, and attractive if the middle phase is reversed.

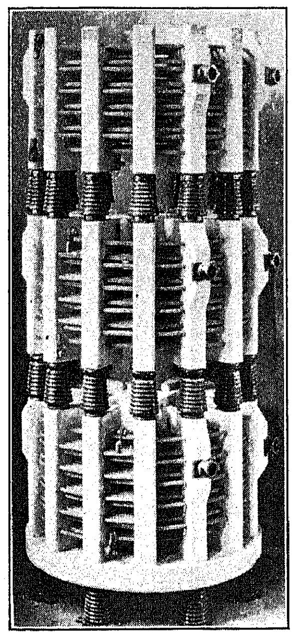

FIG. 9—SET OF THREE-PHASE REACTORS PLACED COAXIALLY WITH PROVISION FOR BRACING AGAINST WALL OF COMPARTMENT

The magnitude of the force between adjacent reactors of a three-phase circuit is greater during single-phase short circuits than it is during three-phase short circuits, (although the single-phase short-circuit current is only 86.6 per cent of the three-phase current) and, therefore, stresses caused by these forces should be based on single-phase short circuits. Forces due to single-phase short circuits are higher because the fluxes from adjacent reactors are in phase or 180 deg. out of phase during single-phase short circuits, while they are 120 deg. or 60 deg. out of phase during three-phase short circuits.

Forces of considerable magnitude may occur between adjacent reactors in different circuits as well as between adjacent reactors in the same circuit. A good example of this is where two feeders in parallel feed the same substation. A failure of either feeder results in a short

circuit on both, and if the failure occurs near the substation, then the current flowing in the two feeders will be approximately equal. If the reactors in these two feeders are adjacent they will exert a magnetic force upon each other. These forces will be greater if the adjacent reactors are connected to the same phase, since the currents will be in phase during either three-phase or single-phase short circuits. If the adjacent reactors are connected to different phases, the forces will have

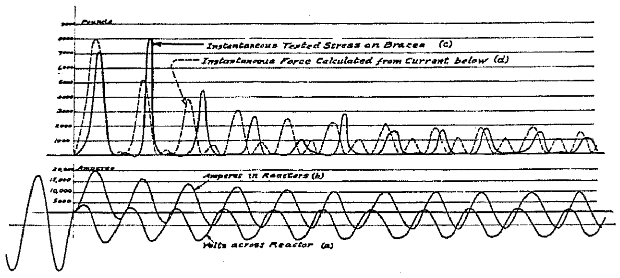

FIG. 10—OSCILLOGRAPHIC RECORD OF SHORT-CIRCUIT TEST TO DETERMINE FORCES BETWEEN ADJACENT REACTORS AND STRESSES ON BRACES

the same value as is the case of reactors connected in the same circuit. The resulting forces will be 33 per cent. greater if the reactors are in the same phase than if they are in different phases. It must be remembered, however, that with two feeders in parallel short-circuited, the current in each reactor will not be as great as it would be if only one feeder was short-circuited, since the station bus voltage will drop more with the

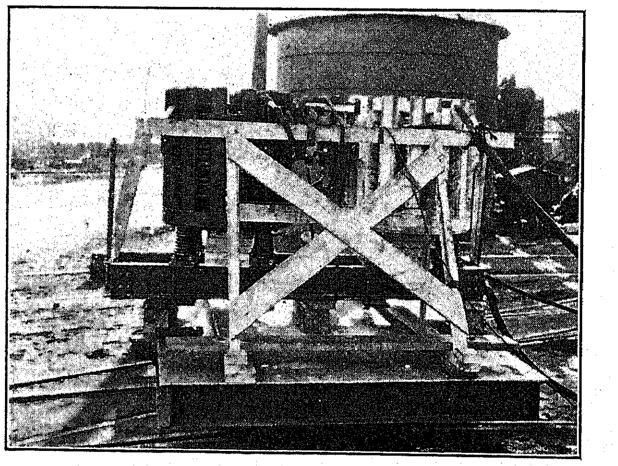

FIG. 11—SET-UP OF REACTORS FOR SHORT-CIRCUIT TESTS RECORDED IN FIG. 10

two feeders short-circuited than with one. The reactance of the feeders out to a substation would further reduce the current. Therefore, it is probable that the forces between adjacent reactors in different feeders never will be as great as those between adjacent reactors in the same circuit.

Formulas for the calculation of the forces between reactors placed coaxially[4] and with their axes parallel[5] have been given by H. B. Dwight. These formulas have been checked and found to give good agreement with tests and, therefore, the method of calculation of these forces is not being given here.

With the formulas developed, the calculation of these forces is a simple problem. However, it is a more difficult problem to determine the stresses on the members which support the reactor against this force, for the reason that it varies with time after short-circuit in a very complicated manner, as shown on Curve c, Fig. 10. Curves a, b, and c have been reproduced from an oscillogram taken during a short-circuit test in an investigation to determine these stresses, while Curve d is a calculated curve. Fig. 11 shows the set-up of the apparatus for these tests. The tests consisted in exciting a 25-cycle 27,000-kv-a. generator for 13,200 volts, then throwing a switch which short-circuited two reactors connected in series across two of the terminals of the generator and measuring the voltage across the reactors, current in the reactors and the forces on the

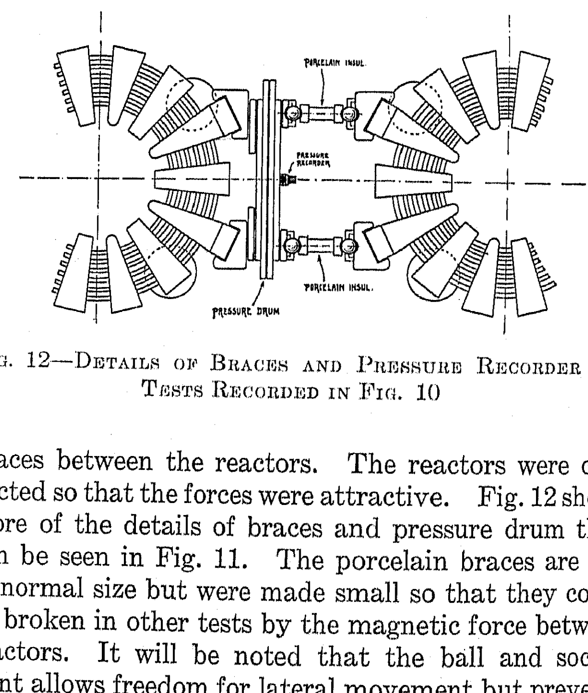

FIG. 12—DETAILS OF BRACES AND PRESSURE RECORDER FOR TESTS RECORDED IN FIG. 10

braces between the reactors. The reactors were connected so that the forces were attractive. Fig. 12 shows more of the details of braces and pressure drum than can be seen in Fig. 11. The porcelain braces are not of normal size but were made small so that they could be broken in other tests by the magnetic force between reactors. It will be noted that the ball and socket joint allows freedom for lateral movement but prevents lengthwise motion. The wooden structure around the reactors was intended to prevent the reactor falling when tests were made to determine the magnetic force necessary to break the porcelain supports and braces.

Curve a Fig. 10 gives the voltage across the reactors, Curve b gives the current in the reactors and Curve c gives the pressure exerted upon the braces by the magnetic force. Curve d was obtained from Curve b by multiplying the square of the current at any instant by the force constant. This curve thus gives the mag-

4. "Repulsion and Mutual Inductance of Reactance Coils with the Same Axis" by H. B. Dwight, *El. Journal* 1918, page 166.

5. "Some new Formulas for Reactance Coils" by H. B. Dwight, TRANS. A. I. E. E. 1919, page 1675.

netic force exerted by the reactor at any instant while Curve *c* gives the stress placed upon the braces by this force. Attention is called to the fact that the instrument which measured the pressure on the braces was not equipped to measure any tension that may have been placed upon them by the oscillation of the reactors.

It will be noted that while the first peak of pressure on the braces is almost as high as the first peak of the magnetic force, the second peak of pressure is higher than the highest peak of force. Thus, it is shown that not only is it not safe to use the average magnetic force in calculating the stresses on the braces but it is not even safe to use the peak force.

In order to determine the stresses on the supporting insulators with no braces, similar short-circuit tests were made with the supporting insulators bolted down to the frame work but with no braces between the reactors. The tests were started at low current and the current was gradually increased until the insulators were broken. The tests were repeated until sufficient insulators were broken to obtain a good average of the force required to break them. It was then desired to compare this with a steady force applied at the same points of the reactors. Therefore, a calibrated spring was placed between the reactors in such a manner that by screwing up bolts a known force tending to draw the reactors together was applied. The set-up for these tests is shown in Fig. 13. Sufficient insulators were broken so that a good average of the steady force required to break them was obtained. The result of these tests showed that the peak magnetic force (calculated from the observed current) was 2.5 times the steady force required to break the insulators and, therefore, indicates that the average magnetic force is more nearly the correct force to use in calculating the stresses on the supporting insulators when no braces are used.

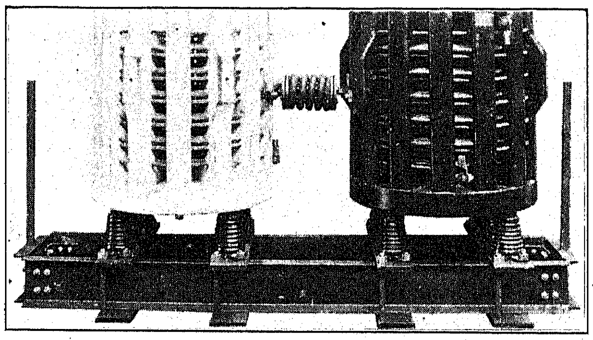

Fig. 13—Method of Applying a Steady Force between Reactors to Determine the Strength of the Supporting Insulators. The Spring was Calibrated and a Known Force Applied Tending to Draw the Reactors Together

The difference between these two sets of tests consists chiefly in the fact that the mechanical frequency of the reactors was changed. In the first set of tests the mechanical frequency was close enough to the electrical frequency so that partial resonance occurred and the pressure on the braces was greater than the peak force. In the second set of tests, the mechanical frequency was naturally very much reduced by the removal of the braces and the inertia of the reactor effectively smoothed out the sharp peaks of the magnetic force thereby materially decreasing the stress on the supporting insulators.

In a paper[6] presented at the Spring Convention last year by Doherty and Kierstead entitled "Short-Circuit Forces on Reactor Supports" the following statement was made. "If a reactor is not held rigidly against all motion, the maximum force on the holding device will depend in a decisive way upon the ratio of the frequency n of natural oscillation to the electrical frequency f." Although the investigation is not completed the results of these tests are given here because they are experimental proof of the accuracy of the conclusions reached in the paper mentioned.

The following data on the reactors tested are given for the benefit of those who may be interested in checking up their mathematical calculations of forces with these tests.

Weight of Reactors	1550 lb.
Force between reactors at one ampere	2×10^{-5} lb.
Force required to decrease distance between reactors 0.0625 in.	
(a) with braces assembled	20,000 lb.
(b) without braces	1100 lb.
Electrical frequency	25 cycles
Pressure between reactors with no magnetic force applied	0

Since the forces between reactors vary with their shape, dimensions, distance between centers and their short-circuit ampere turns, it follows that these forces vary tremendously with different reactors. Peak forces as high as 33,000 lb. have come to the authors' attention. In the average feeder reactor this force is not over 10,000 lbs.

Because of the great force placed upon reactors, both internal and external, they require a construction of very high mechanical strength.

V. Most Economical Losses

It is generally possible to reduce materially the losses in a given reactor by using larger conductors or more conductors in multiple. While this results in greater first cost, the ultimate cost may be less on account of the reduced operating expense. Fig. 14 indicates how the most economical value of losses may be reached. In order for the manufacturer to determine this value, the following data should be available.

1. Cost per kw. hour of supplying losses.
2. The root mean square current in the circuit for an entire year.
3. The investment charge in per cent.

From the first two items the total yearly cost of supplying the losses in a given reactor can be calcu-

6. See Journal A. I. E. E., August, 1923.

lated and the operating expense curve obtained. From the last item, the investment expense curve can be calculated. The total expense curve is obtained from the sum of the ordinates of the other two. The most economical reactor for the given case can be selected from this curve.

The eddy current losses in reactors may be made comparatively small by properly stranding the conductor and by the use of properly placed conductors in multiple. In good designs these losses are rarely over

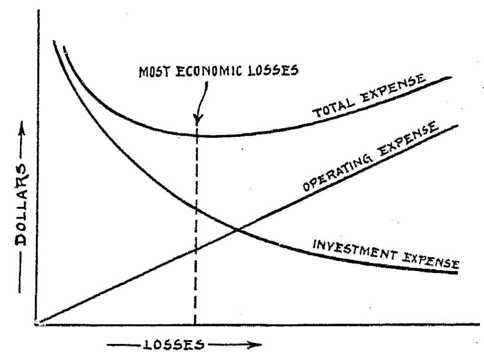

FIG. 14—CURVES SHOWING HOW THE MOST ECONOMICAL VALUE OF LOSSES CAN BE ARRIVED AT

20 per cent of the $I^2 R$ loss and usually not more than 10 per cent.

Structural steel work and other magnetic material if located too close to the reactors will cause additional losses. If a clearance from the winding of the reactor to these materials of one-half the diameter of the winding is maintained, the additional loss from this source is usually negligible.

If the magnetic field of a reactor links a loop of conducting material, as for instance, structural steel or pipe frame-work, current will be induced in the loop and will result in additional losses.

Since the power factor of reactors is very small, their losses cannot be accurately measured by ordinary wattmeters and especially designed low power-factor wattmeters are required.

Installation

The installation of reactors will be considered from the following points of view:

I—Arrangement
II—Compartments
III—Bracing and Securing in Place
IV—Support of the Leads
V—Ventilation

I. Arrangement

Reactors are usually arranged in a station as close to the circuit breakers as possible. A three-phase set of reactors may be placed side by side in the same compartment as is shown in Fig. 8, or one above the other as in Fig. 9. A much better practise is to place each reactor in a separate compartment as is shown in Fig. 15. The great advantage of this is that if anything should happen to cause the failure of a reactor in one phase, the arc will not be communicated to the other phases. This not only saves the other reactors from damage, but what is worth more, it gives to the system the protection afforded by the other two reactors, which is a very substantial percentage of the protection afforded by all three. When reactors are installed in separate compartments, the compartments are usually arranged side by side and often with three tiers of compartments so that the reactors of one circuit are placed one above the other. When reactors in different circuits are placed side by side the forces between them can be reduced 33 per cent if care is taken not to connect adjacent reactors to the same phase. One of the best arrangements for reactors is the so-called phase isolation arrangement where the reactors in different phases are placed on different floors of the station.

II. Compartments

There is a decided tendency to make the compartments for reactors too small for a liberally designed reactor. It should be realized that a reactor is a protective apparatus and conditions should be made as favorable as possible for it to give this protection.

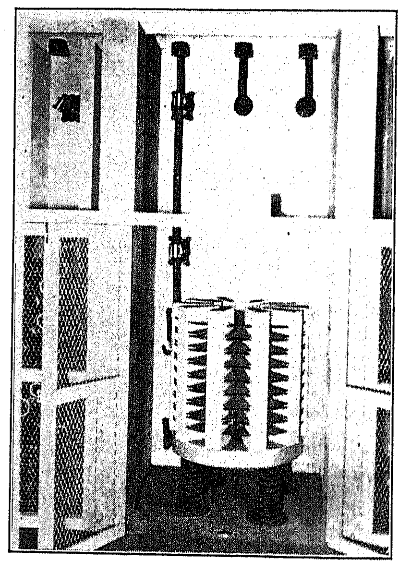

FIG. 15—REACTOR INSTALLED IN A SEPARATE COMPARTMENT

a. Electrical Clearance. In keeping with the principle that the insulation of reactors should be higher than that of other apparatus in the circuit, electrical clearances for reactors should be greater than those allowed other apparatus in the same station.

b. Magnetic Clearance. Clearances are required between reactors and magnetic materials for the reason that reactors have a strong stray magnetic field which will cause magnetic material to heat, and such heating which may or may not be objectionable from a tem-

perature standpoint will result in higher losses in the reactor.

Reinforcing rods in concrete walls and floors while magnetic, usually are not large enough to cause appreciable heating or extra losses. An idea of the size and shapes of iron bodies which are objectionable can be obtained from an investigation made many years ago. The reactor used in the test and the location of the magnetic material are shown in Fig. 16. The reactor was rated 25 cycles, 400 kv-a., 229 volts, 1750 amperes, and was carrying 25-cycle current of 1750 amperes when the tests were made.

A description of the materials of which temperatures were measured is as follows: The Part numbers refer to the numbers shown in Fig. 16.

Part 1—Iron plate ¼ in. by 12 in. by 10 ft.
Part 2—Galvanized iron wire screen 3 ft. by 10 ft.
Part 3—Fine Brass netting 3 ft. by 10 ft.
Part 4—Rolled Steel I-Beam 4 in. by 4¼ ft.
Parts 5, 6, and 7—Rolled steel angles 3 in. by 3 in. by ½ in. by 2 ft.

The following table gives the temperature rises of the above materials and their distances from the winding of the reactor:

TEMPERATURE RISES

Distance from the Reactor	Iron Plate Part 1			Iron Screen Part 2	Brass Screen Part 3
	Top	Middle	Bottom	Middle	Middle
4 in.	54 deg.	84 deg.	36 deg.	4 deg.	5 deg.
8 in.	36 deg.	61 deg.	24 deg.		
12 in.	29 deg.	51 deg.	20 deg.		

Distance from top of Winding	Steel I-Beam Part 4		Distance from Coil	Steel Angles Part No.		
	End	Middle		5	6	7*
14 in.	16 deg.	39 deg.	1 in.	11 deg.	33 deg.	20 deg.
18 in.	13 deg.	25 deg.	8 in.	9 deg.	13 deg.	7 deg.
22 in.	11 deg.	16 deg.	12 in.	9 deg.	9 deg.	5 deg.

*Part No. 7 was 20 in. below winding.

It will be noted that the highest observed temperature rise was on the iron plate and the next highest on the eye-beam. These parts should be expected to get the hottest for two reasons: first, they are the longest parts used, and second, they are each placed with their long dimensions approximately parallel to the path of the flux.

The effect of the magnetic field is enormously different for different ratings of reactors and these rises are not given as a guide to the magnitudes which might be expected with other reactors, but are given to show how the shape and position of the magnetic parts affect the heating.

Special care should be taken to avoid long magnetic bodies with their axes parallel to the field of the reactor. Experience has shown that the clearance between large magnetic parts and any point of the winding should not be less than one-half of the overall diameter of the winding.

Care should be taken to avoid any loops or turns formed by structural steel near a reactor where its field can link them. Plans for a recent installation contemplated reactors on a frame-work similar to that shown in Fig. 17. The legs of this frame-work were to be cast in concrete so that it would be a strong enough mechanically. With this arrangement, the flux from the reactor would pass through the square turn made by the top of the frame-work and cause a circulating current to flow. A temporary set-up was made as shown in Fig. 17 and tests gave a temperature rise of 125 deg.

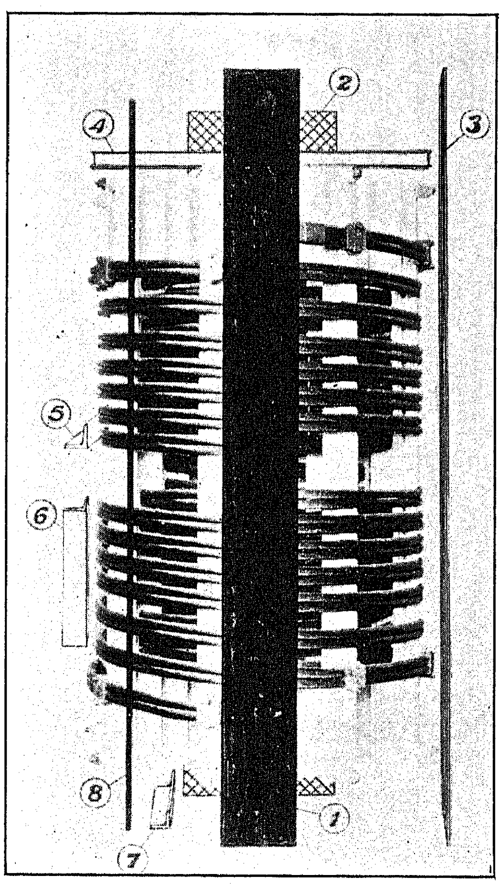

FIG. 16—DISPOSITION OF MATERIALS ABOUT CURRENT-LIMITING REACTOR IN HEATING INVESTIGATION

cent., but when one corner of the frame-work was insulated so as to open the turn, the temperature rise dropped to 56 deg. cent.

A rectangular copper bar loop as shown in Fig. 18 was placed over the structural steel supporting base with the steel loop complete as in the first test. The copper loop effectively shielded the steel structure and with the same current in the reactor a rise of 56 deg. cent. was obtained in the copper loop. The loss and heating of the short-circuited shielding loop can be controlled by varying its cross section. This method of reducing stray losses may prove useful in special cases.

III. Bracing and Securing in Place

Many reactors can be sufficiently secured against the magnetic force of the next adjacent reactor by bolting the supporting insulators to the floor and in such cases they should be rigidly bolted.

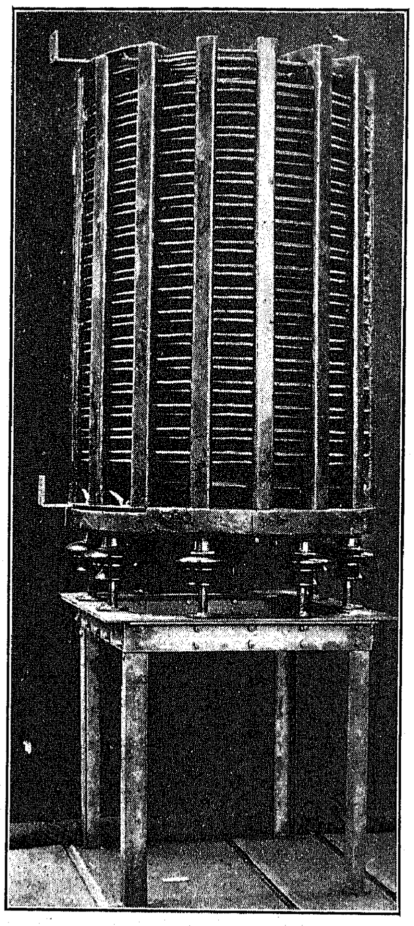

Fig. 17—Set-Up for Measuring Heating in Structural Steel Frame Work Caused by Magnetic Field of Reactor

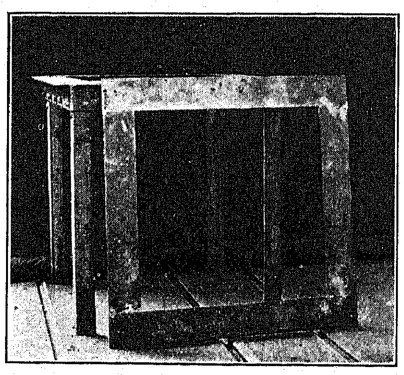

Fig. 18—Rectangular Turn of Bar Copper for Shielding Structural Steel Frame Work from Magnetic Field of Reactor Shown in Fig. 17

Where the magnetic force is large, braces must be used to brace the reactor. Since these braces are generally porcelain, which is many times stronger in compression than in tension, the reactors should be connected so that the magnetic force places compression on the insulators. In the first part of this paper, the direction of the forces for different connections was given. The supporting insulators should be bolted to the floor whether or not braces between reactors are used.

When reactors are placed in separate cells, the distance between adjacent reactors may be such that braces are required and in this case, the reactors must be braced against the cell walls or to the ceiling above, if the lifting force due to the reactor above is sufficient.

IV. Support of the Leads

The reactor exerts a force upon the leads which

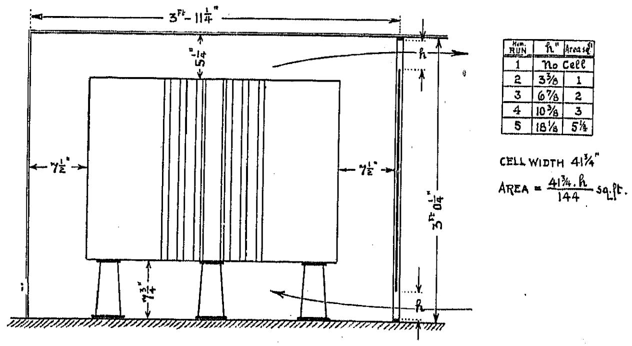

Fig. 19—Arrangement of Reactor in Cell for Tests to Determine Size of Ventilator Openings

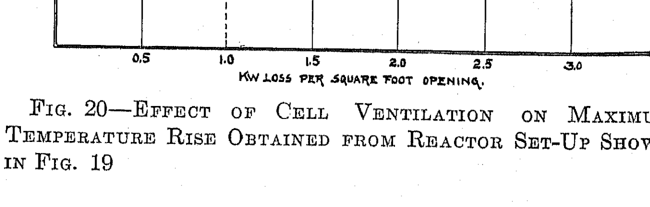

Fig. 20—Effect of Cell Ventilation on Maximum Temperature Rise Obtained from Reactor Set-Up Shown in Fig. 19

connect it in the circuit and the leads should be securely supported, but flexible enough to allow a slight movement. In general, the supports for the leads should be within a foot from the terminal and the direction of the lead as it approaches the reactor should be radial if possible. Potheads in general have been shown to be vulnerable points in a circuit and they should be located where a failure of a pothead will not communicate to the reactor.

V. Ventilation

Reactor cells should be adequately ventilated so as not to increase the temperature rise appreciably. Fig.

19 shows how tests were made with varying dimensions of openings at the top and bottom of one wall of the cell, and Fig. 20 gives the results of these tests. The conclusion reached is that the ventilation should be not less than one square foot of opening at both the top and bottom of the cell for each kilowatt of loss.

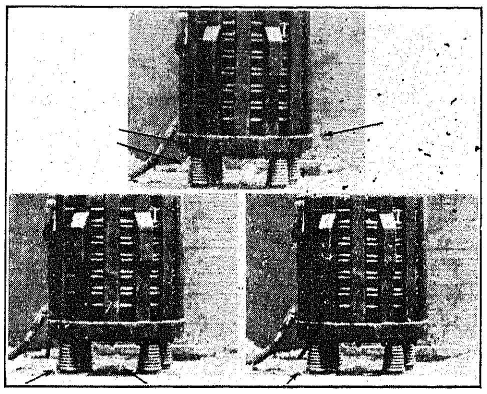

FIG. 21—REPRODUCTION OF SECTION OF MOTION PICTURE FILM SHOWING NAILS (PAINTED WHITE) BEING DRAWN TOWARD REACTOR BY ITS MAGNETIC FIELD. ARROWS INDICATE NAILS.

Operation

In general, reactors require extremely little attention in service but no effort should be spared to keep them free from foreign conducting material. Loose magnetic material, such as nails, etc., are particularly dangerous because the magnetic field of the reactor during short

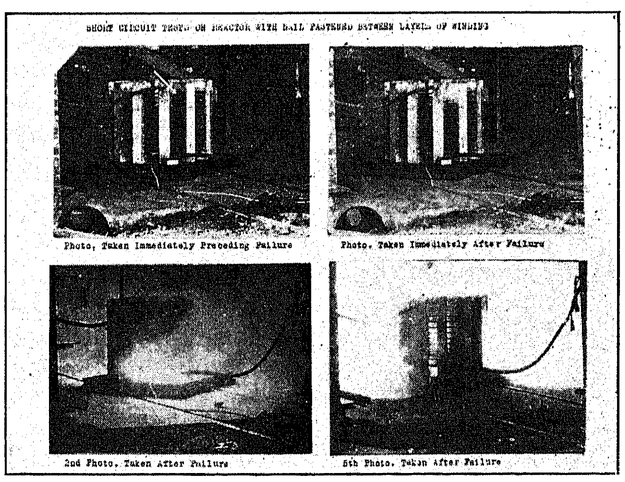

FIG. 22—REPRODUCTION OF SECTION OF MOTION PICTURE FILM SHOWING ARCING UNDER SHORT CIRCUIT CAUSED BY NAIL PLACED ACROSS TWO LAYERS OF TURNS. ARROW INDICATES NAIL. EXPOSURES 16 PER SECOND.

circuits will pick up nails at quite a distance from the reactor and draw them into the winding.

Short-circuit tests were made with nails strewn along the floor under a reactor but tied to strings so that they could not reach the winding. When the short circuit occurred the nails were drawn up from the floor and as close to the reactor winding as the strings would allow. Motion pictures were taken during this test and Fig. 21 gives enlargements of three of these pictures showing the nails (which are painted white) being drawn up from the floor.

A test was also made with a nail tied so as to bridge between the first and second layers of turns at the top. Fig. 22 shows enlargement of motion pictures taken during this test. The first picture was taken immediately before the failure, the second when the arc was just starting at the nail, and the third (one sixteenth second later) shows the reactor subjected to a complete flash-over. This indicates how rapidly an incipient arc may be spread magnetically throughout a reactor under short circuit.

These tests show that it is necessary not only to keep the reactor itself free from foreign conducting material but also to remove all unsecured magnetic material from its vicinity. This is about the only precaution that need be observed in the operation of current-limiting reactors.

Current-Limiting Reactors

BY W. M. DANN

Associate, A. I. E. E.

Westinghouse Electric & Mfg Co, East Pittsburgh, Pa.

Review of the Subject,—*Current-limiting reactors are desirable only insofar as they are strictly reliable protective devices. In this paper general considerations of the factors affecting reliability are outlined, and some of the early weaknesses and the means taken to eliminate them are enumerated. Modern reactors are considered to be reliable and on large systems are considered practically indispensable.*

The thermal duty of a current-limiting reactor is a consideration affecting the reliability which has been the subject of considerable discussion. Various opinions have been expressed ranging from the idea that a reactor should fail first and open the circuit in the event of short circuit, to the idea that it should have enough thermal capacity to withstand short-circuit currents for long periods of time. A middle ground is suggested in this paper where recognition is given both to the protective function of the reactor and to the practical consideration of dimensions and cost.

GOOD voltage regulation was the aim of the electrical engineer in the early days when generating units and systems were small compared with those to which we are now accustomed. Low power factor was the great influence which operated against this ideal. Reactance was the element that produced low power factor. Consequently, reactance was a thing to be eliminated as far as possible.

When generating units and transmission systems became larger and more extensive, voltage regulation began to be of somewhat less importance. The heavy currents developed at times of short circuit became a matter of concern. Gradually reactance began to be recognized as the solution for preventing destructive short-circuit currents and the present extensive use of the current-limiting reactor is a natural accompaniment of the growth of the modern power system.

The reactor is a desirable thing only in so far as it is a strictly reliable protective device. Its cost and its energy losses are undesirable and it takes up valuable space. Moreover, the very magnetic field which is depended upon for it to function may be the cause of troubles in operation. Service experiences, however, in the past few years have enabled manufacturers to offer reactors that are entirely reliable and in large generating systems they are practically indispensable.

Early Installations

The first example of current-limiting reactors, or "choke coils," placed in the circuit to guard against the destructive effects of heavy short-circuit currents, was in the Cos Cob Station of the New York, New Haven & Hartford Railroad, as far as the author's recollection goes. These coils were built by the Westinghouse Electric & Mfg. Co. and were put into operation in 1908 to protect the generating units. Little or nothing was known at that time about the practical design of air-core reactors, while the reactance determination of generators was very well understood. As a result, these first coils were made with an iron core and with very large air gaps which again were similar in general form to the small air gaps of a generator. The punchings were made up with slots to receive the coils, which were very similar to those used in a generator armature. The iron part of the magnetic circuit was worked at a very low normal density, in order to keep the density in the core below the saturation point under short-circuit conditions. As a result, these reactors gave a practically straight line voltage characteristic from no-load current up to the short-circuit current. The general construction of the reactor is shown in Fig. 1.

The second installation of current-limiting reactors, as the author remembers it, was made by the Commonwealth Edison Co. of Chicago. These coils were built by the General Electric Company. No magnetic material was used in their construction. They were made up of bare stranded copper cable wound in cylindrical form on a concrete core with the layers spaced by means of treated wooden strips.

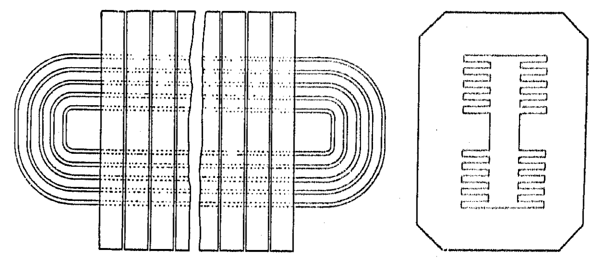

Fig. 1—Iron-Core Current-Limiting Reactor Used by the New York, New Haven & Hartford Railroad in the Cos Cob Station

General Considerations

When engineers first turned their attention to the problem of providing inductance for current-limiting purposes, it was realized that the reactor would be subjected to high electrical and mechanical stresses when short circuits occurred. It was appreciated that on account of its concentrated inductance, high-frequency disturbances would throw great voltage stresses on the reactor, especially on its end turns, but the real magnitude of these stresses was more or less unknown.

It was also recognized that the mechanical stresses

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

in a current-limiting reactor would be very large, on account of the extremely large number of concentrated ampere turns under short-circuit conditions. Mechanical stresses vary with the square of the ampere turns and they depend upon the degree to which these ampere-turns are concentrated or broken up into groups. In a generator, the ampere-turns are distributed over the entire periphery of the armature. In a transformer they are broken up into a number of groups and in the primary and secondary groups these ampere-turns cancel each other to a very large extent, since the currents are in opposite directions in the high-tension and low-tension windings. In a current-limiting reactor, however, the current flows in only one direction and the ampere-turns are very highly concentrated, resulting in mechanical stresses of enormous magnitude.

These forces are in such a direction that the tendency is to make the coil enclose a greater total flux, that is, they tend to increase the diameter of the coil and shorten its axial length. The forces tending to increase the diameter produce a tensile stress in the conductors of the coil. The tendency to shorten the axial length creates a compressive stress on the spacers between the conductors and bending stresses in the conductors themselves.

The strong magnetic field that permeates the coil, due to the large number of turns in the reactor, would produce prohibitively large losses within the conductors if special precautions were not taken to guard against them. A solid conductor, for instance, would give rise to very great eddy current losses within it and these losses would multiply rapidly if the diameter of the conductor were to be increased. For these reasons, a finely stranded cable is the obvious conductor for a current-limiting reactor and the smaller this cable can be made practicably, the better is the conductor from the point of view of low eddy current loss.

Using a small cable requires that a number of them be employed in parallel for currents greater than the capacity of a single conductor. The danger of paralleling circuits in the presence of a strong magnetic field, varying in intensity at different points, will immediately be apparent to one having experience in such matters. In order to avoid unequal division of current or circulating current in the cables, the Westinghouse Company uses a special method of winding for paralleled cables, whereby each conductor passes through a series of positions with respect to the magnetic field which are exactly duplicated for every other conductor in parallel with it. This is accomplished by transpositions in the slots when winding.

As an illustration of this method of winding with two cables in parallel, one cable is carried around one-half the circumference of the inner row of slots in the first layer, and at that point transposed to the next row of slots. The second cable is started at this point in the inner row of slots and is carried around through the second half of the circumference. Consequently, in the circumference of the inner row of slots the two cables pass through positions in the structure which are identical with respect to the magnetic field and they are exposed to the same integrated magnetic conditions. This method of easy transpositions from one row of slots to the next is carried out through the entire structure and the condition of equal resistances and equal inductances in the parallel conductors is accomplished. Unequal division of current in the paralleled paths is in this way effectively eliminated. This method of winding may be employed for any reasonable number of cables by making the number of columns of cleats a multiple of the number of cables used.

The strong magnetic field also causes magnetic forces between adjacent conductors in the winding, especially those close to the top and bottom of the coil where the accumulative effects are greatest. These forces are guarded against by placing the spacer supports between conductors close enough together to keep the maximum forces within the strength of the conductors. Shortening the length of the span between supports must not be carried too far, however, for the greater the number of supports, the less is the radiating surface of the conductors and the higher the operating temperature. The size of the conductors and the arrangement of the structure used must be selected to give full consideration to both of these conflicting factors.

A fairly high operating temperature is permissible, considering the fireproof construction of the modern current-limiting reactor. However, the operating temperature at normal current is often of minor importance compared to the temperature reached during short-circuit conditions. When a very heavy current flows for a short time, the copper must store up the vastly increased energy loss and it appears as a rapidly increasing temperature. The structure in supporting the cables must for this reason provide for the expansion of the conductors at the time of short circuit.

The thermal duty of a reactor can best be appreciated by considering a specific case, for instance, a coil having a reactance of three per cent under normal conditions. Under short-circuit conditions, assuming no other reactance in the system, this coil would carry $33\frac{1}{3}$ times its normal current. The thermal results, like the mechanical stresses, vary with the square of this current, and the temperature will immediately start toward the point corresponding to something over 1000 times the normal heat units. While this rapid increase of temperature lasts over only a comparatively short period, the temperature reached at the end of the period is often the determining point in designing a reactor from the point of view of heating. The 5 per cent reactor would be designed with a higher normal operating temperature than the three per cent coil, for the heat units developed in such a coil at the time of short circuit, again assuming no other reactance

in the system, would be 400 times normal rather than 1000 times. Consequently, it is reasonable to neglect the normal operating temperature in writing specifications for current-limiting reactors, except in cases of reactors for a high value of inductance where the short-circuit current is not a great many times the normal current. The designer's chief interest in the normal operating temperature relates usually to its effects on the temperatures reached under short-circuit conditions.

There are various viewpoints among engineers as to the length of time during which a current-limiting reactor should carry short-circuit current without failure due to excessive temperature.

The extreme point of view in one direction would be that the reactor should be the weak link in the chain and, like a fuse, should fail and open the circuit before the other apparatus can be affected. Most engineers will agree that the premeditated interruption of a heavy alternating current by means of the failure of a highly inductive device like a reactor would be an undesirable thing.

An extreme view in the other direction is that the reactor should have thermal capacity in such abundance that it can withstand its short-circuit current for a period as long as ten minutes. The point of view for such an opinion is based on disturbances of record which have lasted even longer than ten minutes before the source of the trouble has been found. Reactors designed with such thermal capacity would be so expensive and would occupy so much space that they probably would not be found practicable.

Between these two viewpoints is a middle ground where recognition can be given both to the protective function of the reactor and to the practical considerations of dimensions and cost. The maximum current that can flow through a reactor is that which would obtain if full line voltage were applied across its terminals with no other impedance in the circuit. If a reactor were required to withstand such a current for a period of five seconds, it would represent a fair compromise between the cost and dimensions of a reactor having greater thermal capacity and the protection which such a period of time would provide for the system.

The First Westinghouse Reactors

The reactors illustrated in Fig. 2 are typical of the first of the air-core current-limiting reactors built by the Westinghouse Electric & Mfg. Co. in 1913. They were wound in the form of a cylindrical coil with pancake layers of bare stranded copper cable laid in grooved spacers of treated hard wood. The columns formed by these spacers were bolted together with brass tie rods. Insulating supports or feet at the bottom and a terminal board at the top completed the structure. Ordinary transformer practise was followed in designing the terminal board, except that greater spacing was provided between the terminals than used in transformer practise. The conductors were soldered into the terminals which were clamped between nuts at the lower end of the studs shown in the illustration. Fig. 3 shows the coil partly wound.

It is clear now that the type of construction used in these original designs was fully strong enough to withstand the mechanical shocks of short circuit. Rather elaborate factory tests were made shortly after the first coils were built in an effort to find out whether the limit of mechanical strength of these coils could be reached.[1] A 15,000-kv-a. generator was short-circuited a number of times with increasing excitations with a single reactor in circuit and again with a bank of three reactors, and tests made to the limit of the generator excitation failed to find any weaknesses in the design. Large short-circuit currents were produced during these tests and the magnetic forces within the reactor were correspondingly high. For determining the fitness of the design for service on a very large system, such tests are necessarily inconclusive, but service records since that time have abundantly

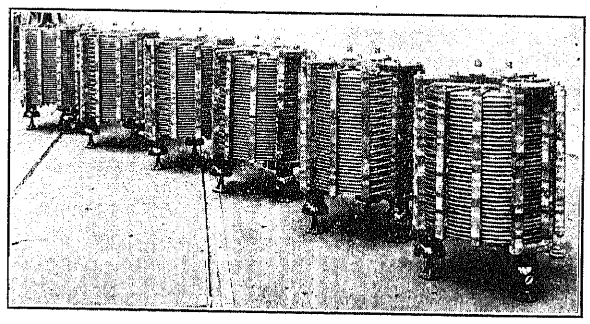

Fig. 2—The First Westinghouse Air-Core Current-Limiting Reactors

proven that the design is adequate, at least for short-circuit currents as we know them up to the present time. The same general arrangement of windings and structure has been used ever since by the Westinghouse Company.

Troubles that have occurred in service have been due mainly to an under-estimate of the excessively high transient voltages that are set up by disturbances in the system and of their effects when concentrated upon the reactor. It was very soon found that these voltages must have been as high as 50,000 volts across the reactor when connected in a 11,000-volt circuit, judging from the distances over which they jumped. This voltage manifested itself principally across the end turns of the coil and across the terminals when they were placed together at one end of the reactor, as in the original coils, Fig. 2.

Another trouble early encountered was found to be due to the metallic tie rods used to clamp the columns of spacers. Surge voltages found a path from con-

1. *Electrical Journal*, Vol. 11, April 1914, pages 188 to 207.

ductors at one end to conductors at the other end across the spacers and through these metallic rods, thus short-circuiting the coil.

A few cases of mechanical weakness in the insulating feet and of flashover to ground of insulators that were inadequate also occurred. Trouble of a different kind developed in one or two instances due to soldered

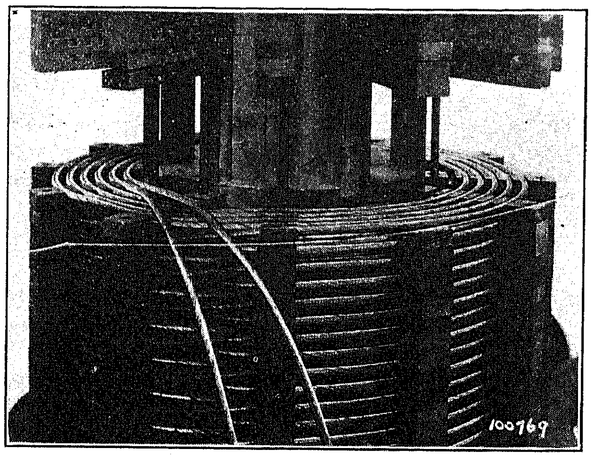

FIG. 3—SHOWING METHOD OF WINDING THE REACTORS OF FIG. 2

terminals which failed and opened up the circuit within the reactor, causing considerable burning due to arcing.

One by one all of these weaknesses have been eliminated. Through the troubles which have occurred in service, the modern reactor has been developed to the point where it is a protective device having the me-

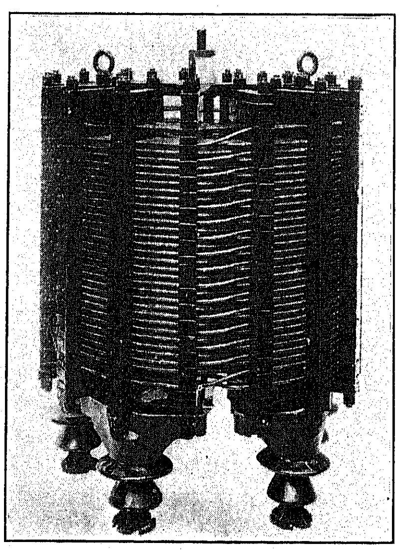

FIG. 4—A MODERN WESTINGHOUSE CURRENT-LIMITING REACTOR

chanical sturdiness and the electrical strength to carry out its function successfully and to justify its use.

SUMMARY OF ELEMENTS OF DESIGN OF THE MODERN WESTINGHOUSE REACTOR

The principal elements that contribute to the strength and efficiency of the modern reactor may be briefly summarized as follows:

1. Finely stranded cables of small diameter keep to a minimum the stray losses within the conductors due to

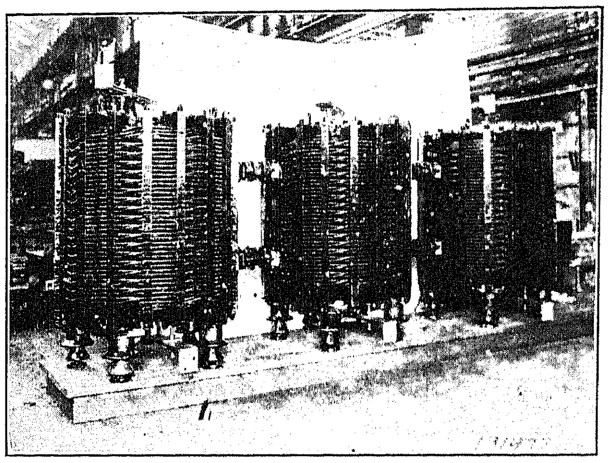

FIG. 5—SINGLE-PHASE REACTORS IN A THREE-PHASE BANK, BRACED TO WITHSTAND FORCES OF ATTRACTION BETWEEN UNITS

the magnetic field. Paralleled sections of windings are used where necessary to carry the current and retain this feature. By reason of the special method of winding, these paralleled lengths of cables have the same resistances and the same inductances, and extra

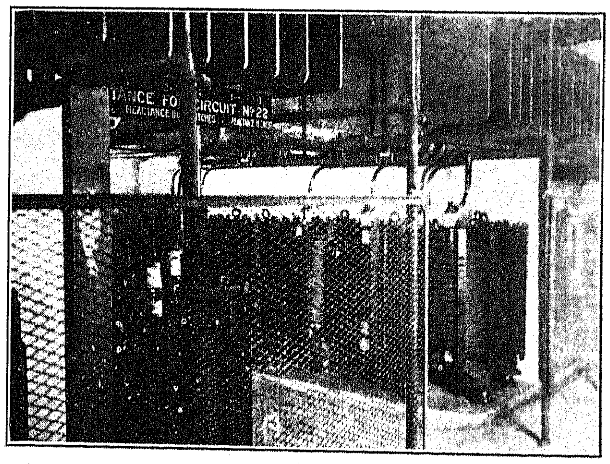

FIG. 6—AN INSTALLATION OF REACTORS

losses, due to unequal division of current, are eliminated. As a final finish, the complete reactor is dipped and baked a number of times in a fire-resisting enamel. This enamel permeates the strands of the cable and helps further to reduce the stray losses. It also serves to stiffen the conductors and give them greater mechanical strength.

2. Extra spacing of end turns eliminates danger of flashover, due to high-frequency transient voltages at times of disturbances on the system.

3. Fire proof composition spacers molded under

great pressure form the supporting structure. The slots into which the cables are laid in the winding operation provide sufficient clearance to permit expansion of the copper, due to the rapid heating at the time of short circuit. Wooden rods of treated straight-grained hickory are used to clamp the columns of spacers together. Being entirely enclosed in the fire-proof spacers, these wooden rods do not form an inflammable element.

4. One terminal is placed at one end of the coil and the other at the opposite end to eliminate the danger of flashing across terminals.

5. Normal current densities are set low enough to keep temperatures within safe limits when the sudden heating, due to heavy short-circuit currents, develops.

6. Solderless clamped connectors are used to connect the ends of the winding to the terminals. Contact nuts, made with a lug having a radial saw-cut through it, are arranged so that they can be bolted after being tightened. Once set, they are permanently locked in position. Brass tubes placed over the leads between the winding and the point of connection to the terminal studs give the necessary stiffness to these leads to eliminate troubles due to mechanical forces exerted on them when heavy short-circuit currents flow.

7. Extra heavy pin-type or pedestal-type insulating supports give the necessary mechanical and electrical strength to eliminate troubles due to mechanical breakage or to flashover to ground.

Figs. 4, 5 and 6 illustrate examples of modern Westinghouse current-limiting reactors.

Discussion

For discussion of this paper see page 940.

Theory of D-C. Excited Iron-Core Reactors and Regulators

BY A. BOYAJIAN
Member, A. I. E. E.
General Electric Co., Pittsfield, Mass.

***Review of the Subject.**—In the usual electrical machinery the magnetic saturation characteristic of iron is a handicap and in a-c. circuits gives rise to such undesirable characteristics as wave distortion and variable reactance, decreasing with increasing load. Furthermore, these characteristics are inherent in the material and can not be controlled by design to suit individual requirements or changing load conditions. Control of these characteristics can, however, be accomplished if the mean magnetic density in the core be controlled by means of a suitable d-c. excitation, in which event, the saturation characteristics of the iron can be put to some useful applications.*

(1) APPLICATION AS A FREQUENCY MULTIPLIER

The second and third harmonics of magnetization have been utilized in radio to multiply the supply frequency. Using a sufficient number of stages, theoretically any desired radio frequency may be obtained from commercial frequencies. However, the efficiency and regulation of the scheme are very poor, and this application has therefore become almost obsolete by the advent of the vacuum tube oscillator and the high-frequency alternator. When used at all, the number of stages would be kept to a minimum.

(2) APPLICATION AS A SERIES CURRENT-LIMITING REACTOR

The ordinary iron-core reactor is saturated at increasing values of load, and thus having a much lower reactance at short circuit than at normal load, is undesirable as a current-limiting reactor. However, its characteristic is inverted over a wide and useful portion of the curve when excited by means of direct current, so that it shows an increasing reactance with increasing load. By suitable design, the maximum reactance may be made to coincide with the short-circuit condition without departing from the usual economical values of flux and current densities and from the economical ratios of core and copper. The ratio of the short-circuit reactance to normal-load reactance may be as high as three to one. This characteristic of the d-c. excited reactor does not mean that the d-c. excitation increases the permeability of the core and the reactance of the winding, but just this, that the fixed d-c. excitation lowers the effective permeability and reactance at normal loads many times more than at short-circuit, and thus the short-circuit reactance becomes much higher than the normal reactance. This highly desirable rising-reactance characteristic of the d-c. excited reactor is at the expense of higher losses and cost, and therefore, unless there is a very particular need for the rising-reactance characteristic, the use of this type of a reactor is not recommended.

(3) APPLICATION AS A FEEDER VOLTAGE REGULATOR

A pair of auto transformers of suitable design (equipped with suitable windings for d-c. excitation) may be utilized as feeder-voltage regulators. A number of such sets have been built and tested and some have been put into service. This type of a voltage regulator has a number of advantages over the other types in that, (a) it has no moving parts, (b) can be designed for any voltage on account of its transformer construction, (c) is four or five times or more as fast in operation as some other types and, (d) can be built mechanically much stronger to withstand short-circuit forces. Its disadvantages are high losses and higher cost in all instances where the induction regulator can be designed for the line voltage without transformers. This type of a voltage regulator is therefore desirable only when high speed of operation is essential or when the circuit voltage is very high.

(4) APPLICATION AS A SHUNT-REACTOR FOR POWER-FACTOR CONTROL

A d-c. excited reactor may be used also as a shunt-reactor constituting a variable reactive load on the lines to control power-factor by varying the d-c. excitation. A possible application is to the neutralization of charging current of high voltage transmission lines and control of line regulation. In this application the wave-shape of the reactor current becomes of importance. Many oscillograms taken in various three-phase connections are given, which seem to indicate that although very pure sine wave of current can not be obtained economically, yet the harmonics may be reduced to practically harmless proportions.

RATIO OF CONTROLLING AND CONTROLLED KV-A.

The control of the output of a reactor may be by alternating current as well as by direct current, the frequency of the controlling current being independent of the frequency of the controlled current. To a first approximation, and ignoring the copper losses, the ratio of the kv-a. of the controlling current to the kv-a. of the controlled current is that of the ratio of the respective frequencies. This principle has been taken advantage of in Alexanderson's "Magnetic Amplifier" in the modulator circuit of his system of radio transmission. In d-c. control, the necessary control kv-a. is just the copper loss approximately corresponding to the controlled kv-a.

Introduction

THE superposition of d-c. excitation on an iron-core static alternating current apparatus, such as a reactor, or transformer or autotransformer, modifies its characteristics very profoundly and leads to new problems and a variety of applications. Some of the more important applications are[1]:

1. Frequency converter, or high-frequency generator, suitable for use in radio.
2. Short-circuit current-limiting reactor having inherently low normal reactance and inherently high short-circuit reactance.
3. Feeder voltage regulator with no moving parts, for central station and laboratory use.
4. Variable series reactor with no moving parts, with d-c. control of its reactance to regulate load current or voltage.
5. Variable shunt-reactor with no moving parts, with d-c. control of its a-c. exciting current, constituting an adjustable reactive load, for use, for instance, for the neutralization of the charging current of high-voltage transmission lines and also thereby for the control of their regulation.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

General Theory

Three characteristics of iron-core reactors (without d-c.) are commonly known: *viz.*

(a) The reactance of an iron-core reactor depends on the core-density on account of the variable permeability of iron.

(b) Due to this same cause, the current taken by such a reactor at sine wave voltage (or the voltage consumed at sine wave current) is distorted; and

(c) Such a reactor is entirely unsuited for short-circuit protection because, due to saturation, its short-circuit reactance is much lower than its normal reactance, while the requirements of a desirable protective reactor are that if possible it should have a low reactance at normal loads and a high reactance at short-circuit.

From the first characteristic mentioned above, it follows that if the mean density of the core be controlled by the superposition of a d-c. excitation, the reactance of the apparatus can be controlled thereby. This is the basis of the applications 3, 4 and 5 mentioned above.

From the second characteristic mentioned above, it follows that by biasing the core density by means of d-c. excitation, more wave distortion may result. This feature is taken advantage of in the application for the generation of high frequency for radio. This application, however, has been rendered obsolete by the advent of the vacuum-tube oscillator and will, therefore, not be discussed in this paper. In other applications, wave distortion and harmonics are objectionable and must be eliminated or minimized. While at first sight it might appear that wave distortion will be so bad that no applications other than the production of harmonics could be practicable, yet experience shows the reverse to be true, so that while wave distortion can be minimized so as not to be a limitation to most applications, it can not be accentuated and loaded for the production of harmonics to as great a degree as one would expect.

The characteristics that have been indicated so far do not as yet give any clue as to the suitability of a d-c-a-c. excited reactor for short-circuit protection. This application results from the fact that the d-c. excitation accentuates very markedly the lower bend of the magnetization curve of iron, as will be discussed in detail under the heading of "Volt-Ampere Characteristics of D-C-A-C. Excited Core."

Schemes for the Application of D-C. Excitation

In applying d-c. excitation to an a-c. apparatus, provision must be made for protection against three possible disturbances, *viz*:

1. The d-c. supply circuit must be protected from induced alternating voltages, and, if possible, also from alternating currents.

2. For all applications, except for the generation of high frequency for radio, the line currents and voltages should be symmetrical and of as good shape as possible.

Both of these conditions can be satisfied by using two subunits balanced against each other as shown in Figs. 1, 2, 3 and 4 instead of using a single-core single-unit. In these figures the arrows show relative directions of a-c. and d-c. fluxes, a consideration of which will show that normally no a-c. voltage will appear between the d-c. terminals. For instance, considering Fig. 1, it will be evident that the a-c. voltages induced in the d-c.

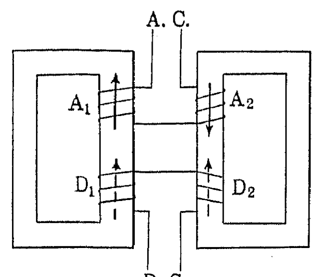

Fig. 1—Connection of Two Single-Phase Transformers as a Reactor Suitable for D-C. Excitation. Solid Arrows Represent A-C. Flux, Dotted Arrows, D-C. Flux.

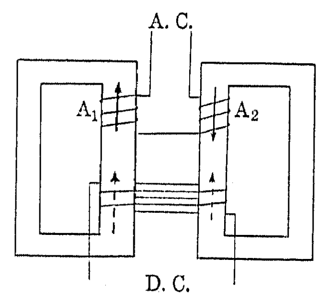

Fig. 2—An Improvement over the Arrangement Shown in Fig. 1. The D-C. Coil Surrounds both Units at Once, and Therefore no A-C. Voltage of Fundamental Frequency can Build up in it. Solid Arrows Represent A-C. Flux, Dotted Arrows D-C. Flux

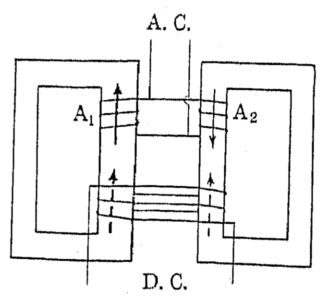

Fig. 3—An Improvement over the Arrangements Shown in Figs. 1 and 2. A Second Harmonic Current Circulates in the Parallel Branches of the A-C. Circuit, and no Appreciable Second Harmonic Voltage Appears Anywhere

coils D_1 and D_2 will neutralize each other, and no -c. voltage of normal frequency will appear between the d-c. line terminals. However, in this case there will be an a-c. voltage to ground from these terminals, and this high potential stress will be impressed on the d-c. supply system. Usually the d-c. winding has many times the turns of the a-c. windings, and this voltage would amount to a great deal. This disadvantage may be

practically obviated by grounding the d-c. supply system or one of the terminals, but, even then, the d-c. winding will require insulation corresponding to its maximum induced voltage. The difficulty is completely obviated by making the d-c. winding to enclose the two cores at once as shown in Fig. 2. Here the induced voltage is neutralized in each turn and therefore no large a-c. voltage can appear in any part of the d-c. circuit, regardless of the number of turns of the d-c. coil.

Although the normal frequency voltages induced in the d-c. winding neutralize each other in every turn in the design of Fig. 2, yet, whenever there is wave distortion (and there always is some wave distortion) the even harmonics of the induced voltages do not cancel each other in each turn of the d-c. coil but add to each other, and if the impedance of the d-c. supply circuit is high enough not to short-circuit this voltage (as for instance in the case in which the current of the d-c. coil represents full load to the d-c. generator), destructive even harmonic voltages may appear across the d-c. circuit. This difficulty is practically completely eliminated by connecting the two a-c. coils A_1 and A_2 in parallel as shown in Figs. 3 and 4, instead of in series as in Fig. 2. The even harmonics are then short-circuited and circulated in the a-c. coils without appearing anywhere in the outside circuits. This is a desirable feature, not only on account of the elimination of avoidable voltage stresses, but also on account of the additional advantages that by this means, (a), the wave shapes of currents and voltages in the external lines are improved, (b), the effectiveness of the d-c. excitation in controlling the a-c. reactance is increased, and (c), the time constant of the apparatus is reduced and its speed of response to changes in the controlling d-c. excitation is increased.

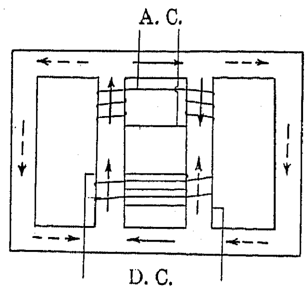

FIG. 4—SHOWING THE CORE CONSTRUCTION WHICH IS PREFERRED AS ELIMINATING THE STRAYING OF A-C. FLUX AND REDUCING LOSSES

VOLT-AMPERE CHARACTERISTICS

The volt-ampere characteristics of a device like that of Fig. 3 is shown in Figs. 5 and 6, the former taken with sine-wave voltage, the latter with sine-wave current. Before discussing their differences, we might discuss the features common to both, as in general they are alike. A number of characteristics may be observed as follows:

1. By applying sufficient d-c. excitation, the a-c. current taken by the device at a given voltage (or the voltage consumed at a given current) may be controlled over a very wide range. The lowest limit to this voltage consumed, or the highest limit to the current taken, is fixed by the impedance which the device would have without the iron core. That is, at increasing relative values of d-c. excitation, the volt-ampere characteristics of the device is as though it had no iron core.

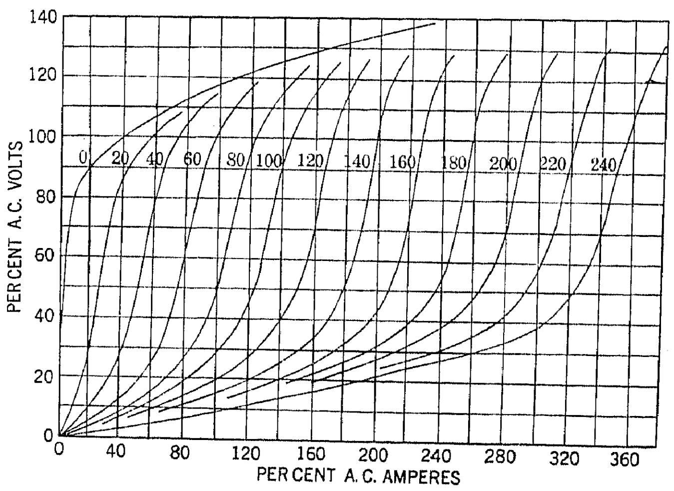

FIG. 5—VOLT-AMPERE CHARACTERISTIC CURVES OF A CORE WITH SIMULTANEOUS D-C. AND A-C. EXCITATION. NUMBERS ON THE CURVES REFER TO THE D-C. AMPERES. TURN RATIO OF D-C. AND A-C. WINDINGS 1:1. TESTS MADE WITH APPROXIMATELY SINE-WAVE VOLTAGE

2. There is an economic limit to the value of d-c. excitation and range of control, because beyond a certain zone the addition of more d-c. excitation does not produce a proportionate change in the a-c. current or voltage. For instance, at 100 amperes a-c., the application of 100 amperes d-c. cuts down the voltage from 118 to 29. If the d-c. excitation be doubled, the

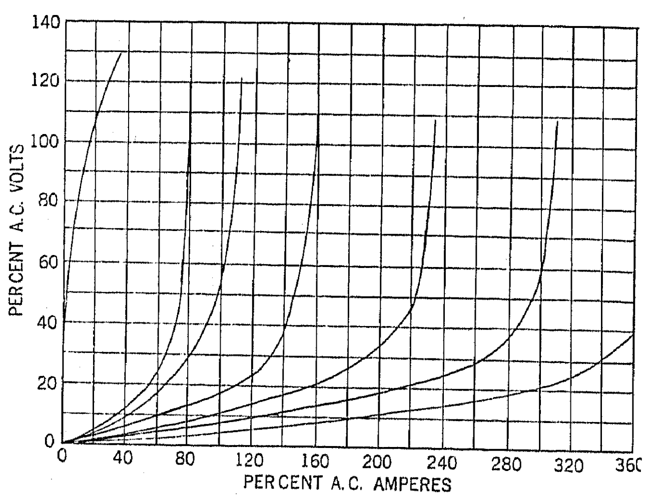

FIG. 6—SIMILAR TO FIG. 5, EXCEPT THAT THE TESTS WERE MADE WITH APPROXIMATELY SINE-WAVE CURRENT. NOTE THE GREATER STEEPNESS OF THESE CURVES

voltage is reduced to 12; if it be doubled again, the voltage is reduced to about 7.

3. The volt-ampere curve for combined d-c-a-c. excitation has two bends—one at the lower densities, the other at the higher densities. The volt-ampere curve for pure a-c. has also two such bends, but just because the lower bend occurs at extremely low core densities and small values of current, it does not show in the usual curves drawn for the working range of currents and voltages. If the initial portion of the a-c. volt-ampere curve for zero d-c. is drawn to a large scale, it looks as shown in Fig. 7, exposing the lower bend.

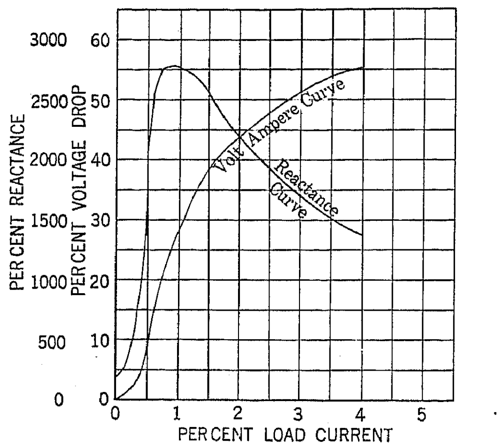

Fig. 7—These Curves show that on a Certain Commercial Size of an Economical Transformer or Reactor Design, the Useful Range of the Core Reactance Corresponds to a Current which is Less than 1 Per Cent of the Rated Capacity of the Winding

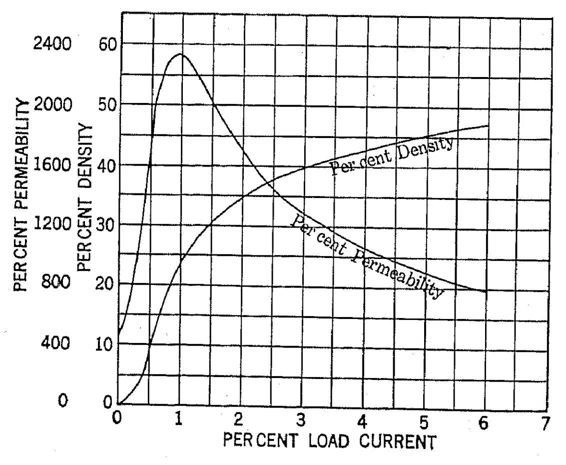

Fig. 8—Similar to Fig. 7 Except that the Characteristics are Given in Terms of Permeability and Core Density Instead of Reactance and Voltage

This lower bend is not merely a characteristic of the a-c. curves, but also is characteristic of the d-c. magnetization curve of iron shown in Fig. 8. In the light of these remarks, and by again referring to Figs. 5 and 6, it will be evident that the addition of d-c. excitation does not introduce a new bend to the curve but shifts the two bends of the a-c. volt-ampere curve far towards the higher values of current and voltage, and this fact makes it possible to make commercial use of the lower bend as in an automatic protective reactor having low inherent normal reactance and high inherent short-circuit reactance.

That the volt-ampere curve with superposed d-c. must have two bends or knees may also be seen with the aid of the following theoretical considerations.

Since the d-c. excitation is kept constant (though of different value for different curves) and only the a-c. current and voltage are varied in these volt-ampere curves, it will be evident that at the initial parts of the curves (near the origin) the d-c. current will be many times the a-c. current, and the reactance of the unit will be completely determined by the d-c. density in the core. The initial part of the volt-ampere curve is therefore straight and has a slope very much smaller than that of the zero-d-c. volt ampere curve. That is, the reactance or voltage drop at this point of the curve is very low as compared with the zero-d-c. curve. This fixes the general character of the initial end of the volt-ampere curve.

Considering the final end of the volt-ampere curve, it will be evident that as we go higher and higher in the a-c. flux density and current, the fixed d-c. excitation will be a smaller and smaller percentage of the total current and will therefore less and less influence the a-c. volt-ampere characteristic. That is, the final end of the volt-ampere curve with d-c. excitation will approach asymptotically the volt-ampere curve without direct-current.

Having thus determined the character of the initial and final parts of the curve, it will be evident that the smoothest or simplest curve that will join these two parts will require two bends or knees.

The place where the mean value of the a-c. current equals the value of the d-c. current would be approximately the inflexion point of the curve, that is, below this point the d-c. will be dominant and the curve will be convex downward; above this point the a-c. will be dominant and the curve will be convex upward.

Examining Fig. 5, it is found that this is approximately true. Assuming sine wave a-c., the inflexion point corresponds to an a-c. of which the mean value is only ten to fifteen per cent higher than the d-c. This is a good qualitative check, as the analysis given above is not intended to be anything but qualitative on account of the varying permeability of the core along the cycle.

Meaning of the Two Bends of the Volt-Ampere Curve

The meaning of the two bends in the d-c. saturation curve is that the iron core has its highest permeability between the two bends,—at the inflexion point of the curve. Above the upper bend and below the lower

bend the permeability of the core is lower. In the a-c. volt-ampere characteristic, the meaning of the two bends is that the reactor has its highest reactance in the zone between these two bends and that above the upper bend and below the lower bend its reactance is lower.

To be more precise in the discussion of permeability (or permeance) and reactance, we might make the observation here that this matter may be considered in two different ways, giving somewhat different results. Thus, if we consider the permeability or reactance as the slope of the curve, it corresponds to that characteristic which is effective for small changes of current at given densities (mathematically proportional to $d\,B/d\,H$, or $d\,\phi/d\,H$, or $d\,E/d\,I$). This view is useful for a number of applications. The author does not know a good name for it, but it has been sometimes called "instantaneous" permeability or reactance, and could probably be called more appropriately "differential" permeability or reactance in contrast with the second point of view which makes the permeability or reactance the ratio of the total B or E to the total H or I, and which may therefore be called the *mean* or integral permeability or reactance. The maximum integral permeability or reactance occurs at the upper bend, not midway between the two bends, as will be shown below. This second definition is the one that is of more importance in the applications discussed in this paper.

Theory of the Application of the D-C-A-C. Excited Reactor as a Protective Impedance

The most desirable characteristic of a protective reactor is that it should have a low inherent reactance for the normal load current and a high inherent reactance for short-circuit. An iron-core reactor (without air gap), that can be commercially or economically designed, fails to meet this condition, because increasing currents saturate the core and reduce the reactance. This statement has to be qualified as applying to "commercial or economical" designs, because if the core be operated normally at densities below the lower bend, the desired characteristics may be secured, although at a very prohibitive cost.

The a-c. volt-ampere curve (with zero d-c.) of Fig. 5 is plotted to a large scale in Fig. 7. In order that the economic significance of the currents and voltages may be easily grasped, the currents are given in per cent of what would correspond to the normal current of a commercially economical transformer of the same proportions as the reactor under consideration and the voltages are given in per cent of the normal rated voltage of the equivalent transformer. The normal density or voltage and the normal current are, of course, somewhat arbitrarily fixed, but inasmuch as these curves are to be used for comparative purposes and not for their absolute values, a very great deal is gained in intelligibility by specifying per cent voltage and per cent current representative of economical practise even though somewhat arbitrary. From the volt-ampere curve, a reactance curve has also been calculated and plotted against the per cent current.

Referring to the reactance curve of Fig. 7, the following characteristics will be observed:

The maximum reactance of the unit, which is desired to occur at short circuit, occurs at about 1 per cent of its normal rated current. To be used as a protective reactor, then, the unit must be operated normally at a small fraction of one per cent capacity so that the short circuit will be about 1 per cent load to it. This is indicative of the degree of its economic merit. The larger the capacity of the unit, the smaller will be the per cent load at which its maximum reactance occurs if no d-c. excitation is used.

The addition of direct current, however, shifts the two bends of the volt-ampere curve and the maximum of the reactance curve towards higher values of current and voltage. By using sufficient d-c. excitation, the

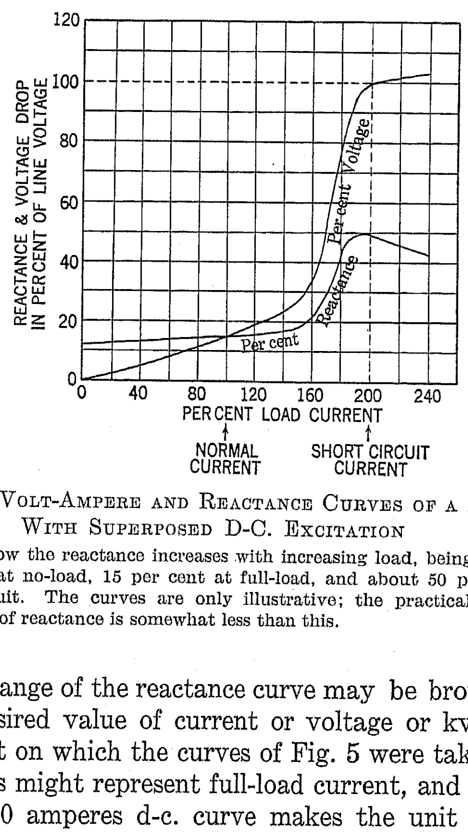

Fig. 9—Volt-Ampere and Reactance Curves of a Reactor With Superposed D-C. Excitation

Note how the reactance increases with increasing load, being about 12 per cent at no-load, 15 per cent at full-load, and about 50 per cent at short-circuit. The curves are only illustrative; the practical range of variation of reactance is somewhat less than this.

useful range of the reactance curve may be brought to any desired value of current or voltage or kv-a. In the unit on which the curves of Fig. 5 were taken, 200 amperes might represent full-load current, and we find that 240 amperes d-c. curve makes the unit a most desirable protective reactor. This curve is plotted in Fig. 9 in terms of per cent load current, per cent voltage drop and per cent reactance. We find that at normal load current the device consumes about 15 per cent voltage, that is, it has 15 per cent reactance; while at short circuit it has 50 per cent reactance, making the short-circuit current only twice normal. While practically in all the other apparatus, the short-circuit reactance is either the same as, or smaller than, the normal reactance, in a properly designed d-c-a-c. reactor, the short-circuit reactance may thus be about three times the normal reactance.

The value of d-c. excitation that brings the useful

range of the reactance curve to the normal working load of the unit is of the order of 120 per cent—160 per cent of the a-c. excitation (effective values). This holds true for apparatus sizes. Theoretically, in "peanut" sizes the d-c. excitation might be dispensed with, since the smaller the unit, the lower the economical core density would be and the nearer its magnetizing current would approach the value of its rated load current.

In a protective reactor of this type, it is not necessary to remove the d-c. excitation on short-circuit. Referring to Fig. 5, it will be seen that above the upper bends of the volt-ampere curves, there is very little difference in the voltage consumed with or without d-c. excitation. This is due to the fact that at this point the d-c. ampere turns, being much smaller than the a-c. ampere turns, have very little effect on reactance. How the ratio of d-c. to a-c. influences reactances is clearly brought out in Fig. 10.

The curve of Fig. 10 is an average for various densities and sizes, and is therefore useful only qualitatively. It

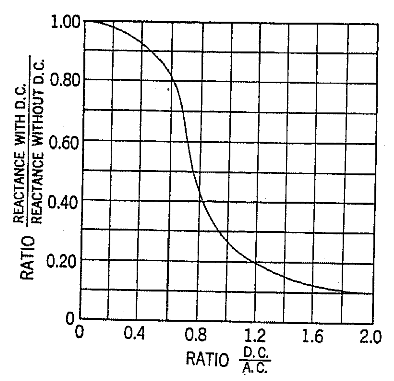

FIG. 10—CURVE SHOWS HOW REACTANCE VARIES WITH RATIO OF D-C. EXCITATION TO A-C. EXCITATION, AND IS ONLY ILLUSTRATIVE, REPRESENTING AVERAGE CHARACTERISTICS OVER COMMERCIAL WORKING RANGES

shows that the ratio of d-c. excitation to a-c. excitation at normal load ought to be in the range of 1.2 to 1.6. It also shows that when this ratio falls below 0.8, the reactance increases very fast. The higher ratio of d-c. is advantageous in leading to smaller core loss and better wave shape.

The d-c. to a-c. excitation ratio must not be misinterpreted as though it were a power ratio, for it is merely an ampere-turn ratio within the reactor, while the ratio of d-c. power to a-c. power or volt-amperes is only of the order of one or two per cent, that is, the d-c. power that is necessary to operate such a device is that required to furnish the copper loss and is, therefore, only a couple of a per cent of the a-c. volt-ampere or less, depending on the kv-a. rating of the unit.

The consideration of the ratio of the power of controlling current (in this case d-c.) to the controlled current (a-c.) has an interesting bearing on the cases where both the controlling and controlled currents may be alternating. Ignoring the resistance losses, we could say, as a general rule, that the ratio of the volt-amperes in the controlling and controlled currents is the same as the ratio of their frequencies. This principle has been utilized by Mr. Alexanderson in radio in what has been called a "magnetic amplifier," being a reactor of this type in which the controlling current is of telegraph key or audio frequency while the controlled current is of radio frequency.

DIFFERENCE IN THE VOLT-AMPERE CHARACTERISTICS ON SINE-WAVE VOLTAGES AND SINE-WAVE CURRENTS

The volt-ampere curve of an iron-core reactor (without d-c. excitation), if taken on a sine-wave voltage, shows distinctly a saturation effect as is commonly known. However, if the tests be conducted on sine-wave current, saturation effect is only slightly marked, the curve being quite steep even far beyond the upper bend. This difference and the reason thereof has already been masterfully discussed by Steinmetz in his book on the "Theory and Calculation of Electric Circuits," in the chapter on the shaping of waves by magnetic saturation, to which the interested reader should refer. (Ordinarily sine-wave current condition is practically approached by connecting in series with the iron-core device a constant impedance of a value considerably higher than that of the former. The higher this ratio, the nearer is the approach to sine-wave current.)

What is true of the relative characteristics of an iron-core reactor on sine-wave current and sine-wave voltage without d-c. excitation, is also true when d-c. excitation is superposed, as shown in Figs. 5 and 6. The latter set of curves is much higher and steeper, that is, it indicates a higher reactance and very much less saturation effect.

The normal operation and characteristics of a series reactor are those for sine-wave current, its short-circuit operation and characteristics are those for sine-wave voltage. At intermediate conditions of load, the characteristics are intermediate. In most applications, the conditions change between sine-wave current and sine-wave voltage, depending on the load conditions, with corresponding changes in characteristics. It is very important, therefore, to bear in mind that many of the characteristic curves given in this paper are for purposes of illustration and can not be used directly for design purposes. In any particular problem, characteristic curves may be obtained and plotted as explained.

WAVE-SHAPE

In considering the wave-shape characteristics of d-c-a-c. induction devices, it should be borne in mind that in most applications the voltage or current of the device is only a small fraction of the total voltage or current of the circuit, and that therefore, a first-order factor in such a device is only a second-order factor for the lines, and a second-order factor for such a device is entirely

negligible for the lines. For instance, if a series reactor consuming 15 per cent voltage has a 30 per cent third harmonic in its voltage wave-shape, this will appear only as a 5 per cent third harmonic in the line or load voltage. For this reason, considerable wave distortion in the voltage or current of the d-c-a-c. device is ordinarily permissible. Not to make the picture too optimistic, however, it might be said here that it is conceivable that some rare circuit constants or connections may lead to an accentuation of these harmonics, in which cases, then, of course, the application of such a device would be limited.

Oscillograms

The following oscillograms were taken on small laboratory models but apply to large units just as well.

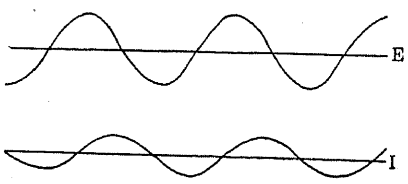

Fig. 11—Wave-Shapes of Current I and Voltage E at Full Load Observed in and Across a Series Reactor Having D-C. Excitation Considerably Larger than the A-C.

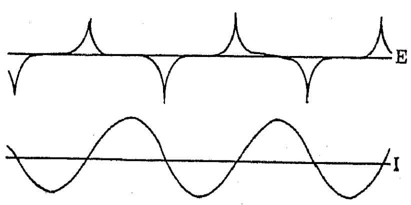

Fig. 12—Wave-Shapes of Current I and Voltage E in and Across a Series Reactor in Which the D-C. Excitation Was About One-Third of the A-C.

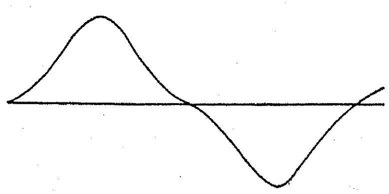

Fig. 13—Wave-Shape of Short-Circuit Current Through D-C. Excited Reactor

Note that it is better than the usual wave-shape of the exciting current of a transformer

Fig. 11 corresponds to the normal load condition of a series reactor, with d-c. excitation well in excess of a-c. excitation. A large constant series impedance was used to insure good wave shape for the currents. It is seen that the wave-shape of both the current and the voltage drop are excellent.

Fig. 12 corresponds to a large overload between normal load and short-circuit, the d-c-a-c. ratio being about ⅓. The current is still of fairly good shape but the voltage drop through the reactor is considerably peaked.

Fig. 13 corresponds to the short-circuit condition. The voltage drop, being the same as the generator voltage, has fairly good wave-shape, but the current is very much distorted. Wave distortion under short-circuit conditions is practically of no consequence in this application.

Advantages and Limitations of the Series Protective Reactor

The main advantages of this type of a current-limiting reactor are: (1) as already explained, it has a much higher reactance at short-circuit than at normal load; and, (2) its reactance is entirely inherent and automatic without requiring any relays, switches or other control equipment.

The main limitations of such a reactor are its cost and losses. (1) The cost of such a reactor may be estimated as follows: the reactor must be good for the normal load current and the line voltage, hence it will have a kv-a. rating of the same order as the load kv-a. Since the reactor has two windings, one for a-c. and one for d-c., it is equivalent to a transformer of the same kv-a. rating as the load. The d-c. ampere-turns are

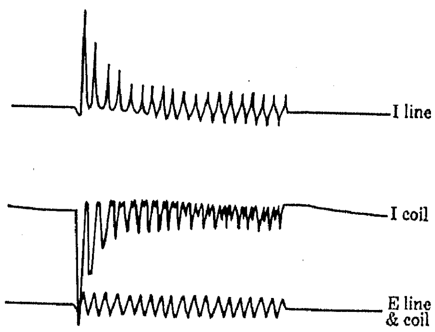

Fig. 14—Transient Rush of Current Due to Sudden Switching of a D-C. Excited Reactor

from 20 per cent to 60 per cent greater than the a-c. ampere-turns, but this is partially offset by the fact that the core density for the short-circuit condition may be designed for a much higher value than that of a normal transformer. That the complete reactor has to consist of two subunits tends to increase its cost somewhat above its equivalent transformer kv-a. rating would indicate. In concrete terms, then, such a reactor for a 1000-kv-a. circuit will have a cost somewhat greater than that of a 1000-kv-a. transformer. This fact naturally limits its very extensive application. If it should be desired to maintain the short-circuit current indefinitely on the ground so that it is only two or three times normal current, the rating and cost of the reactor is naturally further increased.

(2) The losses of such a reactor are somewhat larger than those of the equivalent transformer. Although normally the a-c. flux density of the reactor is between 10 per cent and 20 per cent of the normal a-c. density of the equivalent transformer, yet, due to the superposition of the large d-c. excitation, the core loss of the former will equal or exceed the core loss of the

latter. Those with any electrical design experience will appreciate further that saturation and resultant stray fluxes will lead to considerable stray losses. This matter of losses will be further discussed at a later point.

A further limitation of the series reactor that might be mentioned is, if the short-circuit starts with a large transient flux component, the protective or current-limiting ability of the reactor is temporarily paralyzed, and the current is limited largely by the air-core reactance of the windings, until the transient has practically died out. This transient characteristic is well shown in Fig. 14. Note the initial rush of current at sudden short-circuit. This oscillogram was taken on a connection similar to Fig. 1 and therefore shows a prominent normal second harmonic plus a transient fundamental in the d-c. circuit. This second harmonic would be almost entirely absent in the d-c. circuit if there were a multiple connection in the a-c. circuit as shown in Figs. 3 or 4.

Feeder Voltage Regulator Application

Out of a number of ways in which the d-c-a-c. principle can be applied to voltage regulation, the one

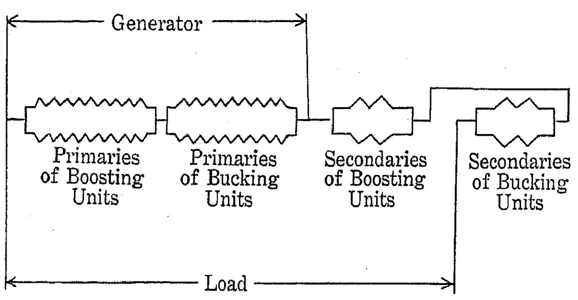

Fig. 15—Connection of Two Auto-Transformers as a Voltage Regulator, One Tending to Boost the Line Voltage, the Other Tending to Lower it. Their Relative Value and Resultant Effect is Controlled by Varying their D-C. Excitation

that has been found to give the best results is as follows: Suppose it is desired to regulate the voltage 10 per cent above and 10 per cent below the normal voltage. Two autotransformers with 10 per cent secondaries and each equipped with a d-c. winding are connected into the circuit as shown in Fig. 15, that is, the primaries of the two autotransformers are connected in series with each other and across the supply lines, and the secondaries are connected in series with each other and in series with the load or feeder lines. One of the secondaries is reversed, so that one unit tends to raise the feeder voltage, the other tends to lower it. Each autotransformer unit consists of two subunits and has therefore two primary windings and two secondary windings, and one d-c. winding enclosing both subunits as shown in Figs. 2 to 4. If one pair of a-c. windings, as for instance the two secondaries of one unit, is connected in parallel, the other pair, that is, the two primaries of the same unit, may be connected in series if desired.

The operation of such an equipment is as follows:

(*a*) *No-load operation.*

Referring to Fig. 15 it is seen that unit No. 1 tends to raise the load voltage and unit No. 2 tends to lower it. As the two units may be assumed duplicates, therefore, normally with equal or no d-c. excitation in either unit, they balance each other and the load voltage is neither raised nor lowered. Suppose the d-c. coil of No. 2 is fully excited, and that of No. 1 is unexcited. Then, unit No. 2 will be saturated and will have a negligible reactance and No. 1 will take up the full-line voltage, and thus the line voltage instead of dividing equally between P_1 and P_2, will be concentrated practically entirely across P_1. If the voltage across P_2 is negligible, that induced in S_2 will also be negligible, and the voltage across S_1 will be practically 10 per cent of the line voltage and will boost the feeder voltage by this percentage. This gives us the maximum boosting condition.

If now the d-c. winding of No. 1, the "boosting" unit, is fully excited, and that of No. 2, the "bucking" unit, is left unexcited, the "boosting" unit will be saturated and will therefore have negligible reactance and negligible voltage drops across its primary and secondary, while the "bucking" unit takes up the full line voltage and its secondary "bucks" the load voltage by 10 per cent. This gives us the maximum "bucking" condition.

Intermediate values of load voltage between maximum "boost" and maximum "buck" are obtained by intermediate values of d-c. excitation in the two units.

(*b*) *Full-load operation.*

Under load conditions the general operation of the device is exactly as described for the no-load condition, except that the amount of regulation is somewhat modified by the reactive drop through the device. The power transformation through the device being proportional to the secondary voltage, the magnitude of the primary current is also proportional thereto.

Thus, with 10 per cent total resultant secondary voltage, the primary-load current is also 10 per cent of the external-load current, and with zero total resultant secondary voltage, the primary-load current is zero. Furthermore, the phase angle of the primary-load current is also controlled by the phase angle of the total resultant secondary voltage, and therefore the primary currents for the "bucking" conditions are reversed in direction with respect to the primary currents corresponding to the "boosting" conditions.

It follows, therefore, that at maximum and minimum load voltages, one unit acts as a transformer, the other as a reactor. At intermediate values of voltages, the units act partially as transformers and partially as reactors.

When a unit is acting purely as a transformer (that is, as autotransformer), its primary and secondary ampere-turns are equal and opposite, exactly as in any transformer, neutralizing each other's reactance so far

as the core is concerned, and producing a reactive drop only through leakage.

When a unit is acting entirely as a reactor, its primary and secondary ampere-turns are again equal, but in phase with each other, and, therefore, instead of neutralizing each other, their resultant produces a reactive drop in virtue of the core. Of course, when a unit is acting as a pure reactor, its core is saturated by a large d-c. excitation, and the reactance of the unit is reduced to a very small fraction of what it would otherwise be. In practise, this reactance is found to be of the order of three or four per cent, effective at the load terminals. This may appear as very small but it is about twice the reactance that an induction regulator of similar capacity introduces into the circuit, and causes considerable regulation at low power-factor loads. Regulation introduced by this reactive drop has to be taken care of by overwinding the secondary of the "boosting" unit if load is dominantly lagging, and overwinding the secondary of the "bucking" unit if the load is dominantly leading, or overwinding both secondaries for interchangeable units and for general application.

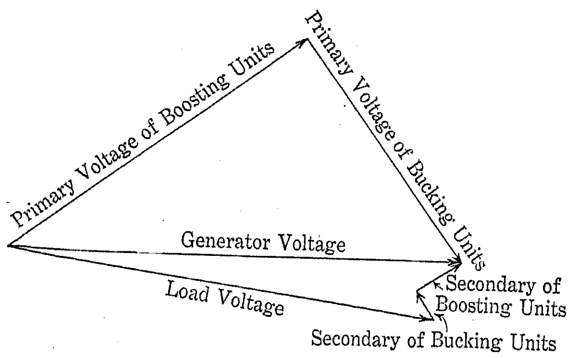

FIG. 16—VOLTAGE DIAGRAM OF REGULATOR AT NEUTRAL POINT WITH HIGH POWER-FACTOR LOAD

At intermediate values of load voltages between maximum and minimum, the primary and secondary load ampere-turns are not equal in either unit, the per cent difference between the primary and the secondary ampere-turns changing gradually (in the inverse order in the two units) as operation changes from maximum "boost" to maximum "buck," and produces a reactive drop. This reactive drop at intermediate values of load voltage does not do any harm of primary importance since any regulation that it causes may be corrected by raising the voltage to the desired degree by means of the d-c. control. The effect of reactance and d-c. excitation at those intermediate points is observed more in the exciting current and losses.

With unity power-factor loads, the reactive drop is in quadrature with the line voltage and, being rather large at the neutral point of voltage-regulation, raises the voltages across the units considerably as shown in the vector diagram of Fig. 16. This is mentioned to explain the vector relationship of the reactive drops which, however, are of no very particular practical harm or utility.

The influence of reactive drop on exciting current is this, that with the regulator running "bucking" at lagging power-factor loads, or "boosting" on leading power-factor loads, the reactive component of the

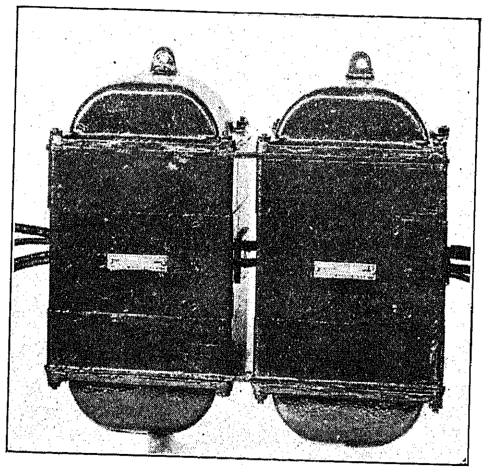

FIG. 17—A SMALL REGULATOR DESIGNED FOR CONTROL BY D-C. EXCITATION

secondary current acts as magnetizing current and therefore the primary current is reduced considerably; while at lagging power-factor loads with the regulator operating "boosting," or at leading power-factor loads with the regulator operating "bucking," the reactive component of the load current demagnetizes the core

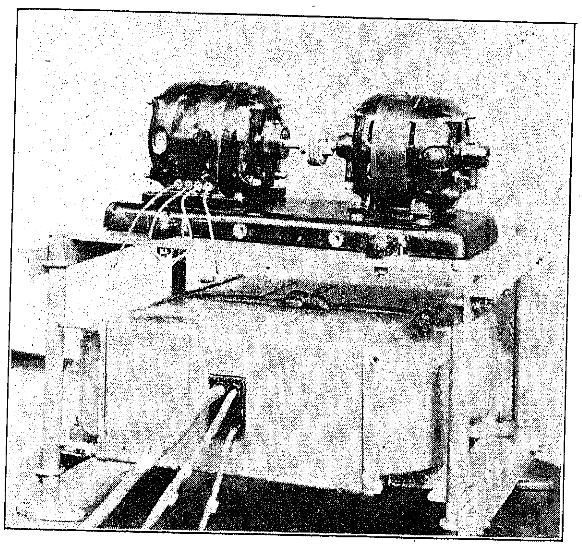

FIG. 18—A SMALL REGULATOR AND ITS MOTOR-GENERATOR SET FOR CONTROL OF REGULATION BY DIRECT CURRENT

and increases the exciting current and total current in the primary.

A number of such regulators have been built and tested in sizes from a few kv-a. up to 460-kv-a. feeders. Some of these have been put into service and are giving perfect satisfaction. Two small regulators are shown

in Figs. 17-19, and a large regulator for (460-kv-a. feeder) is shown in Figs. 20 and 21. The two units constituting the regulators are clearly seen in these figures. In Fig. 20 one is mounted on top of the other, although the subunits constituting each autotransformer unit are not easy to distinguish, because the outside coil is the d-c. coil and encloses both subunits at once. The top view of this is shown in Fig. 21. Fig. 22 is the voltage time curve on a feeder with and without the small regulator shown in Figs. 18-19.

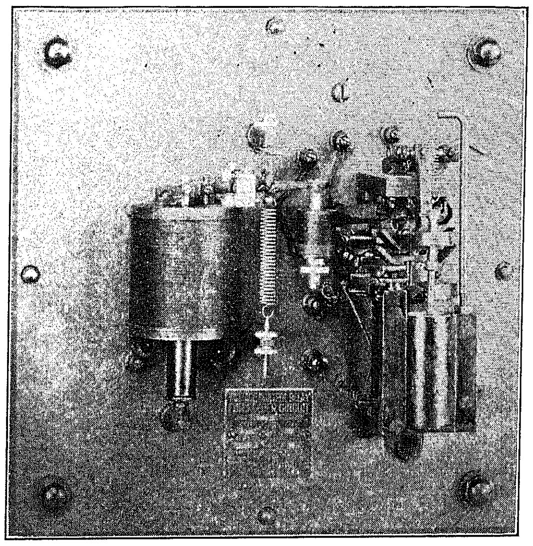

FIG. 19—AUTOMATIC CONTACT MAKING VOLTMETER FOR REGULATOR

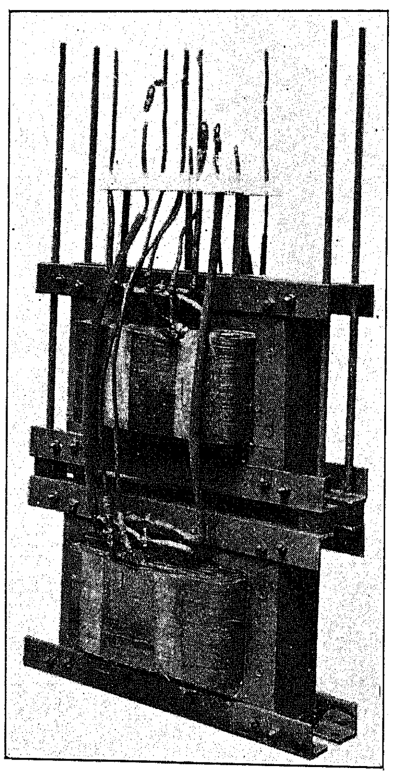

FIG. 20—CORE AND COILS OF A 46-KV-A. REGULATOR (460-KV-A. OUTPUT) FOR 60-CYCLE, 2300-VOLT CIRCUITS

AUTOMATIC CONTROL OF D-C. EXCITATION

Since a commercial voltage regulator must be automatic, it is necessary that the control of d-c. excitation be automatic and be governed from a contact-making voltmeter. This can be accomplished in a number of ways, one simple method being as follows: Referring to Fig. 23, No. 1 and No. 2 are the d-c. coils of the "boosting" and "bucking" units, and A and B are small generators capable of furnishing the $I^2 R$ losses in these d-c. windings of the regulator. Generator A is continuously excited, while the field of B is controlled by a contact-making voltmeter somewhat similar to those used for generator field control. If the field of B is open, A will excite winding No. 1 fully, the current flowing through the armature of B. Winding No. 2 having a large resistance, as compared with the armature of B, little or no current will flow through it. On the other hand, if the field of B is closed, the voltage of B opposes and neutralizes the voltage of A in the circuit of winding No. 1 and no current flows in it, while winding No. 2 is fully excited from B. By varying the duration of closing and opening of the field of B, or by cutting resistance in and out at suitably fast intervals of proper duration, any desired ratio of d-c. excitation in the windings No. 1 and No. 2 may be obtained. D-c. generators and automatic control equipment are shown in Figs. 18 and 19.

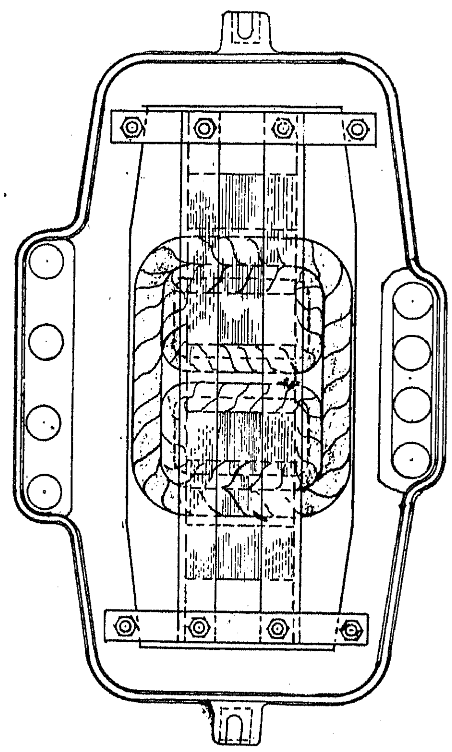

FIG. 21

WAVE-SHAPE

A large number of oscillograms were taken on some of these regulators, and those which are representative of various conditions of operation are here reproduced.

No-Load Oscillograms

Fig. 24 represents the maximum "boosting" condition. Excellent wave shape is observed in the voltages of generators, feeder, secondary of "boosting" unit, and in the total secondary voltage. The voltage of the "bucking" unit (the saturated unit in this case) is considerably distorted, but its effective value is only about one fifth of one per cent, and therefore does not sensibly affect the feeder voltage.

Fig. 25 represents the maximum "bucking" condition. Again, those voltages which are of any importance have excellent wave-shape. Inasmuch as it is the "boosting" unit which is saturated in this case, the distorted voltage belongs to it.

Fig. 26 represents the "neutral" condition. In this case the secondary voltages of the two units are opposed to each other and practically neutralize each other, except for difference in their wave shape which leaves a residue of peculiar wave-shape as the total resultant secondary voltage. The effective value of this was immeasurably small.

Full-Load Tests

Fig. 27 represents the maximum "boosting" condition on a water box load. Both generator and feeder voltages are seen to be excellent. Maximum distortion naturally occurs in the saturated "bucking" unit: The distortion is small and the voltage is negligible.

Fig. 28 represents the maximum "bucking" condition and was also taken on a water box load. Wave-shape is similar to the preceding case. Of particular interest are the current waves shown in this figure. The line current is symmetrical and of good wave-shape; but the coil-current, *i. e.*, the current in one branch of the multiple paths, is unsymmetrical, showing the circulating second harmonic current very prominently by the succession of peaked and flat half-cycles.

Fig. 29 represents the "neutral" condition. The high reactance and high exciting current ocurring at this condition have impressed on the load voltage and current a visible mark of the general wave-shape of exciting current of a transformer.

Effect of Low Power Factor and Dynamic Loads

To secure data on the performance of the regulator on low power factors and motor loads, a large series of tests was made on a synchronous motor load.

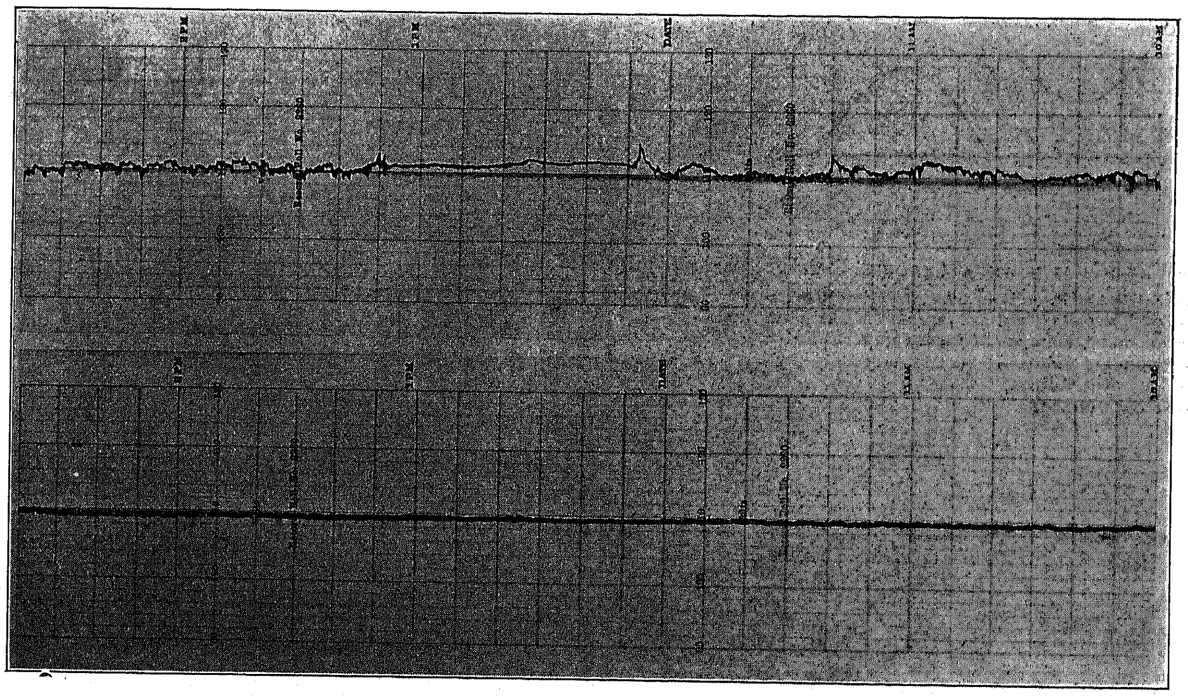

Fig. 22—Regulation Chart of a Circuit with and without the Regulator

Fig. 30 represents unity power-factor load on a synchronous motor at maximum "boosting" condition and differs in no essential respect from those for a water-box load, except that feeder and generator voltages are purer in shape on account of the fact that a motor of

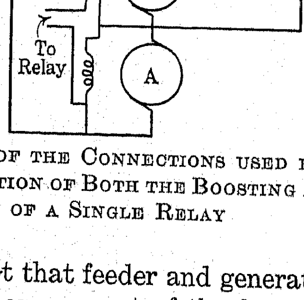

Fig. 23—One of the Connections used for Controlling the D-C. Excitation of Both the Boosting and the Bucking Units by Means of a Single Relay

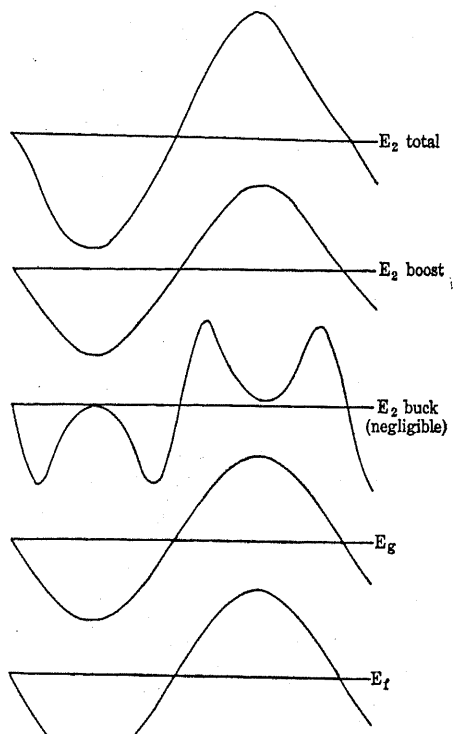

FIG. 24—WAVE-SHAPES IN A CIRCUIT CONTROLLED BY D-C. EXCITED REGULATOR. NO-LOAD, MAXIMUM BOOST CONDITION

E_2 total = Total secondary voltage (across the series windings)
E_2 boost = Secondary voltage of boosting unit
E_2 buck = Secondary voltage of bucking unit
E_g = Generator voltage.
E_f = Feeder voltage.

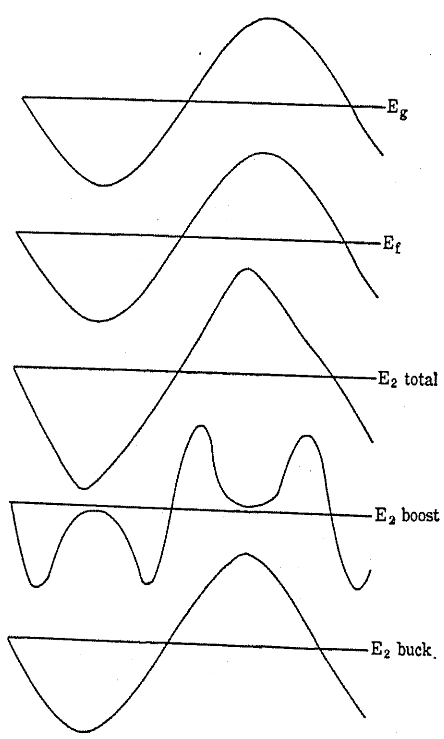

FIG. 25—WAVE-SHAPES UNDER NO-LOAD, MAXIMUM BUCK CONDITION

proper design tends to maintain the line voltage in pure form. However, the current taken by a motor tends to be considerably distorted if there is an appreciable distortion in the line voltage, due to the fact that the motor short-circuits those harmonics which do not exist in its own e. m. f. The distortion in the total series secondary voltage is negligible as a percentage of the load voltage.

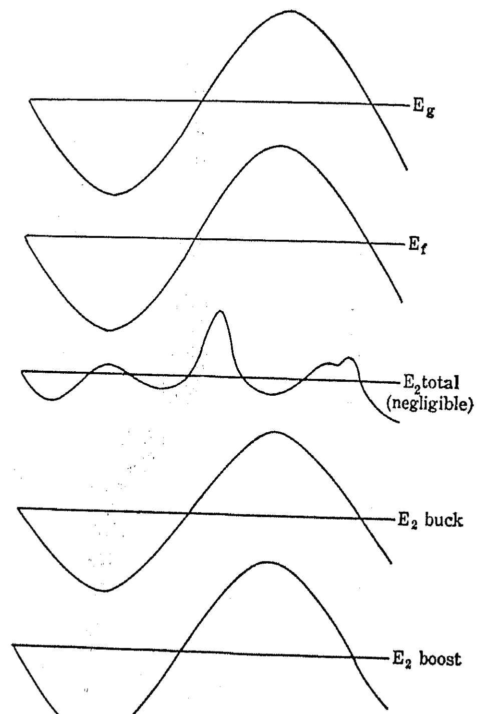

FIG. 26—WAVE-SHAPE AT NO-LOAD, NEUTRAL POSITION

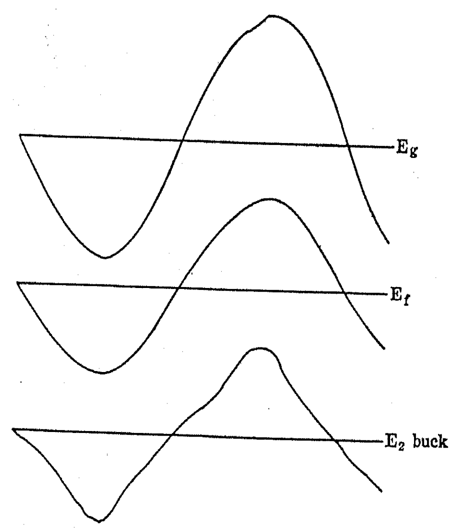

FIG. 27—WAVE-SHAPES AT UNITY POWER FACTOR, FULL-LOAD, MAXIMUM BOOST

Fig. 31 represents the case of 84 per cent leading power-factor at the maximum "boosting" condition. The load voltage is still pure, but the generator voltage shows some distortion. It may not be amiss to emphasize here the fact that a certain amount of wave distortion at full loads of various power-factors is a

common characteristic of many commercial generators of medium and small sizes and therefore it must not be assumed that all wave distortions observed in these tests were due to the regulator.

Fig. 32 represents the case of 70 per cent lagging power-factor on synchronous motor. All the important quantities have good wave-shape. The distortion in

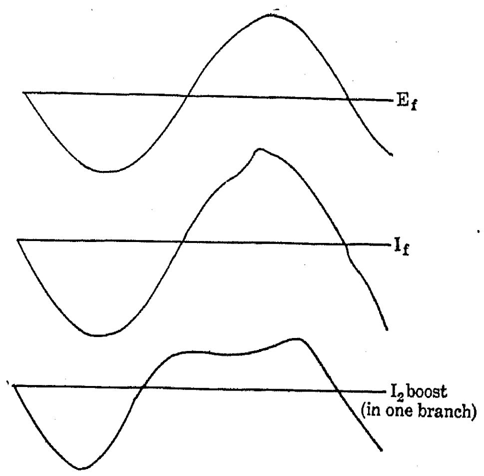

Fig. 28—Wave-Shapes at Unity Power-Factor, Full Load, Maximum Buck

Note that the currents in the two branches of the series windings of the boosting unit are unsymmetrical due to large circulating second harmonic component, but their resultant, which is the feeder current (I_f), is very symmetrical.

the secondary voltage is not distinguishable in the feeder voltage. The coil current in the saturated ("bucking") unit shows the circulating second harmonic. The current in the primary coil betrays the wave shape of excitation current.

Switching Oscillograms

Fig. 33 represents switching the d-c. excitation so as

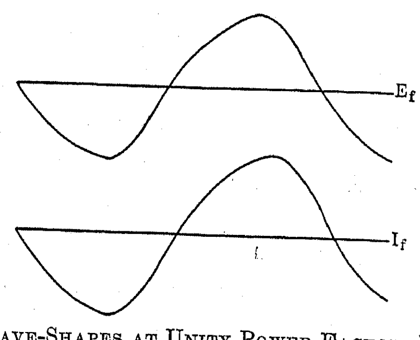

Fig. 29—Wave-Shapes at Unity Power-Factor, Full-Load, Neutral Position

to change the operation from maximum "boosting" to maximum "bucking" at no load. It takes a good many cycles before the change in the direct current shows itself in the secondary resultant voltage. This latter, which "boosts" the load voltage, gradually dies down to zero and then builds up in reverse phase angle to "buck" the load voltage.

Fig. 34 represents a similar switching test but made under full load. Here the secondary resultant voltage does not die down to zero during the transition but

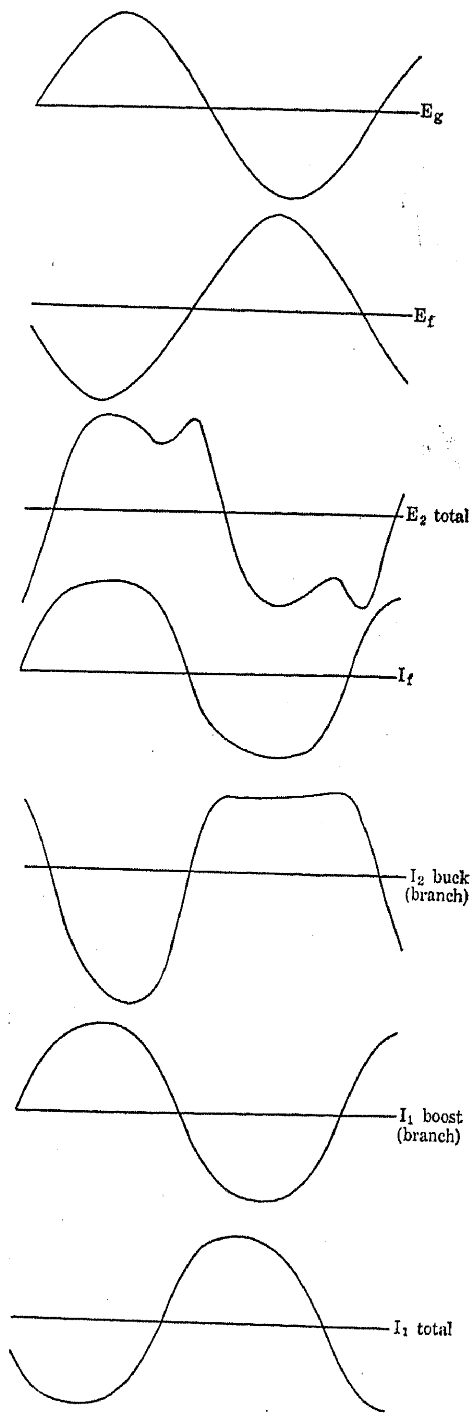

Fig. 30—Wave-Shapes at Unity Power-Factor, Synchronous Motor Load, Maximum Boost

Note that the voltage wave-shapes are very much improved but the current wave-shapes are not so good. The effect of circulating second harmonic current is seen in the branch current of the secondary of the saturated bucking unit, "I_2 buck." No circulating second harmonic is found in the unsaturated boosting unit.

builds up to about double value and then comes down to normal value, reversing its phase angle gradually during the transition. The total secondary voltage does not

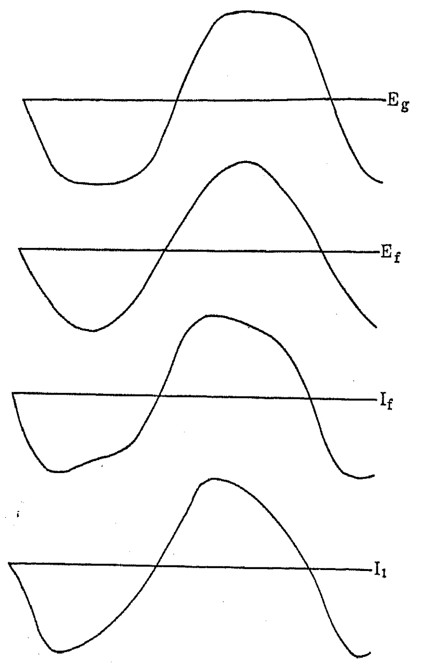

FIG. 31—WAVE-SHAPES UNDER CONDITIONS SIMILAR TO THOSE OF FIG. 30 EXCEPT THAT THE POWER FACTOR IS ABOUT 85 PER CENT LEADING

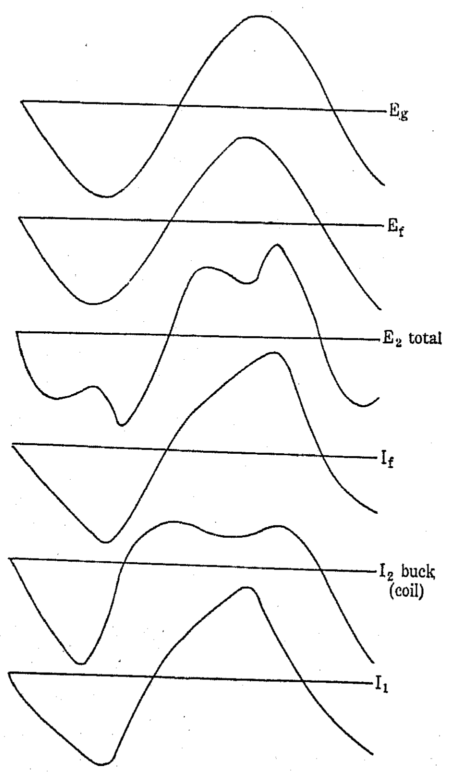

FIG. 32—CONDITIONS SIMILAR TO THOSE OF FIGS. 30 AND 31, EXCEPT THAT THE POWER FACTOR IS LAGGING, AND THE VOLTAGE IS ONLY PARTIALLY BOOSTING

come down to zero in this case because the large load-current flowing through it produces a large reactive drop.

ADVANTAGES AND LIMITATIONS OF THIS TYPE OF REGULATOR

A. *The main advantages are:*

1. *Speed of Operation.* While the average induction regulator requires 8 to 12 seconds to go from maximum "boost" to maximum "buck," this type of a voltage regulator requires only between one and two seconds for a similar change. The time required is the combination of the time constants of the regulator, d-c. generator, and control equipment.

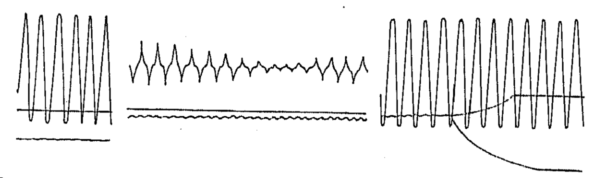

FIG. 33—SWITCHING TEST AT NO-LOAD, CHANGING FROM MAXIMUM BOOST TO MAXIMUM BUCK. FILM CUT AND SHORTENED AT TWO POINTS. TOP WAVE: TOTAL SECONDARY SERIES VOLTAGE

Note how it decreases to zero and then builds up in reversed phase, so as to change from "boost" to "buck." Middle and bottom waves: the D-C. currents in the two units one building up, the other dying down

2. *Suitability for High Voltages.* Since the construction of this regulator is that of a transformer, it can be designed for any voltage desired, while induction type regulators may be said to have an upper limit of 13,000 volts. For circuits above that voltage, an induction regulator requires two transformers, one for its primary, and one for its secondary.

3. *Greater Mechanical Strength.* Since this type of a regulator has no moving parts, it can be built much stronger than movable or rotatable regulators to withstand the short-circuit stresses which are very severe in

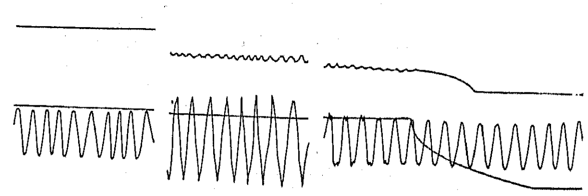

FIG. 34—SWITCHING TEST AT FULL-LOAD, CHANGING FROM MAXIMUM BOOST TO MAXIMUM BUCK. BOTTOM WAVE: TOTAL SECONDARY SERIES VOLTAGE

Note that it does not diminish but actually increases during the transition period, the change from *boost* to *buck* being accomplished by a gradual reversal in the phase of the total secondary (series) voltage

all regulators on account of their autotransformer connection. The ability of this static regulator to withstand short circuits is further improved by its higher inherent reactance. This advantage probably is not as great as one might expect on account of the fact that on short circuit all autotransformers are severely overexcited and hence the saturation of the cores must be reckoned with.

B. *The limitations of this type of a regulator are:*

1. *Higher cost for low voltages.* At 6600 volts or

lower, this type of a regulator costs somewhat more than an induction regulator of the same capacity. This is due to the fact that the equivalent transformer rating of such a regulator is about four times the maximum kv-a. which it transforms. Thus, first, the fact that a "boosting" and a "bucking" unit must be provided, doubles the size of the apparatus. Second, the fact that d-c. ampere-turns of sufficient capacity to neutralize the total primary and secondary a-c. ampere-turns must be provided for each unit, at least doubles the size of the apparatus again, and thus we have a regulator of which the equivalent transformer capacity is about four times the maximum kv-a. which it transforms.

However, at those high voltages for which an induction regulator would need insulating transformers, this type of regulator may prove more economical.

2. *Higher Losses.* Both on account of the duplication and multiplicity of windings, which tends to increase the copper losses, and on account of the superposed d-c-a-c. excitation of the core, which tends to increase the core loss, this type of regulator has higher losses than an equivalent induction regulator.

On account of these limitations, this regulator is as yet considered in a developmental stage and is not available for general commercial use.

Historical Note

Attempts to make use of the saturation characteristics of iron for purposes of voltage regulation date as far back as 1900. A. R. Everest, W. T. Williams and William Stanley experimented with various connections, in all of which, however, no direct current was used. The basic principle underlying them was the fact that a theoretically saturated reactor would not sensibly alter its voltage drop with varying loads but would alter its phase angle. On no-load, such a series reactor would be made to carry a magnetizing current load, and its drop, being in phase with the line voltage, would lower the feeder voltage. When a unity power-factor load is put on, the resultant power-factor of the current flowing through the reactor would be very high and the drop through the reactor would be shifted into approximate quadrature with the line voltage. Thus, the full-load feeder voltage would become higher than at no-load. Looking back with our present day knowledge, we can see that such schemes could not be a success, inasmuch as they yield no means for control and depend on a high power factor of load for their operation, being inoperative for low power-factor loads.

One of the earliest workers with d-c. excited reactors for regulation was Francis B. Crocker. He used an autotransformer to obtain a boost in voltage which might be neutralized by a reactive drop as desired. By putting d-c. excitation on the autotransformer, the exciting current of the latter could be altered, and this exciting current being large would produce a reactive drop and regulation through the leakage reactance between primary and secondary. The scheme was intended for application to rotary converters, with two d-c. coils on the autotransformer, one being in shunt and the other in series with the d-c. lines, so that the variations in the d-c. load would automatically control the a-c. voltage.

The regulator connection described in the present paper is the William Stanley connection to which d-c. control is added. Considerable work has been done recently by E. F. Alexanderson on the applications of d-c. excited reactors. Much inspiration has come from him in these investigations both directly and indirectly.

Shunt Reactor Application

The shunt reactor application of such a device for the neutralization of the charging current of transmission lines has been considered in a number of instances by operating and consulting engineers, but no actual application has as yet been carried out. In such service, not only would such a device reduce the charging current load on the central station, but also would control the voltage of the line. In this latter service it would take the place of an underexcited synchronous condenser, and would have a number of advantages over it, namely, (a) a static device with no rotating parts and requiring practically no attention, (b) can be designed for any voltage, and, (c) would be more economical and more efficient than a synchronous condenser outfit requiring transformers. It would, however, have three disadvantages over the synchronous condenser outfit, in that, (a) while the voltage-regulating character of the synchronous condenser is inherent and very marked, so that it could perform to quite an extent without a contact making voltmeter control on its field, the performance of the static device has to be dependent on such a control and is therefore somewhat slower. In order that the losses of this device may not be excessive, it has to be operated not much above the upper bend of the magnetization curve and hence advantage can not be taken very economically of the flat saturation portion of the volt-ampere curve which corresponds to high losses and also to greater distortion. (b) While a synchronous condenser can operate either leading or lagging, this device can operate only lagging. (The range of lagging load, minimum to maximum, could easily be made 1 to 10 or 20). (c) The static device is bound to have a certain amount of wave distortion. The harmonics, however, would be in the current not appreciably in the voltage, and would, therefore, probably not do any appreciable harm except as a small useless reactive kv-a. to be furnished from the generating system. What wave-shapes of current are to be expected may be estimated from the following oscillograms.[2] Any such application must, necessarily, be polyphase, and although there are many possible poly-

2. The author is indebted to Messrs. L. H. Junken and E. W. Hawley for the oscillograms in Figs. 35-45.

phase connections, only a few have reasonably good wave form and all-around desirability.

It is interesting to note that polyphase applications are capable of yielding much better wave-shape than single-phase applications, on account of the fact that the triple harmonic, the most prominent harmonic, can be eliminated from the lines and circulated internally in three-phase connections but not in single-phase connections.

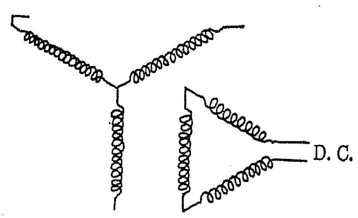

FIG. 35

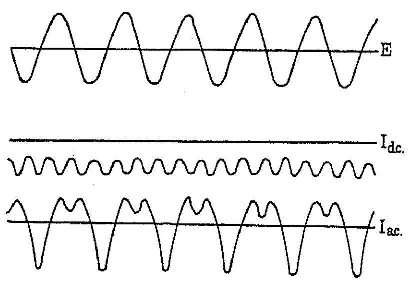

FIG. 36—WAVE-SHAPES IN THE CIRCUIT OF FIG. 35. TOP WAVE: LINE-TO-NEUTRAL VOLTAGE. MIDDLE WAVE: CURRENT IN D-C. CIRCUIT. BOTTOM WAVE: LINE CURRENT

Note the third harmonic in the D-C. circuit, and the second harmonic n the A-C. lines

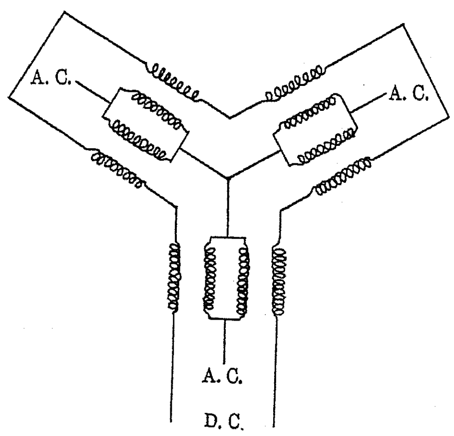

FIG. 37

OSCILLOGRAMS OF POLYPHASE SHUNT REACTORS

Y-Delta Connection of Three-Units.

In this connection (Fig. 35) the direct current is circulated in the delta. It is self-evident from theoretical considerations and may be observed in the oscillograms of Fig. 36 that this connection forces a third harmonic current into the d-c. circuit and a second harmonic into the a-c. lines, and is therefore worthless for such applications.

Y-Delta Connection with Six-Units.

In this connection (Fig. 37), the a-c. current having two parallel paths (excited by d-c. in opposite direc-

tions) the even harmonic circulates between the two parallel subunits and does not appear in the lines, as will be observed in Fig. 38. This connection is one of

the best. If the two parallel subunits, constituting each phase, are built as in Figs. 3 or 4, the three d-c. windings may then be connected either in series or in parallel. Another possibility is to have two d-c. windings, each enclosing three polyphase subunits at once. The two d-c. windings may then be connected either in series or in parallel.

Y-Delta Connection with Six-Units, Parallel Connection on the D-C. Side. (*Fig. 39*)

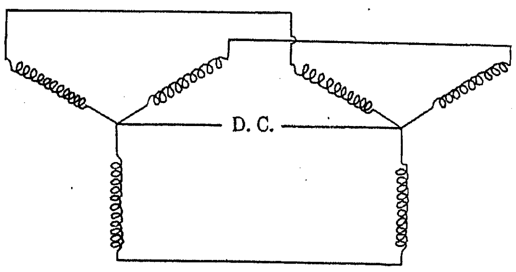

FIG. 42

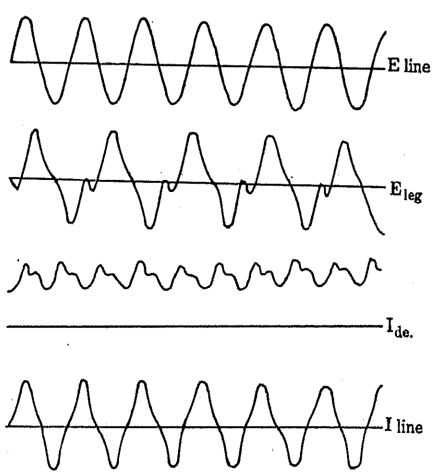

FIG. 43—WAVE-SHAPES IN THE CIRCUIT OF FIG. 42
Note the third harmonic in the leg voltage and D-C. current

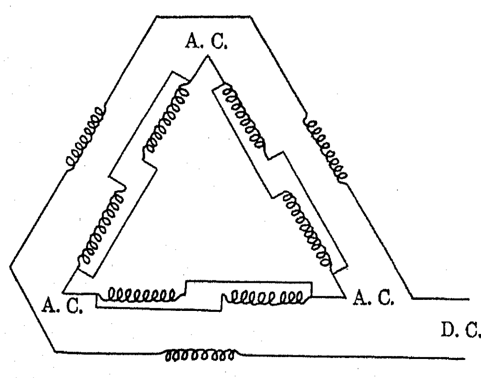

FIG. 44

In this connection the even harmonic currents circulate in the d-c. windings but do not appear in the external d-c. lines. Considerable third harmonic voltage is generated line-to-neutral. Fig. 40 shows excellent wave shape because it has been taken at only 26 per cent rated voltage. Fig. 41 is more representative, being taken at rated voltage. Fig. 40 has been given here to show how undervoltage improves wave shape, and this points to a possible solution of the problem of wave shape: to design for as low a density as is economically practicable.

Y-Y Connection. (*Fig. 42*)

This connection is economical in windings by circulating the direct current in the a-c. windings. It suffers from large third harmonic voltages line-to-neutral. If the neutral is grounded, this third harmonic voltage may be intensified to destructive values through line capacitance. If the neutral is isolated, the d-c. circuit would be subjected to destructive voltages in case of

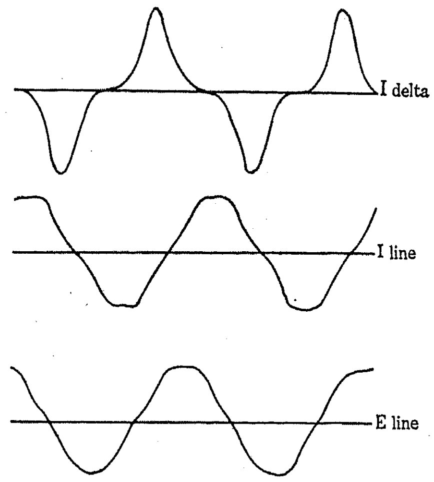

FIG. 45—WAVE-SHAPES IN THE CIRCUIT OF FIG. 44

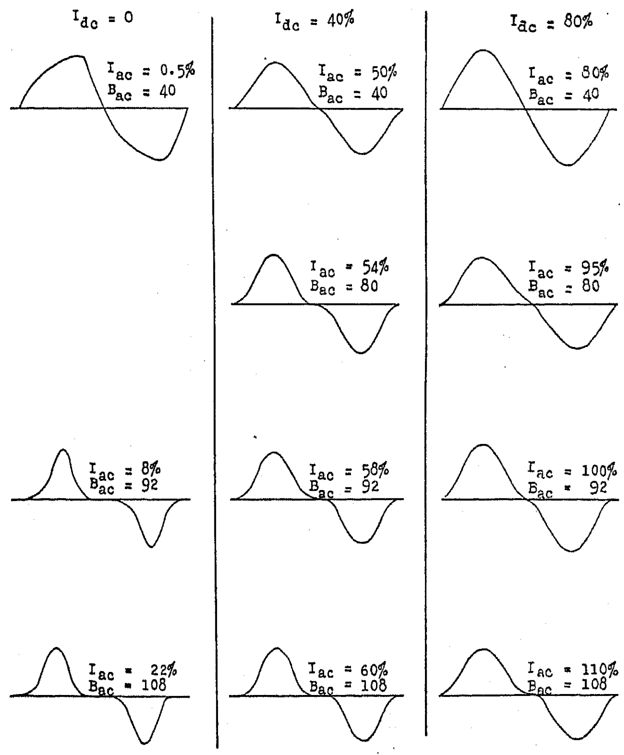

FIG. 46—OSCILLOGRAMS SHOWING THE EFFECT OF A-C. DENSITY, AND OF THE RATIO OF D-C. TO A-C. EXCITATION, ON WAVE-SHAPE OF A SHUNT REACTOR

line grounds. This connection can be used only if equipped with a delta winding to circulate the third, and the neutral solidly grounded. Fig. 43 shows the line voltage (normal rated value), line current, leg voltage and d-c. current. Note the harmonics in the leg voltage and in the neutral current.

Delta-Delta Connection. (*Fig. 44*)

This connection, although not very suitable for the highest voltages, gives a better wave-form than most others. The wave-shape of current (Fig. 45) is pretty good considering the shape of the impressed line voltage. Fifth harmonic is evident in the line current, third harmonic in the delta current.

General Remarks on Wave Shape of Shunt Reactor

Although the second harmonic is eliminated from the lines by means of a suitable parallel connection in each phase, and the third harmonic is eliminated by virtue of a symmetrical three-phase connection, no simple means seems to be available for the complete elimination of the fifth, seventh, and higher odd harmonics from the line current, and it appears, therefore, that in any shunt reactor application, these harmonics will have to be tolerated to some extent. However, some oscillograms to be discussed below show that these harmonics can be reduced to negligible proportions by designing the reactors for rather low densities.

The three-phase oscillograms discussed in the foregoing were taken by very small laboratory apparatus and are not very representative of what would be obtained by power size apparatus. They were given and discussed here so as to show the relative merits of different three-phase connections. To get an exact idea of the wave shape which would be obtained on power size apparatus, some single-phase tests were made on a reactor of suitable design loaded to as high as 500 kv-a. The oscillograms taken under various conditions are grouped in Fig. 46 in three columns. The first column shows the exciting current wave-shapes at various core densities with no d-c. excitation. The second column shows wave-shapes at various densities with 50 per cent rated d-c. excitation, and the third column shows wave-shapes with 100 per cent rated d-c. excitation. It is evident that the larger the d-c. excitation and a-c. current, the purer is the wave-shape. The current wave at 80-kiloline density in the third column is so good that it seems to leave little to be desired. Judging from these oscillograms, it appears as though the additional a-c. current which is drawn on account of the presence of the d-c. current is very much purer in wave shape than the exciting current without d-c., and that therefore the numerical value of the harmonics at moderate densities are more or less constant or increase very little with increasing a-c. current drawn. Thus, with increasing a-c. current drawn, the percentage of the harmonics rapidly diminishes and the wave shape improves.

General Discussion of Core Loss

Rather large core losses were observed in these investigations due, no doubt, to large stray losses occasioned by leakage of flux to clamps and tank, for which reason also attempts at a theoretical calculation of the losses proved futile. One point is certain, that core loss increases very little as compared with the exciting current in the presence of d-c. excitation. In the light of these considerations, it will be evident that considerable reduction of losses may be accomplished by confining the leakage flux and by limiting the portion of the core which is saturated. These two objectives are accomplished in a large measure by a core construction as shown in Fig. 4. Here the middle yoke, carrying only the a-c. flux and no d-c. flux, prevents the fringing and flaring out of the a-c. flux as it comes out from the inside core legs, and also limits the portion of the core which carries superposed d-c-a-c. flux in a saturated condition. This aspect of the investigation is not as yet completed. However, this is a matter of improvement and refinement, and does not directly affect the operation of the devices in the applications described in the foregoing.

The Application of the Saturated-Core Reactor and Regulator

BY DAVID K. BLAKE
Associate, A. I. E. E.
Central Station Engineering Department, General Electric Company, Schenectady, N. Y.

Review of the Subject.—The purpose of this paper is to state briefly the use of voltage regulators and reactors in transmission and distribution systems and to mention operating requirements which might be best met by the use of saturated-core type regulators or reactors. The saturated-core type regulator and reactor consists of an iron core with two sets of coils. One set of coils is connected to a d-c. circuit and the other set to an a-c. circuit. The theory, design and construction of the saturated-core type regulator and reactor is discussed in A. Boyajian's paper.

* * * * *

Voltage Regulator

The economic operation of large transmission and distribution systems and the rendering of satisfactory electric service from these systems require voltage regulation and control in various parts of the system, owing to the change in voltage with load variations. Generator voltage regulators are generally employed to maintain constant voltage at either the generator or substation bus. Synchronous condensers are also used extensively to maintain a constant voltage at a substation bus by supplying wattless kv-a. to the system, thereby changing the power factor of the energy transmitted over the transmission lines. Induction type regulators are generally used in distribution feeder-circuits to maintain a constant voltage at the feeder load center. To a less extent they are used in industrial plants for regulating lighting circuits, electric furnace loads, welding loads, and electrolytic processes.

The tying together of two large stations or systems and the formation of networks or meshes by the interconnection of substations, generating stations or systems requires the use of voltage regulating equipment to control the voltage, the flow of reactive kv-a., and the energy component. Synchronous condensers are used to meet many of these conditions but there are some conditions where they will not accomplish all that is required. Synchronous condensers are generally used to hold constant voltage at certain points of the system by supplying reactive kv-a. to the system. The condensers have no control over the division of the reactive kv-a. flowing in two or more parallel paths between two points as this is determined by the impedance of the paths. Induction regulators and transformer tap-changing equipments are also used to hold constant voltage at certain points of the system, and where required, to determine the value and path of flow of either reactive kv-a., energy component, or both. Where it is required that the voltage adjustment shall follow a smooth curve, the tap-changing equipment alone is not applicable, as this equipment changes the voltage in steps as great as 2½ per cent and 5 per cent. The induction regulator, the combination of tap-changing equipment and induction regulator, and the synchronous booster give a smooth voltage adjustment. The induction regulator and the synchronous booster, however, cannot be built for very high voltages and it is necessary, therefore, on a high-tension line to use shunt and series transformers between the regulator or booster and the high-tension line or bus.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

The construction of the saturated core type regulator is similar to a transformer, consisting of an iron core and coils. The saturated core type regulator, therefore, can be built for as high a voltage as can the transformer. For a 220,000-volt circuit a 220,000-volt saturated-core regulator could be built. From the voltage standpoint then, in order to justify the choice of the saturated core type regulator, it must have a lower annual charge than either the induction regulator or synchronous booster with their accompanying transformer equipment. No large, high-voltage, saturated core regulators have been built so far, and therefore, the operation and exact costs are uncertain; but from a general study of the situation the indications are that the saturated core regulator would probably be cheaper for high voltage than the well-known combination of induction regulators with shunt and series transformers.

The induction regulator meets most requirements for distribution feeder-circuits. It requires about 8 to 11 sec. to go from full buck to full boost. One of the important factors in perceptible lamp flicker is the time required for the voltage to return to normal after a sudden change in value. For satisfactory service to lighting, it is important that fluctuating loads, which will cause sudden voltage changes at the feeder load-center, should not be supplied from the combined power and lighting feeder. They should be supplied from a general power feeder or from a special feeder entailing a consequent increase in distribution cost. Even general power feeders have connected to them resistance and motor loads which require close voltage regulation. If the fluctuating load is of sufficient magnitude, it would cause voltage changes at the substation which would affect the other feeders. Such voltage fluctuations would not be permissible and would prohibit connecting the load to the system.

The automatic tap-changing regulator has been used to a small extent for quick voltage adjustment. It requires about three seconds to go from full buck to full boost. It is limited in ampere capacity and voltage, it costs more than the induction regulator and has a high maintenance.

The synchronous booster is fast but expensive; it is noisy and has a high maintenance.

The saturated-core regulator can go from full buck to full boost in about one or two seconds, which is two to three times as fast as the tap-changing regulator and five to eleven times as fast as the induction regulator. While one or two seconds may not be a fast enough adjustment for some loads, it should be sufficiently fast to permit connecting most fluctuating loads, which previously required special feeders, to the regular feeders and connecting loads to the system which could not otherwise be connected. Where the tree-system of distribution feeder is used, the loads between the substation bus and the load center will still have voltage fluctuations. These fluctuations are due to the voltage drop from the substation bus to the load-center and for a given circuit the amplitude of the fluctuations depends on the proximity of the load to the substation. The load-center system of distribution eliminates this difficulty. Any loads connected to the same branch or mains as the fluctuating load are also subject to voltage fluctuations, the amplitude of which depends on the distance from the load center. Many important industrial loads which require close voltage regulation could be connected to mains other than the one supplying fluctuating loads. In other cases, it may be more economical or feasible to equip the industrial load with a saturated core regulator.

The saturated-core regulator is applicable to laboratory work where close regulation and fast operation are required to give a stable condition of voltage. A saturated-core type regulator was developed for the Mellon Institute of Industrial Research, Pittsburgh, Pa. to correct the voltage fluctuation of $\pm$ 6 volts occurring over their 110-volt supply. Very close regulation was needed in order to keep constant voltage on various heating units under tests.

The saturated-core regulator has higher losses and costs about 25 per cent to 50 per cent more than the induction regulator. It, therefore, might be used in place of the induction regulator only when fast adjustment is required or in high-voltage circuits. The saturated core regulator is still in a developmental stage and is not available for general commercial use.

Current-Limiting Reactor

The most frequent disturbances to which a transmission and distribution system is subjected are short circuits or heavy overloads which cause excessive currents, low frequency, and low voltage over the system. The effect over the system of these disturbances depends on the layout, extent, and capacity of the system and its protective equipment. The protective equipment consists first, of relays and oil circuit breakers to remove the faulty circuit from the system, and second, of series reactors or neutral grounding resistors to limit the amount of current flow into the fault.

The air-core type of current-limiting reactor is used in busses, tie lines, feeders and generator circuits, as

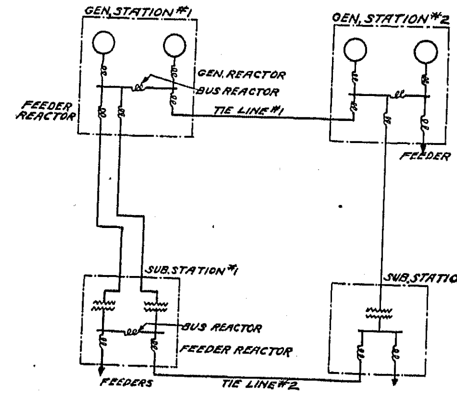

Fig. 1—Application of Current-Limiting Reactors to a Central Station System

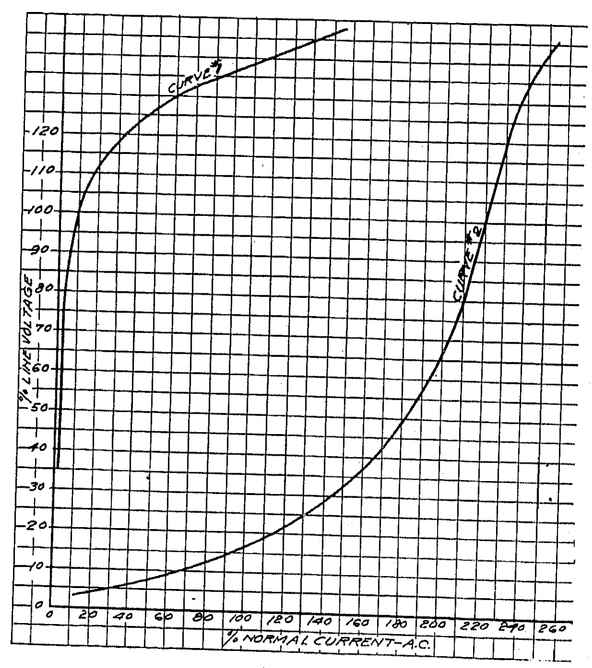

Fig. 2—Characteristic Curve of the Iron Core Reactor with and without d-c. Excitation

shown in Fig. 1. The voltage drop across the air-core reactor increases directly with the current flowing through it. The voltage drop across the iron core reactor increases directly with the current up to a certain point only, and then the voltage curve bends over as shown by Curve 1, Fig. 2. If the iron core reactor is magnetically saturated by the application of direct current, then the voltage drop across the reactor increases in a greater proportion than the cur-

rent between certain points as shown by Curve 2, Fig. 2. It is this characteristic of the saturated core type reactor which will determine its application in place of the air-core type reactor. The reactor can be designed with a ratio, of reactance under short circuit to reactance at normal load of 3 to 1, *i. e.*, if the normal load reactance is 10 per cent, the reactance under short circuit will be about 30 per cent. Three and one third times normal, then, would be the maximum current possible to force through the reactor at normal voltage of the system.

The change from normal value of reactance to short-circuit value is not instantaneous, but is similar to the time element of the synchronous reactance of an alternator under short-circuit conditions. Magnetic flux in the core cannot change instantly, but changes along an exponential curve of time. Approximately full reactance will be reached only after 0.08 to 0.16 sec. Since the reactance is not instantly available, the saturated core type reactor possesses no advantage over the air-core type reactor in protecting a system from the initial electromagnetic forces under short-circuit conditions. It does, however, reduce the current to be interrupted by an oil circuit breaker in series with the reactor, since the full protective effect is realized in a time shorter than the usual interval between the beginning of the short circuit and the parting of the oil circuit breaker contacts.

Current-limiting reactors are used in generator circuits of large modern generating stations, using the isolated phase arrangement of busses, to prevent a generator failure from being virtually a bus short circuit. They are also used in the circuits of generators of old design which will not stand short-circuit stresses. Bus reactors are used to sectionalize the main bus to limit the amount of power that can be transferred from a good bus section to a faulty bus section. Feeder reactors are used to limit the amount of power flow into a feeder fault. Limiting the flow of power into a fault by reactors reduces the duty on oil circuit breakers, the stresses and heating of busses, of cables, of current transformers and of disconnecting switches, and maintains the system voltage. Reactors in tie-lines between stations, substations and different systems are effective in limiting power transfer through the tie-lines under short-circuit conditions. They are particularly desirable where a small kv-a. capacity station, substation or system ties in with a large kv-a. capacity station, substation or system. The air-core type of current-limiting reactors successfully meets most requirements for generator, bus, feeder and tie-line reactors. In case the air-core reactor, to give the protection required, would cause too large a voltage drop under normal load, the saturated core reactor may then be substituted. In such cases, the saturated core reactor could be used giving approximately 33 per cent of the reactive drop of the air-core reactor under normal load. This type of reactor has several times the loss of the air-core type and a much greater cost, both of which will prevent its use except in special cases.

Application of the Saturated-Core Type Reactor to Station Auxiliary Bus

To improve the station economy and insure continuity of service, house alternators for the station auxiliaries are operated in parallel with the main generators. The house alternator is usually of a lower voltage than the main generators and is usually connected to the main generator bus through house transformers. The power transfer through the house transformers may be from the main generator bus to the house service bus or vice versa, depending on operating and load conditions.

Certain auxiliaries such as boiler feed water pumps, circulating water pumps and motor-driven exciters are essential to the operation of the station and they must be protected from interruption due to system disturbances.

The effect of the system disturbances on the continuous auxiliaries can be reduced by dividing the house service bus into sections with a current-limiting reactor

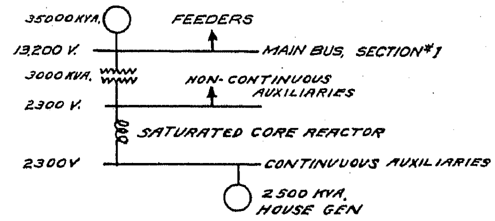

Fig. 3—Saturated-Core Current-Limiting Reactor Applied to Station Auxiliary Bus

as shown in Fig. 3. The house transformer and non-continuous auxiliaries would be connected to one section and the house alternator and continuous auxiliaries to the other section. The effectiveness of the reactor depends upon its ohmic value, the greater the reactance the less effect will the disturbance have on the house alternator and continuous auxiliaries. The reactor will not be required to carry the full kilovolt ampere output of the house generator or transformer and, therefore, may be designed for a smaller voltage drop than if designed for full output of either house transformer or generator. Even under this condition the ohmic value required will probably be so high that the voltage drop would be prohibitive. Therefore, the air-core type of reactor is undesirable for this service since its ohmic value is constant. The saturated-core type of reactor may be suitable for this service since its ohmic value increases with an increase in alternating current. The saturated core reactor would be designed for the required reactance under short-circuit conditions. The reactance under normal conditions could be about 33 per cent of the short-circuit reactance.

An installation of saturated-core current-limiting reactors connected similar to Fig. 3 is now in operation at the new Cahokia Station of the Union Electric Light & Power Co. near East St. Louis, Ill. The house transformers are rated at 3000-kv-a. and the house turbine at 2500 kv-a. The reactors are designed to carry 660 kv-a. under normal conditions at a 15 per cent reactance drop. The short-circuit reactance is approximately 38.5 per cent, which means that it is impossible to force more than 1710 kv-a. through the reactors at normal voltage. If the house generator should be carrying full load with 660 kv-a. flowing from the continuous bus through the reactors to the non-continuous bus, it would be impossible to add more than 1050 kv-a. or 42 per cent overload to the house generator in case of a disturbance on either the system, main generator bus or non-continuous bus. If it is required that the reactor shall carry the continuous auxiliaries in case of the house alternator failure, the

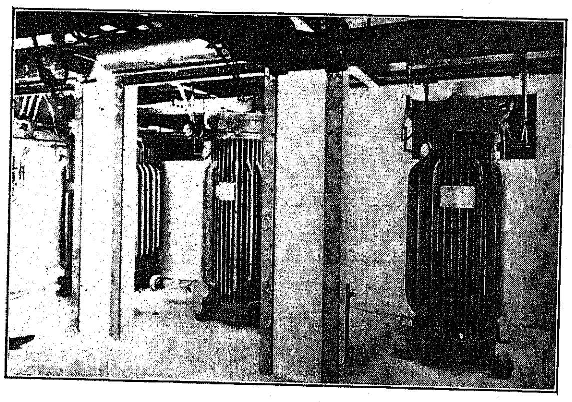

Fig. 4—Installation of Single-Phase Auxiliary Bus Saturated-Core Reactors at the Cahokia Station of the Union Electric Light & Power Company

reactor would have to be designed with less reactance but would not be so effective. This requirement may be best taken care of by oil circuit breaker and relay equipment which would shunt the reactor in case of house alternator trouble. Fig. 4 gives some idea of the general appearance and size of the reactors. Each single-phase unit requires 15.7 amperes, 125-volt d-c. excitation. The estimated total loss is approximately 7 kw. for each unit.

Variable Reactance

The saturated-core reactor may be used as a variable reactance by varying the d-c. excitation. It is being used in this manner in transoceanic radio communication to modulate the antenna current of the Alexanderson alternator and to control the speed of the induction motor driving the Alexanderson alternator.

When used to modulate the antenna current the variable reactance is known as the "magnetic amplifier." It is inductively coupled to the antenna circuit by a special combination of tuned circuits. By this method the small current in the d-c. winding of the amplifier can be made to control a very large antenna current. The d-c. circuit may be controlled by a telegraph key or amplified telephone current. Because of its fast magnetic action it is well adapted to high-speed telegraphic transmission and to telephonic transmission.

When used to control the speed of the induction motor the reactor is connected in series with the motor primary leads. The d-c. excitation of the reactor is controlled by a voltage regulator similar to a generator voltage regulator. The voltage regulator is controlled by a rectified current from a tuned circuit connected to one of the coils of the Alexanderson alternator. The tuned circuit resonates at a frequency slightly above normal. When the antenna circuit is detuned by the magnetic amplifier, the alternator drops its load. In order to reduce the power input to the motor, after losing its load, the speed tends to increase but is checked by the action of the tuned circuit, the regulator and the reactor which reduces the voltage applied to the motor. Reducing the voltage applied to the motor reduces the power input to the motor to correspond with the light load condition at normal speed. A more complete description of the magnetic amplifier and speed-regulating equipment may be found in the *General Electric Review*, October, 1920.[1]

The saturated-core reactor could be used as a variable shunt reactance to control the lagging kilovolt-ampere required to counteract the charging current of very long, high-voltage transmission lines during light load conditions, but up to the present time they have seemed unnecessary as synchronous condensers are required to supply leading kilovolt-amperes under heavy load conditions and either inherently possess or can be built with sufficient lagging kilovolt-amperes to meet the requirements at little added expense. For example, a 250-mile 220-kv. transmission line requires at no load, 31,200-kv-a. lagging at the receiver end to maintain the receiver voltage equal in value to the generator end. For a 120,000-kw. unity power factor load 16,500-kv-a. leading is required to maintain the receiver voltage equal to the generator voltage. Some condenser capacity is necessary for correcting the load to unity power-factor which would be approximately 58,000-kv-a. for a 0.90 power-factor load. Then, the total condenser capacity required is about 75,000 kv-a. Three 25,000-kv-a. condenser units of normal design could supply 55,000 lagging kv-a. which is much more than is required for the no-load condition.

Discussion

PAPERS ON CURRENT-LIMITING REACTORS

(Oesterreicher, Stephens and Kierstead, Dann, Boyajian, Blake)

Chicago, Ill., June 26, 1924

N. L. Pollard: There are only a few points which I wish to emphasize. One is the question of thermal capacity which has been causing the committee considerable worry during the last two years.

If reactors having too small a thermal capacity are used,

1. "The Transoceanic Radio Communication" by E. F. W. Alexanderson.

"The Alexanderson System for Radio Communication" by Elmer E. Bucher.

it is possible for them to fail thermally in case the relays on the circuit do not function properly. On the other hand, if reactors having a long-time thermal capacity are purchased, the cost is excessive. In order to get some idea of the increase in cost, I secured a quotation from one manufacturer for a reactor having a thermal capacity o' 13 seconds and an alternate price on another reactor of the same capacity having a thermal capacity of 22 seconds. The price of the 22-second thermal capacity reactor, if I recall correctly, was approximately 35 per cent greater. The price increases very rapidly as the thermal capacity goes up.

Some operating men are of the opinion that if a reactor has a thermal capacity slightly in excess of that of the cable, it will be sufficient.

Mr. Dann brought out in his paper the fact that there were two extreme points of view. One that the reactor might act as a fuse and be the first to fail in the circuit; the other, that the reactor should have enough thermal capacity so that it would be the last thing in the circuit to fail. The reactor is supposed to be a protective device and cuts down the amount of the short circuit so that the oil circuit breaker can safely rupture it. If it should fail, the oil circuit breaker might not be able to rupture the increased current and what was originally a feeder short circuit becomes a bus-short circuit. This, as we all know, is a very serious matter in a large generating system.

From what information the committee has been able to obtain, the failures this last year have been fewer, although there have been several serious failures which only demonstrate the fact that the reactor is not yet a perfect piece of apparatus and that improvements can be made that will make it even better than it is at present. During the last few months several serious failures have been called to my attention.

R. S. Schurig (by letter): I wish to discuss the paper by Messrs. Kierstead and Stephens and wish particularly to refer to the mechanical stresses occurring in the insulators during short circuits. The test data submitted by the authors in Fig. 10 show clearly that the observed peak stress on the braces is slightly in excess of the peak electromagnetic force. The authors thus reach the important conclusion that the peak stress on the braces is likely to exceed not only the *average* electromagnetic force but also the *peak* electromagnetic force.

The peak stress will, of course, be a maximum in the immediate vicinity of resonance.[6] Since the peak stress varies materially from a relatively low value in some cases to a relatively high value at resonance, it is desirable to know—

1. How to predict roughly whether a reactor is resonant or not and

2. How to estimate the peak stress at resonance.

These two items will be discussed in the following:

1. In order to predict whether a reactor is resonant, one must determine its natural frequency, which may roughly be calculated from the following approximate formula:

$$f = 3.13 \sqrt{\frac{S}{W + \frac{I_0}{r^2}}} \text{ cycles per sec.} \quad (1)$$

where

S is the stiffness of the reactor unit in pounds per inch, the stiffness being the force (applied at the center of gravity of the reactor and acting in the direction of the displacement) to give unit deflection. In the set-up of Fig. 8, for instance, the stiffness would be measured in a horizontal direction.

W is the weight of the reactor in pounds.

r is the distance from the base of the foot insulators to the center of gravity, assuming that the reactor when displaced rocks about an axis in the plane of the base of the foot insulators. The minimum value of r for a rigid reactor is the distance from the base to the center of gravity, not including the height of the base insulators.

I_0 is the moment of inertia of the reactor about an axis perpendicular to the vertical axis of the reactor and passing through the center of gravity. If the reactor is considered as a hollow cylinder having outer and inner radii R_1 and R_2, and a height h, measured without insulators, all in inches, I_0 is

$$I_0 = \frac{W}{4}\left(R_1^2 + R_2 + \frac{h^2}{3}\right) \text{lb.-in.}^2 \quad (2)$$

The above formula for natural frequency is based on the following assumptions:

(1) that the reactor displacement is one of translation and rotation combined. In the total absence of rotation the natural frequency becomes simply:

$$f = 3.13 \sqrt{\frac{S}{W}} \text{ cyc. per sec.} \quad (3)$$

(2) that the displacement is elastic. Insulators are, of course, not perfectly elastic, but tests of busbar insulators, for instance, have shown that their behavior, in vibration, may be closely approximated by assuming them elastic.

(3) that the damping is small.

(4) that, for the derivation of the moment of inertia I_0 as expressed in (2), the center of gravity of the reactor is at the geometrical center of the unit and that the mass is uniformly distributed within the volume of a hollow cylinder.

(5) that the reactor base insulators are bolted to a rigid, massive foundation.

Example 1. Reactor without Braces

Estimate the natural frequency, when the constants are:

W = 1550 lb.
R_1 = 16 in.
R_2 = 6 in.
h = 30 in.
r = 15 in.

$S = \frac{1000}{\frac{1}{32}} = 32{,}000$ lb. per in. assuming that a horizontal steady force of 1000 lb. applied at the center of gravity of the reactor displaces the center 1/32 in. horizontally.

Solving first for I_0:

$$I_0 = \frac{1550}{4}\left(256 + 36 + \frac{900}{3}\right) = 230{,}000 \text{ lb. in.}^2$$

Then

$$\frac{I_0}{r^2} = \frac{230{,}000}{225} = 1020 \text{ lb.}$$

It is seen that the effect of the rotation due to rocking is equivalent to adding more than 1000 lb. to the weight of the reactor. Hence the natural frequency is from (1)

$$f = 3.13 \sqrt{\frac{32{,}000}{1550 + 1020}}$$

or f = 11 cycles per sec. approximately.

If no rocking occurred, *i. e.* if the motion were pure translation, the frequency would approximately:

$$f = 3.13 \sqrt{\frac{32{,}000}{1550}}$$

or f = 14 cycles per sec.

Example 2.

Reactor similar to that of example 1, but ***equipped with braces,***

6. Resonance occurs when an electromagnetic force having a frequency equal to the natural frequency of the reactor is applied, the natural frequency being the frequency of free vibrations, such as would occur, for instance, if a heavy direct-current were suddenly applied to a pair of adjacent reactors.

such that a steady horizontal compression force of 20,000 lb. applied to two adjacent reactors at the level of their centers of gravity shortens the distance between the centers by 0.01 inch. Hence

$$S = \frac{20{,}000}{0.005} = 4{,}000{,}000 \text{ lb. per in.}$$

If the other constants are as above, the natural frequency is roughly, from (1)

$$f = 3.13 \sqrt{\frac{4{,}000{,}000}{1550 + 1020}}$$

or $f = 123$ cycles per sec.

If total absence of rotation were assumed here, the natural frequency would be

$f = 159$ cycle per sec.

It is seen then that, for a reactor of a given size, the stiffness of the base supports and braces is the chief factor determining whether or not mechanical resonance can occur. Thus, a reactor which is not resonant when set up without braces, may become resonant or near resonant when braces are used.

(2) *The resonant peak stresses* may be calculated[7] by assuming elastic supports and braces, if the following items are known:

initial value of average electromagnetic force, (defined as the electromagnetic force due to the r. m. s. initial short-circuit current).

natural frequency of reactor

mechanical damping of reactor unit

decrement of short-circuit current.

If the current decrements given by Hewlett, Mahoney and Burnham,[8] for heavy short circuits (*i.e.*, system reactance up to 30 per cent) are used, and the free-vibration decrements due to the mechanical damping of the reactor insulators are assumed to be the same as those for busbar insulators,[9] the calculated peak stresses, expressed in terms of the initial value of average electromagnetic force, are approximately as follows for 60-cycle short-circuits:

If the natural frequency is one tenth the current frequency or lower, the maximum stress is 1.0 times the initial average magnetic force.

If the natural frequency is half the current frequency, the maximum stress is 2.2 times the initial average magnetic force.

If the natural frequency is equal to the current frequency, the maximum stress is 4.5 times the initial average magnetic force.

If the natural frequency is twice the current frequency, the maximum stress is 3.2 times the initial average magnetic force.

If the natural frequency is four times the current frequency, or larger, the maximum stress is 2.5 times the initial average magnetic force.

For 25-cycle short-circuits, the peak stresses are somewhat reduced being as much as 25 per cent lower.

The above data indicate that the highest stress is due to resonance at current frequency, while the stress due to resonance at twice the current frequency is less. The high resonant stress at current frequency is due to the d-c. component of short-circuit current.

It follows from the above figures, that a low natural frequency, well below half the current frequency, gives lower stresses than any high natural frequency whether resonant or not.

A further point to which attention is to be called is the occurrence of *tension stresses in the braces*. The reactors although connected so that the average stress on the braces is compression, resonance, or near-resonance, will bring about heavy tension stresses of the order of twice the initial average electromagnetic force.

R. A. Hentz: That a reactor is a protective device pure and simple has been pointed out and this fact should be kept prominently in mind. In large metropolitan systems the reactor is second only to the oil circuit breakers in protecting the system. Furthermore, it aids the circuit breakers in performing their duty by keeping the tremendous concentrations of energy occurring at times of short circuit within safe limits.

Unlike the oil-circuit breaker, some part of the cost of which may be charged to the normal operation of the system, the current-limiting reactor must function entirely as a protective device and the entire cost is chargeable as a premium on the insurance obtained from such protection. This premium is very high, consisting as it does not only of the operating losses in the reactors but also of very considerable capital charges. These capital charges include not only the reactors themselves but also, what is a very sizeable item, the extra cost of building and compartments to house them and the leads and insulators to reach them. Obviously with such a heavy charge for protection, operating engineers want to be sure that they are actually obtaining the insurance being paid for. With this before us, it hardly seems that the matter of reliability could be stressed too emphatically and by reliability is meant not only that of the reactors themselves for which the manufacturers are responsible, but also that of the design and installation made by the operating companies.

The thermal capacity of reactors has been touched upon and this is a most important consideration affecting their reliability. Certainly, any protective device, which due to insufficient capacity, would burn up just at the time it was to justify its installation, should not be considered. The total cost including building, compartments, etc., is so large that the little extra investment for increased copper cross section to obtain a device adequate for all conditions to which it may be subjected, is well worth while. Indeed, when considering the total investment, the difference between reactors with scant copper and ones built upon safe design is a very small percentage, and this is partially returned through decreased operating losses. It would seem that a copper cross section with a thermal capacity above that of the underground cable it protects is advisable.

Reference was made in Messrs. Kierstead and Stephens' paper to shunting resistors. The effectiveness of these devices is something about which definite information is much to be desired. Some of the early troubles with the reactors, thought at first to be over-voltage but later determined to be insufficient mechanical strength, and referred to at the bottom of the third page, second column, of this paper, occurred on The Philadelphia Electric system, and a large number of resistors were added. Of a total of some 378 feeder coils supplying mainly underground cables, about one-third of these have shunting resistors. Uniformly good service has been obtained from coils with and without resistors.

A number of uses of reactors have been brought out in the several papers this morning, but one to which I personally am somewhat partial has not been touched upon, namely, their use for starting large 2300-volt motors driving generating-station auxiliaries. It is now generally considered that the best way of starting these motors is on full voltage, but in certain cases, particularly with some high-speed motors, this is not advisable, and in such cases reactor starting is a very satisfactory method.

7. The theory of the calculations is that employed in the paper by Doherty and Kierstead "Short-Circuit Forces on Reactor Supports"; A. I. E. E. JOURNAL, August 1923.

8. "Rating and Selection of Oil Circuit Breakers," A. I. E. E. TRANS. 1918, p. 123.

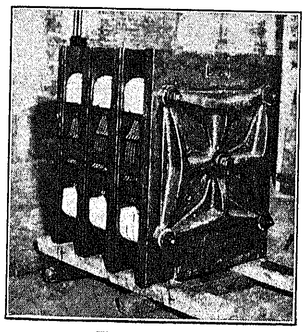
9. The amplitude of free vibrations of bus insulators was found by tests to diminish as $e^{-0.5 \frac{q}{n} t}$ diminishes with time, where q is 2π times the natural frequency of the insulator and n, the sharpness of resonance, is a constant averaging about 5 for a variety of tests of porcelain bus supports. Thus for a 20-cycle support, the decay of the free vibrations is expressed by

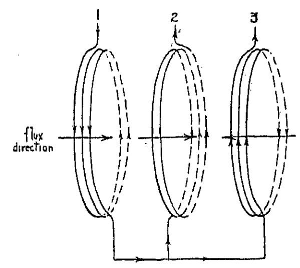
$$e^{-0.5 \frac{q}{n} t} = e^{-12.6\, t}$$

It is quite likely that the reactor insulators and busbar insulators have similar rates of decrement at corresponding natural frequencies, because in both cases the stress is absorbed by insulator units consisting of porcelain members held in metal supports.

It possesses an additional advantage where differential relay protection is used, as the currents in the line and in the motor neutrals are always equal. We have several motors driving air and condensate pumps so equipped, and they start with entire satisfaction.

W. B. Kirke: In the paper by Messrs. Kierstead and Stephens on Current-Limiting Reactors, the authors make a general statement that in three-phase reactors the mechanical forces between coils will be repulsive if symmetrically connected, and attractive if the middle phase is reversed. This statement is true only if one is considering the average force throughout a cycle after the transients of the short-circuit currents have died out. If one is considering peak forces during the transient periods there are times when repulsive forces of very great magnitude can be built up between an outside coil and the other two of a three-phase reactor, even with the middle phase reversed. This condition is shown in the accompanying diagram where the instantaneous value of the current is near the maixmum in an outside coil and returns in the other two.





Three-Phase Current-Limiting Reactor

Due to the very great space limitations in the galleries of the two Waterside stations of The New York Edison Company, we were compelled to install reactors of minimum dimensions. Three-phase insulated-winding type of coils offered the only practical possibility. In these reactors there are developed under the worst possible conditions with a short circuit at the terminals of the reactors, with full 11,000-volt connected capacity and with the short circuit occurring at a certain point on the voltage wave, repulsive forces whose values are in the neighborhood of 100 times the weight of the reactors. To withstand such forces, the reactors are equipped with non-magnetic manganese-steel headers which are designed to withstand a breaking load of 400,000 lb. They are held together by four chrome-nickel steel bolts and one center bolt of Tobin bronze. The headers are designed to eliminate, as much as is consistent with mechanical strength, circulating currents induced in the headers. This is accomplishd by placing the metal in four Y sections which gives the minimum volume of metal in the positions where the currents circulate.

Joseph Slepian: The matter of resistor-shunted reactors has received considerable discussion in the past, and Messrs. Kierstead and Stephens mention this briefly in their paper. It is not often that we get in such a brief account a clear statement as to two rather distinct actions that such a resistor may have. First of all, it may convert energy into heat, and also being a conductive shunt, it may by-pass energy. Messrs. Kierstead and Stephens point out that there will be dissipation of energy in the case of surges from the outside of the system coming into a protected station. On the other hand, they point out that the resistors will permit energy to pass out from any disturbance that occurs within a station on the line. It is clear that these actions do take place, but the action of passing energy may take place equally well when the disturbance occurs outside on the system and the resistor will permit some of this energy to pass by the reactor and into the protected station.

It is on this ground, I believe, that a good deal of theoretical opposition to shunting resistors has been based. It is evidently a quantitative matter. It is the relation between the value of the resistor and the values of the circuit constants that is going to determine what effect is predominant, and a general qualitative statement cannot, I believe, be made. The question to be determined is whether the constants that arise in practise and the resistance values that may be used are of such values as to make one action or the other predominant.

Mr. Boyajian's paper has been of very great interest to me, and on one point I believe I differ a little. In the curve for the d-c. excited reactor under variable a-c. excitation, Mr. Boyajian, as I understand it, correlates or identifies the first bend with the small inflection that one gets in the magnetization curve on direct current. It seems to me that is not at all an essential element here and that one would get the same effects that Mr. Boyajian speaks of if this inflection were not there. One must consider a complete curve for positive and negative excitations (Fig. 1 herewith). The little inflection at the origin is then hardly apparent. With zero d-c. excitation, if one super-imposes an alternating magnetomotive force the ampere turns vary between two equally spaced limits on either side, and the flux variation are determined by the curve above and below the axis. If one gives, however, a d-c. excitation that brings one to a point as in Fig. 2, then superimposes alternating magnetomotive force, the extremes of magnetomotive force then occupy points in the curve that are not symmetrical with respect to the origin. One may get only a small change of flux with one direction of current and a large change of flux with the other direction of the alternating current. It is evident that we may interpret the application of direct current as a shifting of the origin on the excitation curve, so that with direct current imposed the curve may be shifted up, or with large enough direct current it may be shifted so that the lower saturation is shifted through the origin and the curve becomes displaced.

When we have two cores, with opposite d-c. excitations, and add the two fluxes together the resultant curve will be as in Figs.3 and 4. With the alternating current applied, for small alternating current, the extremes of current give only small changes of flux, but with large alternating currents the extremes of flux begin to be large. Thus I identify the lower bend in Mr. Boyajian's curves with the saturation and not with the inflection that one gets for small magnetizations, in the usual virgin magnetization curve.

Another point of considerable interest to me is the relation that Mr. Boyajian gives between the kv-a. of controlling frequency in such apparatus as Alexanderson's modulator, and the controlled frequency. Sometime ago I carried on an analytical investigation as to what relations necessarily exist between powers, which may be exchanged between frequencies in an iron reactor, and for simplicity and shortness of time I will just state the nature of the results for a simple inductance. When an inductance has iron in it, instead of there being a straight-line relation between flux and ampere-turns, it is curved, and we may express the inductance of a coil as a power series in terms of the current. That is $L = L_0 + L_1 i + L_2 i^2 + \ldots \ldots \ldots$ The constant terms would correspond to ordinary inductance, and we are all familiar with its effects. It is the higher terms that tie the frequencies together. If we consider the second term alone

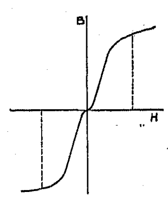


Fig. 1

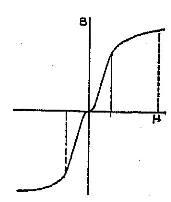

Fig. 2

by itself, we find that it operates to tie frequencies together in groups of *threes* and exchange power between these frequencies. A group of three frequencies which this ties together will necessarily be related in such a way that the sum of the frequencies with properly chosen signs will equal zero.

Then there is a further very interesting relation between the powers that are exchanged between these three frequencies. If power P_1 of frequency F_1, power P_2 of frequency F_2 and power P_3 of frequency F_2, are tied together by the term L_1 in a power exchange, then these powers are all proportional to their respect-

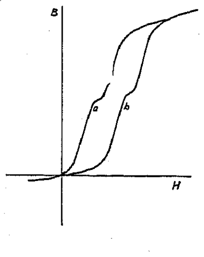

FIG. 3

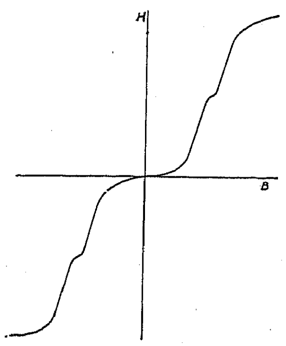

FIG. 4

ive frequencies, and the sum of the powers with the properly chosen signs must necessarily be zero.

Just as an example to make this clear, we may take the case of the Alexanderson modulator or amplifier. We may have normal radio frequency of 50,000 cycles, and a controlling frequency of 1000 cycles. Then as the result of the interaction in the iron core, some energy from the 50,000 cycles may be converted into 51,000 cycles. The first relation which I mentioned is satisfied because 50,000 + 1000 − 51,000 = 0. Furthermore, the powers corresponding to the three frequencies are proportional to the frequencies themselves, so as Mr. Boyajian points out, if you have a controlling frequency of 1000 cycles and a controlled frequency of 50,000 cycles the power of the 1000-cycle frequency is to the power of the 50,000 frequency input as one is to fifty.

V. Karapetoff: Designers of reactors would benefit by a wider use of the concept of permeance, both in testing and in computing reactors. Generally speaking, the inductance of a coil can be written in the form

$$L = n_c^2 P_c + \Sigma n_p^2 \Delta P_p \qquad (1)$$

where n is the number of turns, P is a permeance, the subscript c stands for "complete" and the subscript P for "partial."[10] The two terms on the right-hand side can be combined into one, using the so-called equivalent permeance, so that eq. (1) becomes

$$L = n_c^2 P_{eq}$$

This formula will be found useful in predetermination of the inductance of a coil from test data. Let a coil of dimensions a, b, c, and whose number of turns is N, have an inductance L, determined by an actual test. The equivalent permeance of the coil is

$$P_{eq} = L/N^2 \qquad (3)$$

Let it be required to design a reactor of the same proportions but for a different inductance L_1. Let the dimensions of the new reactor be $m\,a$, $m\,b$, $m\,c$, and the number of turns N_1. The permeance of similar magnetic circuits varies as their linear dimensions (as is also the case with the conductance of similar electric circuits). Thus, the permeance of the new circuit is $m\,P_{eq}$, and its inductance is

$$L_1 = B_1^2 P_{eq}\, m \qquad (4)$$

Knowing L_1 and P_{eq}, the designer can choose m and N_1 to satisfy this equation. Out of an infinite number of solutions he can select one which gives a minimum cost, or a minimum loss, or standard dimensions, etc.

The foregoing formulas are also useful in judging about the best proportions of a coil. It will be seen from eq. (1) that for a maximum inductance the permeance must be as great as possible, and moreover as many linkages as possible must be complete rather than partial. This means short magnetic paths of large cross-section and avoiding turns which link only with a small fraction of the total magnetic flux.

The concept of permeance is also useful in the determination of electromagnetic forces acting upon a reactor (*ibid.*, the last chapter). The derivative of the permeance in a given direction is proportional to the component of the mechanical force acting in that direction. Therefore, these forces can be estimated on the principle of virtual displacements. Moreover, mechanical forces become zero when the inductance reaches its maximum, because then its derivative becomes equal to zero. This shows the advantage of choosing coil proportions corresponding as nearly as possible to maximum inductance. Mechanical stresses are then smaller and can be more readily controlled.

So far the shape of protective reactors has been largely determined by manufacturing considerations and by space economy. It would be of interest to ascertain, both experimentally and mathematically, nature's own shapes of maximum inductance. The following experiment is suggested. Let an extremely flexible coiled conductor of a definite length be immersed in transparent insulating oil, and supported at several points say by means of floating corks, to be in an indefinite mechanical equilibrium. Let a strong d-c. current be passed through the conductor. The conductor will then tend to assume the shape of a coil of maximum inductance, and useful conclusions may be drawn from its final shape. Guides and obstacles may be placed in the tank to limit the motion in certain directions, and in this way practical shapes may be obtained, perhaps unknown at present.

In Fig. 5 of the paper by Kierstead and Stephens the mechanical forces are shown to be of the nature of compression, indicating that the reactor tends to increase its permeance to a maximum by shortening the magnetic paths and increasing their cross-section. On the other hand, in Mr. Oesterreicher's Fig. 20 some of the arrowheads seem to indicate a repulsion between the turns. While it is possible to connect turns or layers for mutual repulsion, such an arrangement would correspond to a non-inductive winding and therefore would not be suitable for a protective reactor. The sketches in these two papers should be reconciled.

Mr. Oesterreicher's Tables I and II are not clear. If a summation over half a cycle is desired, the readings corresponding to 180 deg. should be omitted because they belong to the beginning of the second half cycle.

S. I. Osterreicher: The two paramount requirements of every reactor are thermal capacity and mechanical strength. From the standpoint of the design, these two requirements go hand in hand. Large thermal capacity during short circuits demands large conductor volumes, which automatically gives the reactor mechanical strength. The limitations imposed upon these conditions are mostly economic and partly space requirements. Both are within the sole control of the operating engineer.

Regarding the conductor stranding of which Mr. Dann speaks, I believe it is well to use as large individual wires in a stranded cable as consistent with a conservative design. The advantage of large individual wires is a natural stiffness of the stranded cable. During short-circuit stresses, this cable stiffness gives the reactor additional mechanical strength.

To limit the eddy currents to reasonable values in a coarse cable stranding, our firm uses enameled wires in stranded cables. The eddy-current losses in such enameled-wire cables are equal to or less than, those in the fine stranding.

Among the many interesting points of the Kierstead and

10. See V. Karapetoff, "The Magnetic Circuit," Chap. X.

Stephens paper I find a number in which I readily agree. To a few however I wish to make some comments. One of the statements—that reactors must be made of fire-proof materials only—needs additional qualification.

It so happens that we manufacture reactors made of fire-proof materials as well as some with fibrous materials. Our experience with the fibrous-type coils is as good as with the fire-proof reactors. The limiting feature in both cases is the thermal capacity. If these limits are greatly exceeded, both types suffer equally. While I am greatly interested in the test which the authors cite about a fire-proof reactor which has been driven up to 725 deg., what I would like to ask is do the authors still consider this reactor safe for central-station operation after the test.

At 725 deg. cent. the copper loses almost 75 per cent of its original tensile strength and will rupture readily when subjected to mechanical vibrations caused by the magnetic fields surrounding the conductor.

I have data of several reactor conductor ruptures caused by what I believe is nothing else than excessive heating of the copper.

The authors also mention some flashover test made upon certain types of reactors, which showed dielectric strength up to 100,000 volts. If such is the case I can see no reason for installing auxiliary devices within the reactor to protect against over voltages. If a 13,200-volt system is subjected to over voltages anywhere near the 100,000-volt mark, such system will break down at dozens of places before the critical breakdown voltage of the reactor is reached.

The expression given by Prof. Karapetoff for the permeance factor is a great help to the reactor designer. This factor is also known as the inductance or shape factor of the winding.

I believe, Prof. Morgan Brooks in University of Illinois Bulletin No. 10 as well as the late Dr. Rosa in the Bureau of Standards Bulletin calls attention to a similar permeance or inductance factor of solenoids.

In regard to Figs. 20A and 20C of my paper, which show the winding turns in repulsion toward each other, I wish to call Prof. Karapetoff's attention to my statement, "whether the forces are attractive or repulsive, depends upon the interconnection between turns or layers and upon the current distribution throughout the winding."

In multilayer windings all layers or turns cannot be placed in the same magnetic planes, thus it must be evident that their inductances and mutual inductances cannot be the same. If this is true, it cannot be claimed that all turns are always trying to locate themselves in the common magnetic center of the solenoid. From my experience, as far as the end layers and turns of a solenoid are concerned I saw a number of windings, distorted in a general direction as indicated by the arrows.

It seems that Prof. Karapetoff, himself, thinks that the experiment which he suggests if carried out, will lead to some unknown shapes in solenoid design, which I believe, can be caused only by the uneven self and mutual inductances between layers and turns. The discrepancy in the summation of Tables 1 and 2 is due to the step-by-step method used and should not be expected to be analytically exact.

F. H. Kierstead: In his book entitled "The Magnetic Circuit," Professor Karapetoff has presented a very rational method of calculating magnetic forces, which we have used and found to be of very great value not only in predetermining the exact value of a magnetic force and its direction, but also in predetermining how changes in the circuit conditions will affect the force.

In regard to the direction of the force on a particular turn of a reactor, I wish to say that it is our conception that the turn tries to move in a direction such that the inductance of the circuit will be increased. Now if a turn of a reactor moves away from the rest of the turns, the inductance will be decreased but if it moves toward the rest of the turns the inductance will be increased. Therefore, the forces on the turns of a reactor are in such a direction as to try to cause them to move together. An exception to this is conceivable in the case where the conductor of a reactor consists of several strands in parallel and the paralleling of these strands is so poorly done that the current in one of the strands is actually reversed in direction to that in the other strands. In this case, the former strand would be repelled by the latter strands. That would mean tremendous losses in the reactor, and I don't think it occurs in any modern reactor.

In answer to Dr. Slepian's discussion in which he points out that some energy is by-passed by the resistor into the protected station, I wish to state that it is our practise to make the resistance of the resistor well above the surge impedance of the circuits to which it is connected so that the energy which it by-passes is of very much reduced voltage.

We have in our paper stated that the resistors permit a portion of the high-voltage energy of a disturbance that occurs within a station to pass out into the lines. Dr. Slepian has stated in his discussion of our paper that the resistors will equally well permit a portion of the high-voltage energy of a disturbance which occurs on the lines to pass into the station. Dr. Slepian is correct in the case where there is only one feeder connected to the bus but where there are several feeders equipped with reactors and resistors a disturbance originating within the station has several paths of escape out into the lines while a disturbance originating out on one of the lines has only one path into the station. Therefore, since there is usually more than one feeder connected to a bus, the resistor will in general by-pass considerably more high-voltage energy from a station into the lines than from the lines into the station.

In regard to whether resistors are required or not, I wish to state it is not a question of protecting a reactor from over-voltages, but rather it is a question of whether a central station company wishes to obtain the advantages of the absorption of high-voltage energy which will take place in the resistor, and thus reduce the value of over-voltages which may arise on the system.

Mr. Kirke in his discussion of our paper has pointed out that in the case of a three-phase set of reactors placed coaxially and connected with the middle phase reversed, there are some conditions under which the force for a portion of the cycle will be repulsive although the average force over a cycle will be attractive. This is true but the peak value of such repulsive forces in the most favorable case is only 1/8 the peak value of the attractive force under the most favorable conditions and the average force over a cycle under the conditions which gives the highest instantaneous repulsive force is zero. It has been our experienc that in general, the distance between adjacent phases of coaxially placed reactors has been so large that the repulsive forces were not large if the middle phase was reversed.

The value of Mr. Schurig's discussion of our paper lies chiefly in the fact that it gives a method of determining the stresses on reactors. The constants he has taken necessarily are only typical of one rating of reactors, and, therefore, cannot represent the great range of reactors which are liable to be encountered.

W. M. Dann: The discussion we have had brings out that not all engineers are in full sympathy with the shunted reactor because the inductance of the reactor is a real barrier to high-frequency disturbances and it seems like folly to add something which might by-pass some of those disturbances into the circuits that are to be protected and in that way detract from the effectiveness of the barrier which is intended to keep those disturbances on the side of the reactor where they originate.

Mr. Osterreicher referred to the Cos Cob iron-core reactors. It really was a sort of bold stroke to design those reactors and put them in the circuits. I remember that at the time all of us looked with more or less awe on those big iron-core reactors.

I think that my remarks about finely stranded cable may have given Mr. Osterreicher a wrong impression because, of course, the strands in the cable are large enough to give it mechanical strength. There have been no cases of trouble that I know of where the cable itself has not had sufficient mechanical strength to withstand the mechanical stresses.

A. Boyajian: As mentioned in my paper, Messrs. W. B. Kirke and F. Dubsky cooperated with the writer in this investigation at one time, and I was very much pleased that Mr. Kirke was here and discussed the subject. I agree with him in the discussion which he has offered.

I am pleased that Dr. Slepian has verified by profound mathematics the conclusion at which I arrive from a simple physical consideration relative to the ratio of controlling and

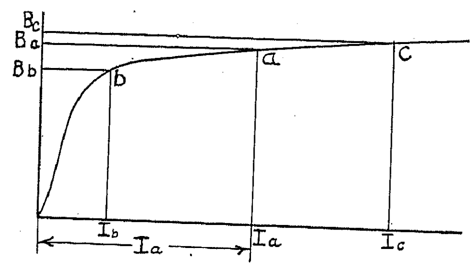

FIG. 1—D-C. MAGNETIZATION CURVE

controlled kilovolt-amperes being equal to that of respective frequencies.

As to the shape and interpretation of the volt-ampere curve, on which subject Dr. Slepian feels that he differs a little from me, I doubt if there is any essential difference. In my paper I have first stated the fact that each one of the three representative magnetization curves (*viz.*, I—the simple d-c. *B-H* curve, II—the simple a-c. volt-ampere curve, and III—the a-c. volt-ampere curve with superposed d-c. excitation) have two bends. This is a fact regardless of our interpretations, and is a satisfying parallelism to know. The bends of case III are shifted to the right as compared with those of case II, the more so the larger the d-c. excitation. The existence and position of the two bends in the case of combined d-c-a-c. excitation, I have interpreted as follows.

Referring to the accompanying Fig. 1, let the d-c. excitation correspond to the point a of the magnetization curve. Superposition of alternating current will vary the flux in the directions of b and c. In the range between b and c the alternating-current reactance will be very low and practically constant,—very low on account of the saturated condition of the core, and practically constant on account of the fact that the magnetization graph is a straight line in this zone. It follows, therefore, that for values of alternating current up to $(I_a - I_b)$, the volt-ampere curve will be straight and of small slope like the initial solid portion of Curve III (Fig. 2).

For large values of alternating current, the presence of direct current will exert only a small influence on reactance, so that Curve III must finally approach Curve II, (Fig. 2), asymptotically, never crossing it. Having the initial and final portions of Curve III, we can draw in its intermediate portion as shown dotted. At the initial part, *i. e.*, up to the first bend, wave shape is fairly free from harmonics. At the final part, that is above the second bend, wave shape is more and more that of simple a-c. excitation without d-c. Between the two bends, *i. e.*, in the part shown dotted, wave-shape has a very prominent second harmonic. The substance of this detailed explanation will be found in the text of my paper. Whether the point of view of "the shifting of the origin" offered by Dr. Slepian is any more illuminating or satisfying than the point of view of "the shifting of the two bends" (which latter, by the way, is a statement of fact) is a matter to be decided by every person for himself. In either case, recourse has to be taken to the d-c. magnetization curve for a detailed explanation and here the two explanations coincide.

I have learned from Prof. Bush that tests at M. I. T. gave smaller losses than those obtained by us, and it is hinted that the difference is due to second harmonic copper losses in the d-c. circuit. The oscillograms given in my paper indicate an entirely negligible second harmonic current in the d-c. circuit, this being accomplished by proper balanced design. The correct explanation of the differences seems to be in stray losses.

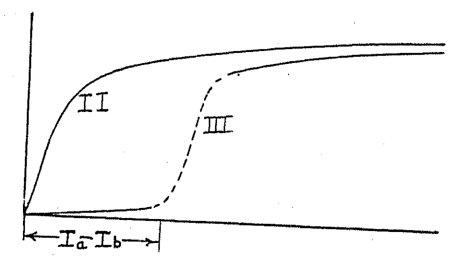

FIG. 2—II. A-C. VOLT-AMPERE CURVE WITHOUT D-C.
III. A-C. VOLT-AMPERE CURVE, D-C. SUPERPOSED

Since the writing of this paper, our units were tested with and without tank, with and without steel clamps, and considerable changes in losses were observed. Although stray losses are more or less unavoidable phenomena with large units, especially with saturated cores, it appears that the determination of their exact location and magnitude may lead to considerable improvements in losses by suitable design to reduce them to a minimum.

High-Voltage Impregnated Paper Cables

BY WM. A. DEL MAR
Fellow, A. I. E. E.

and

C. F. HANSON
Member, A. I. E. E.

Both of the Habirshaw Elec. Cable Co., Yonkers, N. Y.

Review of the Subject.—*A limit of carrying capacity was reached in high voltage cables due to high dielectric losses, and in order to overcome this limitation, science had to be called upon to introduce measurements and tests to control this quality. The exact experience gained in the development of these tests by scientific men working in cooperation with the men of practical experience enabled the cable industry to attack the next limitation that confronted it, namely, dielectric strength. The industry has already made considerable progress, and the present problem is the complete elimination of occluded air and vapor from the insulation. Air films have been regarded as causes of low dielectric strength, due to ionization of the air and consequent formation of hot spots. It is advanced, herein, that a more useful conception of the danger of air films, is that they promote internal surface leakage. It has also been generally believed that air films can be detected by the slope of the voltage power-factor characteristic. It is contended herein that such is not the case. It is pointed out that the foundation for future developments has been laid by the equipment and organization of American cable manufacturing plants for accurate quality control by continual testing of raw and process materials.*

FEW tasks are now facing the electrical engineer in which more general interest is being taken than the development of cables for higher voltages.

For many years, cables have been operating with a very fair degree of success at tensions of 19 to 25 kv. When attempts were made to make cables for somewhat higher voltages, dimensional limitations prevented the retention of the potential gradients that time had proved to be reliable and it became necessary to subject the insulation to higher stresses. It was found that at these stresses general weaknesses would develop and weak spots would be revealed in the insulation, which would not show at the lower stresses.

The first step was to reduce the dielectric loss, then to use a compound that would not be too stiff at low temperatures, and then to control the dielectric qualities of the paper. When this was accomplished, factory failures were practically eliminated and field failures greatly reduced.

Analysis of the latter showed three things: first, that at high stresses all mechanical defects, arising either in manufacture or subsequent handling, reveal themselves sooner or later; second, that air films, under certain circumstances may be the cause, and third, that operating conditions with special reference to potential surges have to be more carefully controlled.

It therefore became necessary for the manufacturers to establish a new standard of mechanical construction and to carry out elaborate researches on the elimination of air films. Much progress has been made in both of these matters during the past few years, and cables are now being made having unprecedented dielectric strengths, figures as high as 200 kv. per cm. (average stress) having been attained on single-conductor cables, while three-conductor cables for 25,000 volts and higher cannot be broken down because no way has yet been found to make the ends immune from flashing or failure at the crotch. But more important than this, these cables have unprecedented ability to withstand high stresses for long periods without deterioration.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

These results have been obtained by the careful control of materials and processes. This paper is devoted principally to a description of the principal control tests developed by an American cable manufacturer.

Four types of experimental samples were used for the research work required to ascertain the crucial properties which must be controlled and their optimum values.

1st. Impregnated sheets of paper (usually three deep) were tested between A. S. T. M. electrodes as shown in Fig. 1. Such flat samples are inexpensive, are quickly prepared and eliminate all structural complications, *i. e.*, they enable the material to be tested without introducing any element based on the mechanical make-up of a cable. Thousands of tests on samples of this character were made.

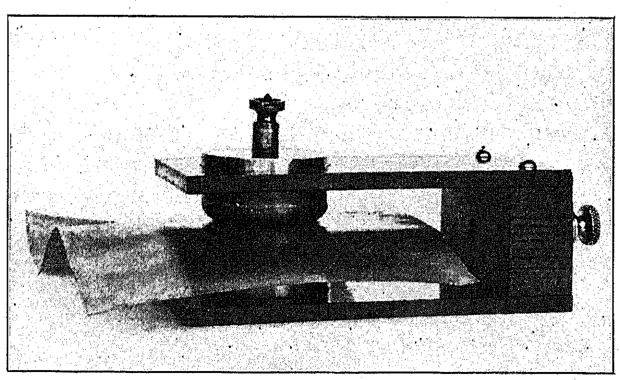

FIG. 1—A. S. T. M. ELECTRODES AS APPLIED TO THE TESTING OF FLAT SAMPLES OF TREATED PAPER

2nd. Samples of cable six in. long, the drying and impregnation of which could be carried out in a miniature apparatus are shown in Fig. 2.

3rd. Samples of cable without sheaths, about 15 in. long were treated with different kinds of impregnating compounds. Tin foil was then applied to the middle part of the sample to serve as a sheath and rolls of insulation were applied at the ends, as shown in Fig. 3 to provide a long leakage path and a barrier to prevent a flashover of the test voltage. The samples were tested with a voltage two to three times the normal

operating voltage for two hundred hours. Periodically, the samples were tested for dielectric loss or power factor.

4th. Samples of cables, with sheaths, about 15 ft. long, dried and impregnated in a small tank and tested with their ends in oil for momentary dielectric breakdown are shown in Fig. 4, or with their ends taped with asbestos for prolonged voltage applications. During the years 1922 and 1923, 526 special experimental lengths of this kind were made and tested.

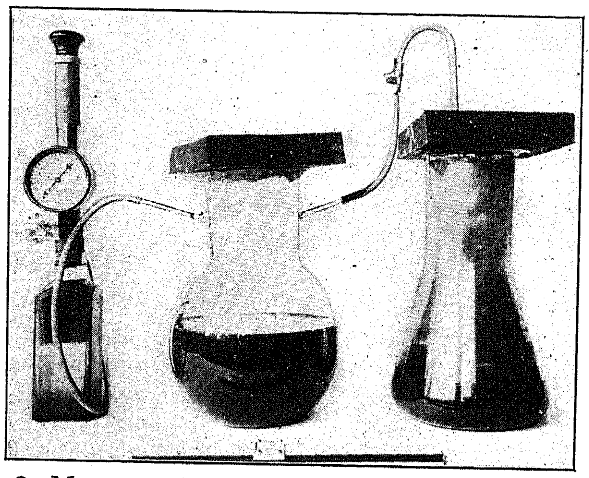

Fig. 2—Miniature Apparatus for Drying and Impregnating Cable

Some of the variables which were altered were as follows: *Oil*: Viscosity, resistivity, dielectric strength, flow point, susceptibility to oxidation, influence of rosin and other substances.

Paper: Amount of manila fiber, amount of rag stock, amount of jute stock, amount of wood stock, hydration, density, thickness, oil reluctance, tearing strength along and across grain.

Taping: Width of tape, tightness, lap.

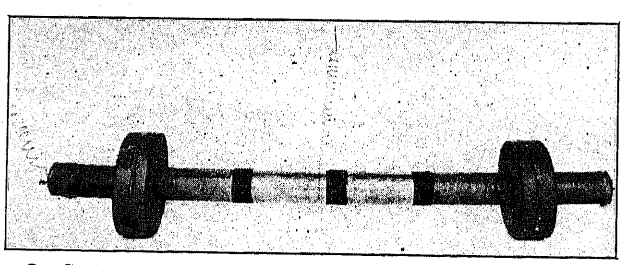

Fig. 3—Sample of Cable 15 In. Long for Artificial Aging

Drying: Time, proportion of time in air and in vacuum, temperature.

Impregnating: Time, temperature, vacuum, pressure maintenance, and freshness of oil.

Cooling: Time, final temperature, interval between tank and press, medium for cooling cable, *i. e.*, oil or air.

This list by no means exhausts all the variables and it should be clearly understood that the optimum value of each variable is not a constant, but depends upon the combination of other variables associated with it.

The experimental determination of the optimum cable, assuming five values of each variable to be tried, would therefore involve the making and testing of at least thirty-six billion kinds of experimental cables.

The reduction of this number to a workable series of tests can only be effected by the application of theory. A theoretical understanding of cable manufacture would include thermodynamics, mechanics, oil-chemistry, paper-chemistry, and electrophysics.

The 15-ft. samples were also tested or examined for some or all of the following qualities: dielectric strength, dielectric loss, ionization, freedom from air films and general appearance. Many were tested for dielectric loss both before and after an aging test at about 2½ times normal working stress.

These tests gave a large amount of valuable data but the most surprising thing learned was that most of the variables could be altered over a considerable range without essentially altering the quality of the cable. On the other hand, quality was found to be very sensitive to a few of the variables.

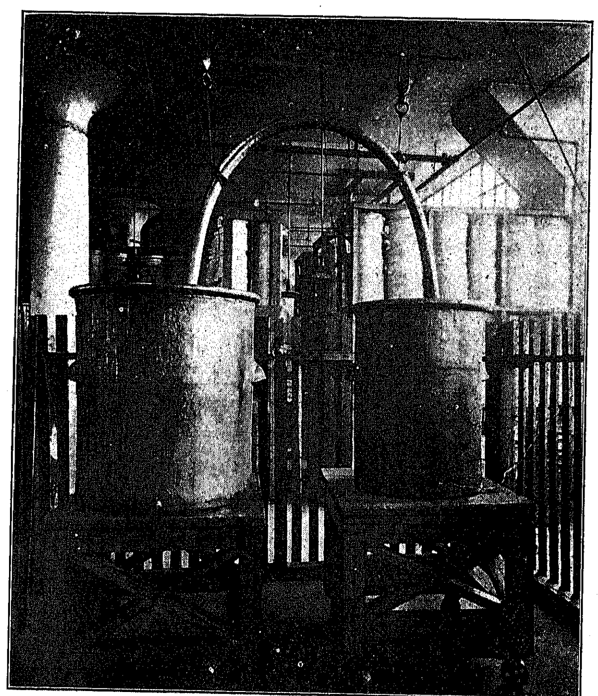

Fig. 4—Samples of Cable 15 Ft. Long Being Tested for Momentary Dielectric Breakdown

Practical advantage was taken of the information gained in these four series of tests, to establish a system of quality control based on careful regulation of those variables to which cable quality was found to be most sensitive.

The remainder of this paper is devoted principally to a description of these essential tests.

Raw Material Control

There is probably no phase of the manufacture of impregnated paper cables more important than the control of quality of the raw materials.

The essential tests on paper are as follows:

1. Dielectric strength when impregnated.
2. Tearing strength.
3. Folding endurance.
4. Air permeability, *i. e.*, compactness of fibers.
5. Oil permeability.

Dielectric strength is measured on three sheets, 10 by 16 in., dried by heating at 105 deg. cent. for 16 hr. and impregnated in standard compound for two hours at 80 deg. cent. Tests were made with a transformer at 60 cycles, using the A. S. T. M. standard electrodes shown in Fig. 1. Three sheets in series are tested at a time and 10 breakdown values are obtained on each series of sheets. A blind sample, taken from a roll of paper which was found to be very uniform, is run with each test. Errors due to differences in impregnating are eliminated by impregnating the test samples and blind sample together and expressing the results on the former in terms of those obtained on the latter. The distance between electrodes being dependent upon the thickness of both paper and oil films is, unfortunately, not strictly comparable from test to test, as it is impracticable to control the relative thickness of these two elements. Furthermore, due to the high heat conductivity of the electrodes, the breakdown voltages should be compared on the basis of the square roots of the thickness. In spite of these difficulties, the test has proven valuable for control purposes as indicated by a record for one year as shown in Fig. 5.

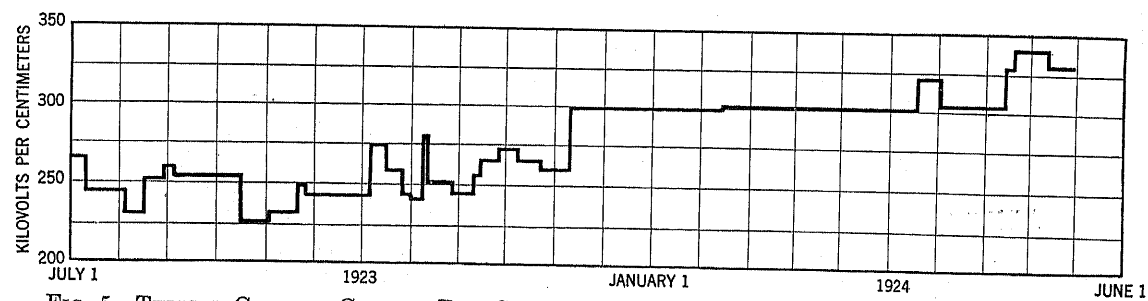

FIG. 5—TYPICAL CONTROL CHART. THIS SHOWS THE DIELECTRIC STRENGTH OF IMPREGNATED PAPER

Tearing strength is measured by an Elmendorf machine as described in the TRANSACTIONS of the A. I. E. E., 1921, Vol. XL, page 143. This instrument measures the energy required to tear a given length of paper. It is shown in Fig. 6.

Folding endurance is measured with the M. I. T. tester shown in Fig. 7. This apparatus holds a strip of paper at approximately constant tension (usually one kg-m.) and folds it over steel edges of standard curvature (0.03 in. diameter) through an angle of about 120 deg. on each side of the straight position.

Density, as it is improperly called, meaning the compactness of fibers, is measured by a Gurley Densometer, Fig. 8, an instrument that measures the number of seconds required for 100 cu. cm. of air to be forced through one sq. in. of paper under a pressure of 570 g.[1]

All physical tests on paper are made in a room kept at a standard humidity of 65 per cent by means of a Bahnson humidifier.

Oil permeability is measured by noting the time required for oil of standard viscosity to make its appearance through a single sheet. The test suggested by Dr. H. H. Brown is made by shaping the paper into a rectangle about 3 by 5 cm. with turned-up edges, and floating it on a dish of oil, as shown in Fig. 9.

The essential tests on oil are as follows:

1. Dielectric strength.
2. Resistivity.
3. Viscosity.
4. Hardness.
5. Solidifying point.
6. Some cable manufacturers test the oil for power factor.

Dielectric strength is measured between electrodes one in. in diameter and 1/10 in. apart at 85 deg. cent. using 60-cycle voltage. The apparatus is shown in Fig. 10. The results are liable to be quite erratic and the average of at least five readings must be taken for each test.

Resistivity is measured by galvanometer method using a cell, Fig. 11, with electrodes of 56 sq. cm. area and 0.5 mm. apart, as described in TRANSACTIONS of the A. I. E. E. 1922, Vol. XLI, page 569. The results vary over a wide range but if care be taken in making measurements, fairly close checks may be obtained on successive tests. Care must be taken to avoid con-

1. It was pointed out by the authors in an Institute paper that impregnated paper insulation is virtually oil insulation improved electrically by the interposition of barriers to break up circulation and ionic migration.

This conception suggested that variations of dielectric strength might be due to variations in the baffling effect of the paper and an attempt was therefore made to find a measure of this effect. Such a measure was finally found by the authors, in collaboration with Dr. H. H. Brown, in the readings of the Gurley Densometer, an apparatus which measures the compactness of the paper fibers by the permeability of the paper to air under pressure.

Control of the air permeability or density, as its reciprocal is erroneously called, led both to a general raising of the dielectric strength level and in great measure to its equalization at that level.

tamination of the specimens and apparatus by oxygen, sweat, condensed moisture and dirt.

Viscosity is measured with a Saybolt Universal Viscosimeter, Fig. 12. The specimen is placed in an

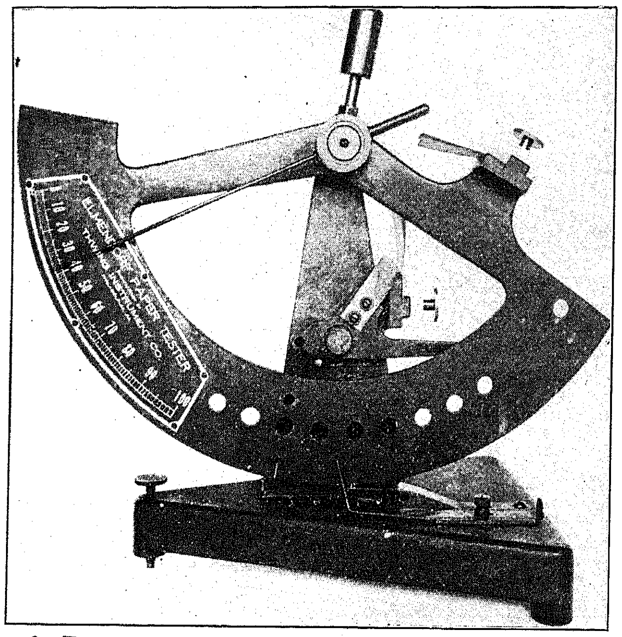

Fig. 6—Elmendorf Paper Tester Used to Test the Tearing Strength of Paper

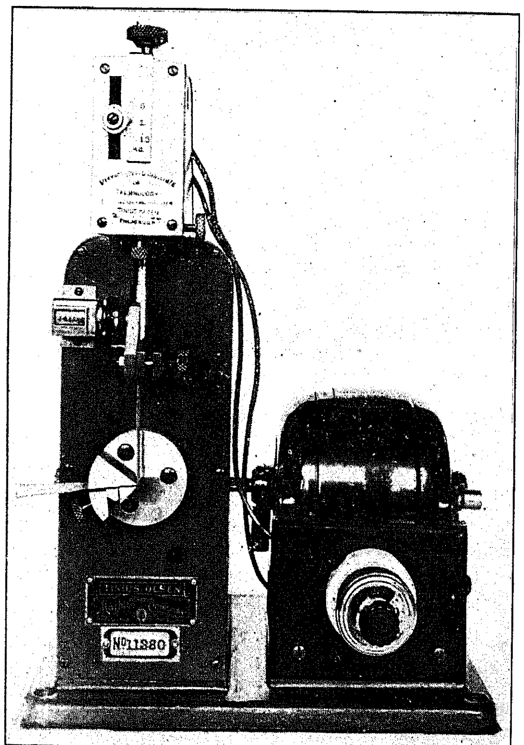

Fig. 7—M. I. T. Folding Endurance Machine

inner receptacle where it is kept at the desired temperature, usually 210 deg. fahr., (99 deg. cent.) by means of oil kept at about 216 deg. fahr. (102 deg. cent.) in the outer bath. The number of seconds required for 60 cu. cm. of compound to pass through a standard orifice is the viscosity. Measurement of hardness have not been developed to a point that justifies a description.

The solidifying point is measured by putting about 10 or 15 cu. cm. of molten compound into a porcelain crucible and stirring with a thermometer while it cools until it is just hard enough not to pour. The temperature is noted and recorded as the solidifying point.

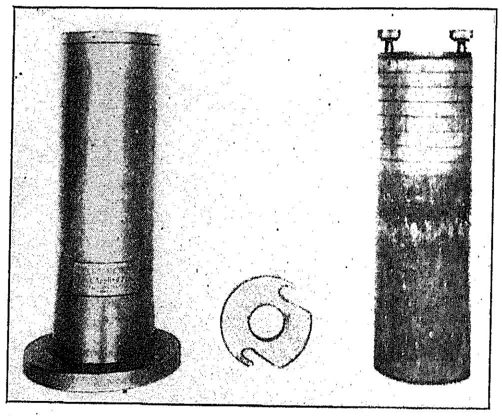

Fig. 8—The Gurley Densometer for Measuring the Air Permeability of Paper

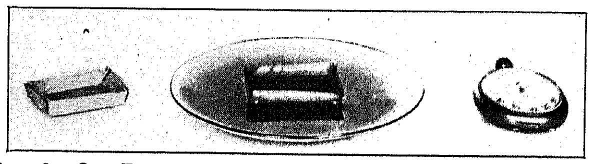

Fig. 9—Oil Permeability is Measured by Floating the Paper Boat on Oil and Noting the Time for the Oil to Penetrate through the Paper

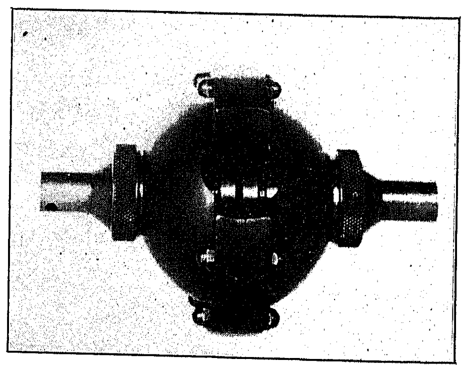

Fig. 10—A. S. T. M. Standard Gap for Testing the Dielectric Strength of Oil

Process Control

Completion of drying is ascertained either by capacity tests made with a 60-cycle a-c. bridge, a capacity meter, or by dielectric loss tests. A typical drying curve is shown in Fig. 13.

The quality of the oil is controlled by tests of resistivity, dielectric strength and viscosity, similar to those described under tests of raw materials.

The impregnated paper on or from cables is tested for

folding endurance, density, saturation and dielectric strength. Saturation is determined by extraction with carbon tetrachlorid in the syphon extraction flask shown in Fig. 14. This gives the ratio of oil to paper on a three-in. sample of cable. The test is supplemented

by visual inspection of samples several feet long which are stripped tape by tape and examined for surface oil throughout. Research work is under way to find a better check upon saturation.

A number of sections 15 ft. long is taken every week from commercial lengths and tested to failure with 60-cycle voltage. A considerable proportion of these lengths is tested for dielectric loss by the compensated wattmeter method (Pender's Handbook, 1922, page 865). Readings are taken at several voltages to determine the so-called ionization characteristic of the cable in order to collect data on this subject.

Periodic aging tests are made with the 15-ft. samples described above. The usual test is at 2½ times normal

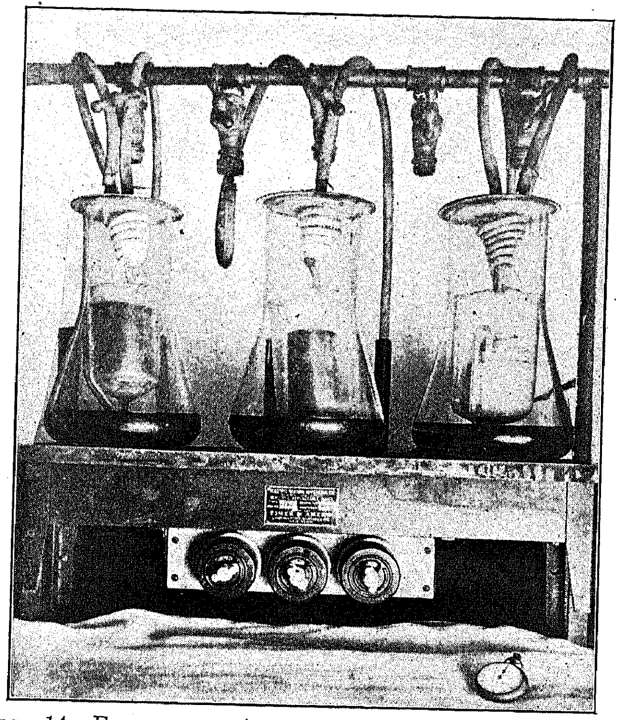

Fig. 14—Extraction Apparatus Used in Determining the Ratio of the Weight of Impregnating Compound to That of Paper

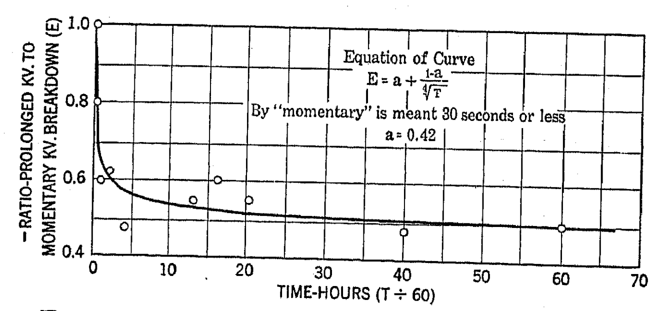

Fig. 15—Time Lag of Paper-Insulated Cables

working voltage, and the criterion is the chemical stability of the oil.

Several sections per week of the same length are submitted to the bending test, broken down with high voltage and examined for tears.[2]

A few 15-ft. sections have also been tested to destruction with prolonged voltage applications to determine

2. It is of interest to note that while European specifications often call for no torn tapes, the criterion is usually the dielectric strength and not a visual examination as in America.

the time lag of impregnated paper insulation as it applies to electric cables. The dots in Fig. 15 are the data obtained from these tests, whereas the curve is the locus of the following equation given by F. W. Peek, *G. E. Review*, November 1915, and V. M. Montsinger, JOUR. A. I. E. E., Feb. 1924, page 146.

$$E = a + \frac{1 - a}{\sqrt[4]{T}}$$

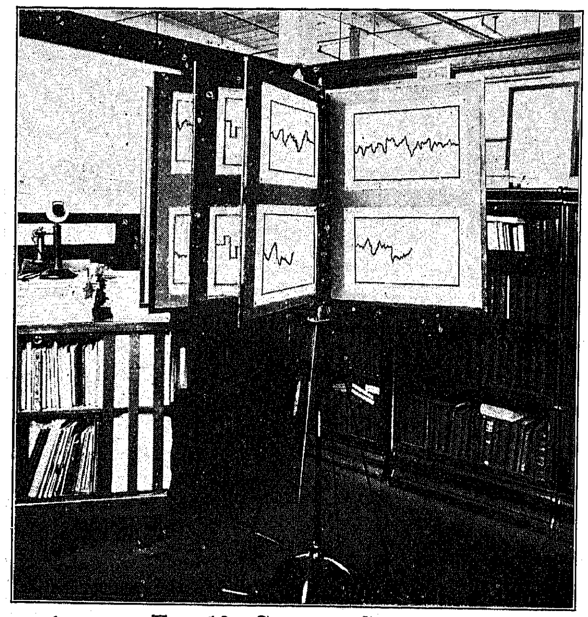

FIG. 16—CONTROL CHARTS

Where

E = the ratio of prolonged breakdown voltage to momentary breakdown voltage. The momentary breakdown voltage is that which causes breakdown in 30 sec. or less.

T = time in minutes.

a = a constant for a given type of cable.

The value of a computed from the breakdown data is 0.42 for these cables. If the value 0.42 is substituted for a in the equation and T made infinite, it would seem that these cables would withstand continuously a voltage equal to 42 per cent of the momentary breakdown voltage. We know, however, from experience that this condition cannot be fulfilled in practise. It follows, therefore, that the equation should be used only for values of T within certain limits. The reason for this limitation, is, perhaps, that other factors of a deteriorating nature enter into action as time goes on.[3]

There are other tests to control processes and materials which cannot be discussed at the present time, but which contribute materially to the results.

3. It should be noted that tests lasting a half hour bear a more or less definite relation to the standard five-min. test and are, therefore, unlikely to be of any more value. Artificial aging tests, on the other hand, are made under conditions designed to promote deterioration, and therefore reveal something not shown by the five-min. test.

The data from all these tests are plotted on charts (Fig. 16) so that the tendency of every characteristic can be noted day by day. One effect has been to reduce the number of high-tension cable failures on factory test, to a negligible number. This saving effected has paid many times over for the cost of the research work upon which it was based.

This work has furthermore, laid the foundation upon which future developments for higher voltages must depend.

Appendix I.

COMPOUNDS WITH AND WITHOUT ROSIN

The American manufacturers were led to abandon rosin largely because of its chemical instability at the temperatures at which American cables are operated. The lower temperatures at which European cables are used, made this consideration comparatively unimportant to them and they probably made their decision on the basis of the greater surface tension between paper and the cylinder oil rosin mixture.

The addition of rosin to a petrolatum or a mineral oil lowers its electric resistivity and various percentages of rosin have an interesting effect upon the resistivity of petrolatum at different temperatures, Fig. 17A

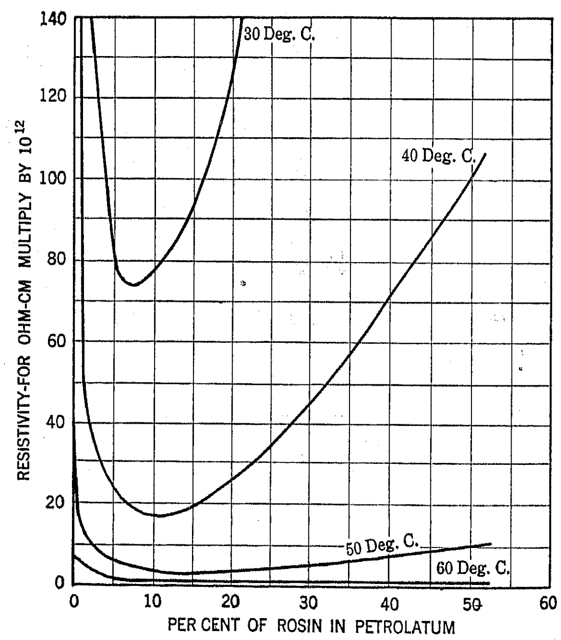

FIG. 17A—THE EFFECT OF ROSIN ON THE RESISTIVITY OF PETROLATUM

and Fig. 17B. At temperatures of 50 deg. cent. or less, the resistivity drops as rosin is added, up to 10 per cent, as shown in Fig. 17A. A further addition of rosin raises the resistivity again, but no amount of rosin added will bring the resistivity up to its original value. At higher temperatures, the addition of rosin up to 10 per cent lowers the resistivity. Further addition of rosin holds the resistivity approximately constant, as shown, for example, by the 80-deg. curve in Fig. 17B.

This reduction of resistivity of petrolatum in itself, does not necessarily have a bad effect upon the quality of the cable, but, unfortunately, the reduction in resistivity is accompanied by an increase in dielectric loss or power factor at the higher temperatures. If low power factor is obtained by the use of a large rosin content, such as 50 per cent, the compound becomes too stiff at low temperatures. In Fig. 18 are given two power-factor curves of two groups of cables.

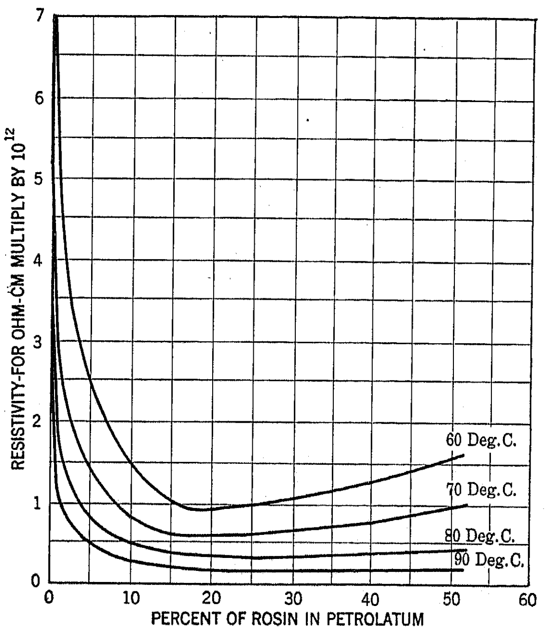

FIG. 17B—THE EFFECT OF ROSIN ON THE RESISTIVITY OF PETROLATUM

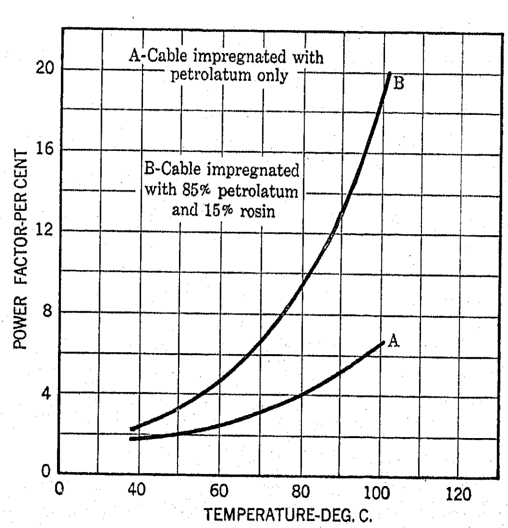

FIG. 18—RELATION BETWEEN POWER FACTOR AND TEMPERATURE OF A PAPER-INSULATED CABLE

These cables are identical, except the *B* cables contain 15 per cent of rosin, whereas the *A* cables contain no rosin. The serious effect of rosin in cables is that it lowers materially the critical temperature of cumulative heating.

The above data are presented to show that the use of rosin was stopped for definite and clearly understood reasons. This should not be construed as a final abandonment of this material, as further research work is under way which may lead to the development of methods of using it without incurring the disadvantages originally found.

Appendix II

HOT SPOTS IN CABLES

It has frequently been observed that impregnated paper-insulated cables, which have been subjected to a high dielectric stress for a considerable period, show hot spots which are regarded as incipient failures. It was recently the authors' good fortune to examine a piece of cable in which several hot spots occurred which showed practically all the characteristics which had been noted individually in previous cases.

The cable was single-conductor stranded, having a cross-sectional area of 600,000 cir. mils and insulated with 39/64ths of manila rope paper, applied with an open butt. The power factor of the insulation was about 1¾ per cent at 85 deg. cent.

This cable was subjected to 135,000 volts alternating for about twenty minutes and opened for examination.

There were 108 layers of paper, of which the outer ones were 8 mils and the inner ones 5 mils thick. The 8-mil paper was found to be entirely free from any evidence of puncture or hot spots. The same applies to the outer few layers of 5-mil paper, but upon reaching about the fiftieth paper from the conductor, evidences of hot spots became numerous.

The first evidence consisted of a tree-like design such as is characteristic of photographs of lightning and other high voltage discharges.[4] Upon examining these "tree" marks it was found that the paper fibers were charred. It was found that while the "tree" design in one layer nearly always crossed the "tree" design in the next layer, these designs were never superimposed, but each "tree" was independently formed, the general direction being across the tape. As more and more layers of paper were removed, the trunks of the "trees" were found to be more and more deeply charred until at about the 44th layer from the conductor, the paper was found to be burned right through. This continued for about fourteen layers when the charring gradually diminished until it ceased at the 18th layer from the conductor. The remaining papers down to the conductor were found to be merely punctured, each paper having a small hole with a charred edge. Other hot spots of a similar character were found which, however, did not extend to the conductor, but were confined exclusively to the intermediate layers of tape. An unpleasant odor was noticed in the vicinity of the tree patterns.

The existence of tree patterns proves the occurrence

4. F. A. S. Kleine, C. F. Proos, and J. C. van Stavern, Conference Internationale des Grands Réseaux Electriques, 1923, observed the same effect in European cable.

within cables of what is generally known as surface leakage.

Surface leakage occurs at all voltages, being merely conduction through films at low voltages, but partaking of the nature of streamers as the air ionizes at higher voltages. Hence, at low voltages, it obeys Ohm's law, but at high voltages, the volt-ampere characteristic depends upon ionic saturation.

The air ionization theory as generally understood, is that at a certain stress, the dielectric loss increases to such a high value that local cumulative heating occurs. Furthermore, according to this theory, a sudden increase of power factor with gradually increasing voltage, presages destructive ionization.

It is our opinion that this theory is not complete and requires a new interpretation; and we believe that the surface leakage phenomena described above, suggest the necessary modification.

Leakage current flows at low voltage without visible manifestation but at high voltages, ionization of the air causes it to flow as streamer discharges with a liberation of energy which varies with the degree of ionization. Failure results from charring of insulation either along the path or at the ends of the streamer.

While the surface leakage theory is based upon visual observations, it is of interest to note how it explains certain phenomena better than the orthodox ionization theory.

1. The lower specific capacity of air films should tend to divert the electrical stress to the surrounding insulation of higher specific capacity. The films, therefore, will not carry k times the ambient stress but considerably less. This would lead one to expect signs of failure around the edges of air films, but these are never found. All the signs of burning occur squarely on the surfaces exposed to the air films, as would be expected if caused by surface leakage.

2. Some cables in which there are numerous large air films in which ionization presumably occurs, have operated satisfactorily at high stresses for years without trouble. In such cases, the reason for the absence of streamers was probably low resistivity of the oil which kept the leakage in the stage of ohmic conduction, and thus restrained the local liberation of energy. Such cables, however, fail from cumulative heating when loaded.

3. It is a part of the film ionization theory that the increase of power factor with voltage is due to air ionization. If a cable be made without adequate drying of the paper and poorly impregnated, the increase of power factor with voltage should be quite marked, as the specific capacity of the solid part of the insulation will be abnormally high, thereby throwing a higher stress on the air films. Experiment shows, however, that in such a cable the power factor will be constant over a wide range of voltage. This is entirely consistent with the leakage theory, because, as suggested above, in a cable made of low resistivity, oil and paper, the leakage current will increase with the voltage according to Ohm's law over the full range.

Discussion

D. W. Roper: A point which should be more prominently set forth is that as the operating voltage of a cable increases, the quality must improve. What is needed at the present time is some method of measuring the quality of the insulation and determining the maximum operating voltage for which a given quality of cable is suited, and to which it should be limited. There are also needed some other tests to be applied to cable at the factory in order to determine whether it will be satisfactory for the service for which it is intended. Apparently some further research as well as cooperation between the manufacturing and operating companies is needed in order to develop the proper tests for this purpose.

W. F. Davidson: The authors refer to the difficulties experienced a few years ago on the use of very stiff impregnating compounds and the resultant formation of voids when the cable was bent. They imply that this difficulty has been entirely avoided by the use of lighter compounds but I am of the opinion that their statement is a little too optimistic. Some day we may reach the point where voids are not developed by bending.

The authors call attention to the fact that many of the phenomena associated with air films in cables cannot be fully explained on the simple hypothesis that ionization results from a stress in the air film K times that in the solid portions of the dielectric. This is a natural consequence of the fact that the air films are not infinite in extent but really are of comparatively small area so that creepage phenomena play an important part. A number of very interesting possibilities are suggested by the considerations of stress distributions with alternating fields and with continuous fields. Some theoretical work has already been started and experimental work has been mapped out. Until more is known of the values of the numerous physical constants it will be impossible to complete studies along this line.

A rough shop method for determining solidifying point of compound is described. Rather more consistent results can be obtained by taking the temperature-viscosity curve by means of a MacMichael viscosimeter. This instrument gives results of very satisfactory precision with a minimum of observational error. Probably in point of time it is rather faster than the method described in the paper. Studies of a considerable number of cable samples have indicated the possibility of getting the temperature-viscosity curve over a wide range from three or four points after the general characteristic has been determined.

R. A. Paine, Jr.: The authors inferred in their paper that if an air film can be maintained at low pressure, they are thus able to get a flat power-factor characteristic. I should be glad if the authors could be able to give us some data or results of any experiments that they have been able to make along that line, as it would seem that it would be almost impossible to maintain this air film at low pressure.

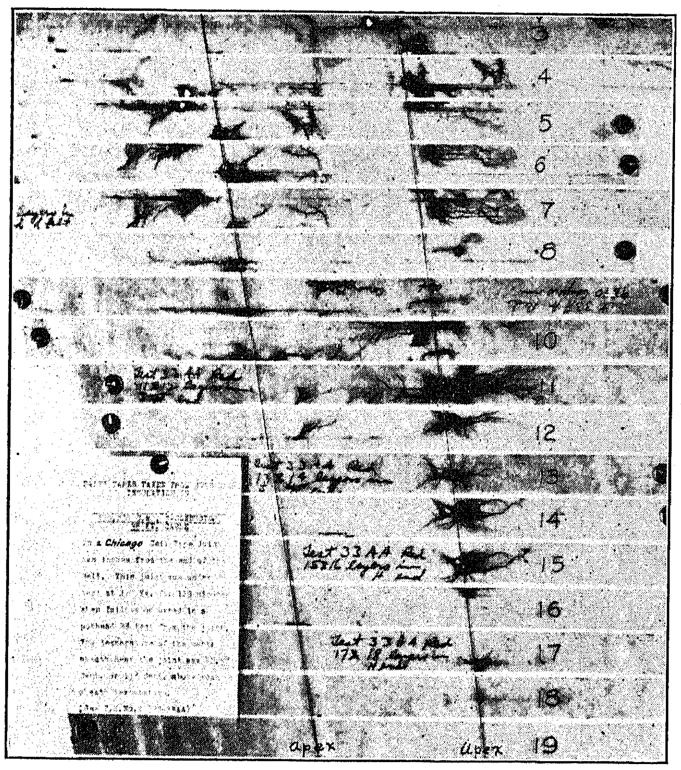
The authors speak of the ratio of oil to paper as a means of determining saturation. I am glad to note they say they are going to do some further research work along that line in order to get a better method of determining the degree of saturation. It seems to me that they are missing one point, and that is what we really want to know is if the complete volume inside of the cable is filled. What we really ought to have, I believe, is the total volume, and then take into account the total amount of paper and the total amount of oil in it rather than work on a ratio basis.

There are at least three of the American cable manufacturers now who can make cables with almost no wrinkles, practically

none, and I think within the next year we ought to be reasonably sure of getting cables that will have no trouble standing up in operation over a period of years.

H. Halperin: I wish to emphasize the remark of Mr. Del Mar, that there is a very urgent need for securing uniformly good cable insulation. In a 10-mile line of three-conductor cable with 350,000 cir. mil. sector conductors, there are about 29,000 sq. ft. of copper surface from which a failure might occur; and defects in a comparatively very small per cent of the total insulation can easily result in poor operation. In dissecting test and service failures of 13-kv. and 35-kv. cable in Chicago, the insulation immediately adjacent to the failure has frequently been found radically different in construction and impregnation from the remaining portion of the same length.

In connection with the carbonized tree patterns that were found by Mr. Del Mar, we have found that these also appeared in the endurance tests at 127-kv., three-phase on the three-conductor, 35-kv. cable. In the illustration shown herewith, these designs were taken from the conductor insulation in a joint



2 in. outside of the belt. Usually the carbonized patterns in the cable were most pronounced at or near the apex of the sector, that is, the portion pointing toward the center of the cable. The most pronounced formation of these tree patterns was found in cables which withstood the test for the longest time.

The authors state that the compound "X" has been found in the outer conductor insulation and inner belt insulation. Frequently in three-conductor, 35-kv. cable we have found it throughout the conductor insulation and in some cases the formation was most marked adjacent to the copper.

In the latter part of the paper a curve of power factor against temperature for a cable with 15 per cent rosin in its compound shows the power factor at 80 deg. cent. to be over 9 per cent; and the discussion is to the effect that the presence of rosin materially affected the critical temperature in cumulative heating. This effect is negligible with the many European cables being made and which have been made, with higher percentages of rosin than 15 per cent and power factors about half or less than those shown in the curve *B* for temperatures of 60 and 80 deg. cent.

E. R. Thomas: I would like to contribute a little discussion to the paper by Messrs. Del Mar and Hanson. We have made some tests in New York of high-potential stresses on impregnating compounds. I will give somewhat of a resumé of our tests. We used some special glass test tubes, the outer diameter of one being a few mils less than the inner diameter of the other. In the larger test tube was put a small quantity of mineral oil, heated very slightly, enough to form a liquid state, dropped the other tube inside and in that way obtained a very thin film of impregnating compound. This was subjected to a high-voltage gradient by putting a mercury electrode in the inner tube, immersing the outer tube in salt water and then applying a high potential between electrodes.

The visual phenomenon which occured when putting this under stress was a very light corona discharge in the tube. There was no occluded air in this very thin film which would be quite readily discernable by holding it to the light. After this had been on test for some two hours, some changes went on. We had sealed the tube at the top with a small rubber balloon which became inflated and thus gave evidence that some gas was given off. The noted change occurring in the oil was that it goes over to a state of solidification and from its resemblance we had termed it Swiss cheese. It changes from the oil, which is amber, to a rather yellow waxy substance with numerous void spaces in it giving a Swiss-cheese appearance.

Several batches of this were run until we had a sufficient quantity to make a breakdown test. This was melted into an oil cup, and, by the way, goes back to a waxy substance after being melted. The breakdown test showed that there was no practical difference in breakdown strength from the original compound. We also have found that by modifying a mineral oil compound with some other things this change over in substance can be somewhat lessened and I believe that there is a considerable field of research open in this line.

H. F. Randolph: The results obtained by Messrs. Del Mar and Hanson on overstressed cables are particularly interesting, since we have noticed a great many of these points in our investigation in the after-performance of underground cables in the past year.

It appears that dielectric loss in high-voltage paper cables has been reduced to a minimum and is no longer a controlling factor. It would be interesting to know if any other qualities were sacrificed in order to accomplish this.

The authors state that although very high voltages are obtained on samples of three-conductor cables, it is practically impossible to break them down in laboratory tests, but still failures occur in actual operation of these same types of cables, although operating conditions previous to, and at the time of, failure are apparently normal. We have examined samples of cable adjacent to some of these failures and have noticed a similar condition to that mentioned by Mr. Del Mar, the perforation of the layers of paper, but we have not noticed any tree designs. It would be interesting to know the approximate voltage that would be apt to cause this condition.

I would also like to ask the question as to whether a percentage of rosin-oil compound mixed with a mineral-oil compound would have any decided effect on the life of the cable.

A. H. Kehoe: I think the real value of the so-called power-factor test is not brought out in the Del Mar-Hanson paper. The test consists in the change in power factor on test samples of cables with an increase in voltage of the proper amount. It may be true, as stated in the paper, that the curve of power factor increases, diminishes, or stays constant, with a certain line of material, but after a certain kind of cable is brought through a factory and this characteristic determined, there is but one thing that changes the quality in the cable and this resolves itself into "air" in the cable. With an increase of air in a cable

the power-factor curve will be increased over the normal characteristic as soon as the ionization point of the air is arrived at on increasing the voltage for the power-factor test.

In the same paper there is described results of tests at two and one-half times normal working stress. It should be realized that the power-factor test intended to indicate the presence of air by change in power factor is not a matter of normal working stress on the cable. It is a matter rather of stressing the cable insulation up to certain definite values where air (if it be in the insulating structure) will be ionized. This becomes a matter of physical dimensions and properties of the insulation and has no definite relation to normal working stress.

G. B. Shanklin: In reference to the theory of ionization the following statement is found on the third page of the paper by Messrs. Del Mar and Hanson: "It is our opinion that this theory is not complete and requires a new interpretation; and we believe that the surface leakage phenomena described, suggest the necessary modification." The surface leakage phenomena mentioned in the above statement refer to the characteristic fern leaf discharge path between paper wrappings, frequently, if not always, found after subjection to high-potential test, that is, a stress considerably higher than normal.

The configuration of this type of discharge is typical of all high-frequency discharges, such as lightning, static discharge over insulators, etc. It is the result of a destructive groping or reaching about for the weakest path, which in this case happens to be along the paper surfaces. The high impedance at these very high frequencies is the cause of these discharges not being directional. They do not necessarily follow air or gas pockets but actually form their own pockets by generation of gas as they travel along.

Apparently, Messrs. Del Mar and Hanson have confused the above phenomena with the slow, steady glow discharge which occurs in gas pockets at lower voltage stressing and constitutes the true ionization with which cable engineers are concerned. The effects of this are much more gradual and the range of travel much more limited. The result is a slow chemical change or disintegration, not necessarily accompanied by charring. It is more to be feared than the first-mentioned phenomena, for it might occur at normal operating voltage, while the first, as far as my observation has gone, always requires considerable over stressing.

This second type of discharge did not escape their observation for they give a very accurate description of its effects. Their explanation, suggesting the formation of fatty acids, seems very reasonable and probable. There is not a sufficient quantity of nitrogen present to form nitro products.

The various methods of factory test and control they describe are now being followed by most, if not all, of the cable manufacturers. Most of these have proved reliable guides to a better quality cable. A few have not. In particular, no reliable test has yet been developed to determine the degree of impregnation. The method of extraction with carbon tetrachlorid or other solvents has not proved satisfactory. So far, the old method of visual examination and expert judgement has not been displaced.

I was very much interested in their characteristic "breakdown versus time" curve, given in Fig. 15, and fully agree with their statement that such curves are of no value in determining ultimate life at normal voltage by extrapolation, due to the fact that other factors of a deteriorating nature enter into action as time goes on.

C. F. Hanson: I should like to make a reply to Mr. Halperin's statement regarding the last part of the paper, referring to Curves A and B. We do not say it is not possible to secure lower power factors using rosin than are given by Curve A, nor do we say that we always need to get as high a power factor as given by Curve B. These curves were given simply to show the relative values when we do and do not use rosin. They are the results of three cables, all treated identically, the same oil being used, only that in one case 15 per cent of rosin was added; while in the other cases, no rosin was added.

The data were obtained some years ago when oil refineries had not developed in refining petrolatum the technique applied today. With present-day oil, lower power factors may be obtained than those shown in Curves A and B.

Wm. A. Del Mar: Mr. Roper is right in pointing out that as the operating voltage of a cable increases, the quality must improve. The term "quality," however, is a somewhat indefinite one and should not be interpreted as applying to all of the characteristics of the cable. Some discrimination is required to determine which characteristics should be improved as the voltage increases. For instance, the quality of the paper as set forth in ordinary specifications should be decreased rather than increased for higher voltages. By this I mean that more or less wood pulp should be allowed. Similarly, flexibility requirements should be reduced rather than increased in the case of high-voltage cables so as to permit the use of materials of greater dielectric strength at the expense of the mechanical qualities.

It is also quite possible that the dielectric loss should not be too low in cables for very high voltages in order to give an opportunity for the dissipation of local transients in the insulation. The main quality which requires to be improved as the voltage is raised is the saturation, with special reference to the elimination of air.

Since the paper was written, an apparatus has been developed by our laboratories, for measuring saturation as a ratio of air to insulation by volume. It consists of an inverted funnel with a graduated closed-top tube. This is filled with water, placed in a jar of air-free water with a section of cable about an inch thick under it. The jar is then evacuated and the vacuum maintained over night. This results in sucking the air out of the cable and causes it to collect in the tube of the funnel. The vacuum is then broken, causing the air in the funnel to contract to its atmospheric volume. The displacement of the cable is noted, its copper and lead removed, and their displacement noted. The volume of insulation is the difference between the displacement of the cable and that of the combined copper and lead. The saturation is expressed as the ratio by volume of air to insulation. The insulation is then examined under water to make sure that all the air has been removed. There is an error which it seems impossible to eliminate, namely that air is sucked from the strands as well as from the insulation, so that if the interstices between strands are not well filled, the insulation will be debited accordingly. This, however, has not affected the practical usefulness of the device which is now in regular use for control tests.

Mr. Thomas has described experiments which, he says, have enabled him to produce a yellow, waxy substance with numerous voids, merely by exposing mineral oil to a strong electrical field. We have repeated the experiment and obtained the same results. The material, as stated by Mr. Thomas, melts and has the same electric strength as the original compound. The reason for this is that it is the original compound, the changed appearance after the application of stress being due merely to an emulsification. Mr. Thomas's experiment did not result in producing the material referred to as X in our paper, as this latter cannot be melted. It is neither fusible nor soluble in any solvent available. Chemical analysis shows it to be free of nitrogen and to contain a very small quantity of oxygen. Research work is now under way which, it is hoped, will lead to its chemical identification.

In reply to Mr. Randolph, the tree patterns are readily formed at three-fourths of the short-period breakdown voltage. The addition of rosin-oil compound to mineral-oil compound does not improve the life of the cable.

An important difference between our leakage tree patterns and the steady glow of ionization described by Mr. Shanklin is that the former are matters of visual observation, whereas the existence of the latter is known only by theoretical deduction. Mr. Shanklin says that tree patterns are the result of destructive groping or reaching for the weakest path. We are entirely in accord with this but believe that the weakest path must be along the air pockets because air ionizes at a much lower voltage than oil.

In conclusion, I would take some exception to the general tendency of some of the speakers to assume that American cable manufacturers have not kept up with the general progress of electrical industry. It should be remembered that they have been laboring under a handicap unknown either to other branches of electrical industry or to cable manufacturers in other countries. I refer to the tendency of American cable users to put into their specifications clauses, the undue emphasis of which is entirely irrelevant to the proper performance of the cables but which forces the manufacturers into competition on unessentials rather than allowing them to concentrate their efforts on factors of major importance. Principal among these irrelevant requirements have been excessive flexibility and excessively low dielectric losses. Another requirement of the same character which is now assuming prominence is the so-called ionization test.

If the American manufacturers succeed in making cables which pass American specifications and have characteristics as good as the best European cables, they will have accomplished an infinitely more difficult task than the Europeans have done, and this goal has actually been reached by some of them.

The Direct Method of Calculation of Capacitance of Conductors

BY HERBERT BRISTOL DWIGHT
Member, A. I. E. E.
Canadian Westinghouse Co., Ltd., Hamilton, Ont., Canada

Review of the Subject.—*The capacitance, or electrostatic capacity, of conductors of various shapes has practically always been calculated by the "inverse method" of first assuming certain charges of electricity and from them calculating equipotential lines and surfaces, which, in the more fortunate cases, agreed exactly with the shapes of the conductors. In other cases, such as that of a three-conductor sheathed cable, the agreement, and therefore the calculated capacitance, were only approximate.*

For multiconductor cables with round conductors, a "direct method" of calculation of capacitance is described in this paper, which uses the exact shape of the round conductors, and which gives accurate expressions for the irregular distribution of electricity on the conductors, and for the value of the capacitance.

Formulas and examples are given for the following cases: 1. Finite wire and infinitesimal wire. 2. Single-phase overhead line. 3. Two conductors and sheath. 4. Three conductors and sheath.

THE direct method of calculation of capacitance, as distinguished from the more usual inverse method, consists in first assuming the shape of the conductors, and from that calculating the distribution of electric charge and the capacitance. In the inverse method, one finds the shape of the conductors from the potential calculated from charges of electricity concentrated at points or uniformly distributed along lines or over surfaces. If the equipotential lines are not true circles, then the calculated capacitance is not correct for circular conductors, but is only approximate. This is the case with two-conductor and three-conductor sheathed cables.

In this paper, accurate formulas using the direct method are given for four cases: first, a finite wire and an infinitesimal wire; second, the capacitance of a single-phase overhead line; third, the capacitance of the sheath on one side and the two conductors on the other side, of a two-conductor cable; and fourth, the capacitance of the sheath on one side and the three conductors on the other side, of a three-conductor cable. For the second case an accurate standard formula is available for comparison. The formula for the third case, given in this paper, was given by the writer in a discussion in the JOURNAL of the A. I. E. E., November, 1923, page 1208.

It appears that practically all formulas for capacitance have been based on the inverse method. This is true, at any rate, of the published formulas for capacitance of multiconductor sheathed cables. It is stated by Clerk Maxwell in Chapter VII of "Electricity and Magnetism," published in 1873, that every electrical problem of which we know the solution has been constructed by the inverse process of finding the shape of the conductors from the potential due to assumed charges of electricity. He also states that the only method by which one can expect to solve a new problem is by reducing it to one of the cases in which a similar problem has been constructed by the inverse process. Maxwell's statement has been quoted in fairly recent articles, and the limitation which he gives that the inverse process must always be used and that one cannot start with an assumed shape of conductor seems to hold in the most recent calculations of capacitance. It seems evident that the direct method described in this paper, which accurately uses the direct process of starting with given shapes of conductors, should be of considerable use.

The demand for greater accuracy in this type of calculation is shown by the paper published by Mr. D. M. Simons,[1] who gave results for two, three and four-conductor cables which are more accurate than those previously available obtained by the inverse process of calculation. Mr. Simons' results were obtained by graphically correcting the length of the lines of flow pertaining to the inverse method of calculation. His results, pointed out in his paper, still contain a certain amount of approximation since the position of the lines of flow is not that corresponding to true circular conductors, and that accounts for some of the discrepancy between his results and those given in this paper.

In connection with the calculation of the numerical example of the three-conductor cable given in this paper, the writer wishes to acknowledge valuable assistance given by Mr. D. M. Simons in checking and locating errors in the preliminary work.

In the direct method of calculation of capacitance described in this paper, one first assumes a uniform electric charge on the surfaces of the round conductors and their images. From this the resulting charge at any point on the conductors can be calculated. This may be called the first additional charge, and it is in the form of a Fourier series, that is, a series involving $\cos\theta$, $\cos 2\theta$, $\cos 3\theta$, etc. The cosines often disappear when integrated around the circle. One can now calculate the second additional charge, which results from the first additional charge, and so on until the terms become small.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

1. "Cable Geometry and the Calculation of Current-Carrying Capacity," by D. M. Simons, JOURNAL A. I. E. E., May, 1923, page 525.

Finite Wire and Infinitesimal Wire

This is not a practical case, but the solution is used in the problems to follow.

Let there be a finite wire A, carrying an electric charge Q per centimeter, and let there be an infinitesimal wire B carrying an electric charge $-Q$ per centimeter. Quantities are in absolute units. Let O be the point of zero potential.

The surface density of the charge on A will not be uniform, owing to the presence of the charge on B. From the symmetry of the arrangement, the surface density $q_{(\theta)}$ at any point P can be expressed as a Fourier series, the angles being measured from the line $B\,D$. Thus

$$q_{(\theta)} = H_0 + H_1 \cos\theta + H_2 \cos 2\theta + \ldots + H_n \cos n\theta + \ldots$$

where H_1, H_2 etc. are undetermined constants. The total charge on the wire A is

$$\int_0^{2\pi} q_{(\theta)}\, a\, d\theta = 2\pi a H_0 = Q$$

Therefore, $$H_0 = \frac{Q}{2\pi a}$$

The work done against the elementary charge $q_{(\theta)}\, a\, d\theta$ at P, in carrying a unit charge from O to N is

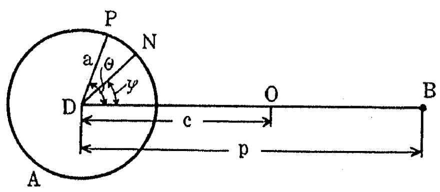


Fig 1—Finite Wire and Infinitesimal Wire

$$2\, q_{(\theta)}\, a\, d\theta \operatorname{logh} \frac{O\,P^*}{N\,P} \qquad (1)$$

The work done against the charges on both conductors is

$$-2\,Q \operatorname{logh} \frac{O\,B}{N\,B} + 2\,a \int_0^{2\pi} q_{(\theta)} \operatorname{logh} \frac{O\,P}{N\,P}\, d\theta \qquad (2)$$

The following expansions are now required:

$$\operatorname{logh} \frac{N\,B}{p} = -\left\{ \frac{a}{p}\cos\varphi + \frac{a^2}{2\,p^2}\cos 2\varphi + \ldots + \frac{a^n}{n\,p^n}\cos n\varphi + \ldots \right\} \qquad (3)$$

$$\operatorname{logh} \frac{N\,P}{a} = -\left\{ \cos(\theta-\varphi) + \frac{1}{2}\cos 2(\theta-\varphi) + \ldots + \frac{1}{n}\cos n(\theta-\varphi) + \ldots \right\} \qquad (4)$$

*Elements of the Mathematical Theory of Electricity and Magnetism, by J. J. Thomson, fourth edition, page 94.

$$\operatorname{logh} \frac{O\,P}{c} = -\left\{ \frac{a}{c}\cos\theta + \frac{a^2}{2\,c^2}\cos 2\theta + \ldots + \frac{a^n}{n\,c^n}\cos n\theta + \ldots \right\} \qquad (5)$$

The derivation of the last series, which is similar to that of the others, is as follows:

$$O\,P^2 = c^2 + a^2 - 2\,a\,c\cos\theta$$

$$\frac{O\,P^2}{c^2} = 1 - a/c\,(e^{j\theta} + e^{-j\theta}) + a^2/c^2$$

$$= (1 - a/c\; e^{j\theta})(1 - a/c\; e^{-j\theta})$$

$$2 \operatorname{logh} \frac{O\,P}{c} = -\left\{ \frac{a}{c} e^{j\theta} + \frac{a^2}{2\,c^2} e^{2j\theta} + \ldots + \frac{a^n}{n\,c^n} e^{nj\theta} + \ldots + \frac{a}{c} e^{-j\theta} + \frac{a^2}{2\,c^2} e^{-2j\theta} + \ldots + \frac{a^n}{n\,c^n} e^{-nj\theta} + \ldots \right\}$$

from which equation (**5**) follows directly. Series (**3**), (**4**) and (**5**) are used in calculations of proximity effect in conductors.

Equation (**2**) can now be written: Work in moving a unit charge from O to N

$$= 2\,Q \operatorname{logh}\left(\frac{p}{p-c}\right) - 2\,Q \left\{ \frac{a}{p}\cos\varphi + \frac{a^2}{2\,p^2}\cos 2\varphi + \ldots + \frac{a^n}{n\,p^n}\cos n\varphi + \ldots \right\}$$

$$+ 2\,a \int_0^{2\pi} \left[q_{(\theta)} \operatorname{logh} \frac{O\,P}{c} - q_{(\theta)} \operatorname{logh} \frac{N\,P}{a} + q_{(\theta)} \operatorname{logh} c/a \right] d\theta \qquad (6)$$

where $$q_{(\theta)} = \frac{Q}{2\pi a} + H_1\cos\theta + H_2\cos 2\theta + \ldots + H_n \cos n\theta + \ldots$$

Now $$\int_0^{2\pi} \cos m\theta \cos n\theta\, d\theta$$

$$= 1/2 \int_0^{2\pi} \{\cos(m+n)\theta + \cos(m-n)\theta\}\, d\theta \qquad (7)$$

This is equal to zero when m is not equal to n and it is equal to π when $m = n$. Thus, in multiplying one series by another in (**6**), most of the terms are equal to zero.

Work in moving a unit charge from O to N

$$= 2\,Q \operatorname{logh}\left(\frac{p}{p-c}\right) - 2\,Q\left\{\frac{a}{p}\cos\varphi + \frac{a^2}{2\,p^2}\cos 2\,\varphi + \ldots + \frac{a^n}{n\,p^n}\cos n\,\varphi + \ldots\right\}$$

$$+ 2\,\pi\,a\Big[-H_1\frac{a}{c} - H_2\frac{a^2}{2\,c^2} - \ldots - H_n\frac{a^n}{n\,c^n} - \ldots + H_1\cos\varphi + H_2\frac{\cos 2\,\varphi}{2} + \ldots + H_n\frac{\cos n\,\varphi}{n} + \ldots + 2\frac{Q}{2\,\pi\,a}\operatorname{logh}\frac{c}{a}\Big]$$

This is true for any value of φ, since the potential is constant for all points on the surface of the conductor, and so the coefficients of $\cos\varphi$, $\cos 2\,\varphi$, $\cos n\,\varphi$ etc. can be separately equated to zero. Therefore,

$$H_1 = \frac{Q}{\pi\,a}\,a/p$$

$$H_n = \frac{Q}{\pi\,a}\,a^n/p^n$$

$$q_{(\theta)} = \frac{Q}{2\,\pi\,a} + \frac{Q}{\pi\,a}\{\,a/p\cos\theta + a^2/p^2\cos 2\,\theta + \ldots + a^n/p^n\cos n\,\theta + \ldots\}$$

$$\text{or } q_{(\theta)} = \frac{Q}{2\,\pi\,a} + \frac{Q}{\pi\,a}\sum_{n=1}^{n=\infty}\frac{a^n}{p^n}\cos n\,\theta \qquad (8)$$

This gives the distribution of the electric charge on the finite conductor, under the influence of a charge concentrated at B. This is a quantity required to be known for calculating capacitance in the problems described in this paper.

Single-Phase Overhead Line

The formula for this case is given to provide a check on the correctness of the direct method. The standard formula, derived by the inverse method, is shorter, and gives exactly the same numerical results.

Let there be two equal wires A and B and let one carry an electric charge Q per centimeter and the other a charge $-Q$ per centimeter. Then the density at P is $\frac{Q}{2\,\pi\,a}$ and at T it is $\frac{-Q}{2\,\pi\,a}$, assuming uniform distribution.

The density at P due to the elementary charge at T,

$$-\frac{Q}{2\,\pi\,a}\,a\,d\,\gamma$$

is

$$\frac{Q\,d\,\gamma}{2\,\pi}\times\frac{1}{\pi\,a}\sum_{n=1}^{n=\infty}\frac{a^n}{d^n}\cos n\,(\theta-\beta) \qquad (9)$$

Now

$$\frac{\cos n\,\beta}{d^n} = 1/s^n\left[1+\sum_{k=1}^{k=\infty}\frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}}\,\frac{a^k}{s^k}\cos k\,\gamma\right] \qquad (10)$$

and

$$\frac{\sin n\,\beta}{d^n} = 1/s^n\sum_{k=1}^{k=\infty}\frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}}\,\frac{a^k}{s^k}\sin k\,\gamma\ * \qquad (11)$$

Integrate expression (9) from $\gamma = 0$ to $2\,\pi$, keeping θ constant. Then the density at P due to the uniform charge on wire B is

$$\frac{Q}{\pi\,a}\sum_{n=1}^{n=\infty}\frac{a^n}{s^n}\cos n\,\theta \qquad (12)$$

Let $\qquad A_n = a^n/s^n \qquad (13)$

This is the first additional charge. A similar expression gives the first additional charge on wire B, namely,

$$-\frac{Q}{\pi\,a}\sum_{n=1}^{n=\infty}A_n\cos n\,\gamma$$

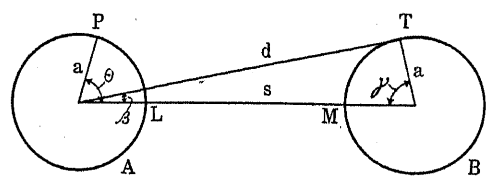

Fig 2—Single-Phase Overhead Line

The density at P due to the elementary charge at T,

$$-\frac{Q}{\pi\,a}\sum_{n=1}^{n=\infty}A_n\cos n\,\gamma\,a\,d\,\gamma$$

is $$\frac{Q\,d\,\gamma}{\pi}\times\frac{1}{\pi\,a}\sum_{n=1}^{n=\infty}A_n\cos n\,\gamma\sum_{m=1}^{m=\infty}\frac{a^m}{d^m}\cos m\,(\theta-\beta)$$

Using equations (7), (10) and (11), and integrating from $\gamma = 0$ to $2\,\pi$, we find that the density at P, due to the first additional charge on wire B is

$$\frac{Q}{\pi\,a}\,[B_1\cos\theta + B_2\cos 2\,\theta + \ldots + B_n\cos n\,\theta + \ldots] \qquad (14)$$

$$\text{where } B_n = a^n/s^n\left\{\frac{\underline{|n+1-1}}{\underline{|n-1}\,\underline{|1}}\,a/s\,A_1 + \ldots + \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}}\,a^k/s^k\,A_k + \ldots\right\} \qquad (15)$$

*"An Integration Method of Deriving the A-C. Resistance and Inductance of Conductors," by H. L. Curtis, Scientific Paper No. 374 of the Bureau of Standards, Washington D. C., April, 1920, Appendix 2.

This is the second additional charge on wire A. Similarly, the third additional charge on wire A is

$$\frac{Q}{\pi a}\,[C_1 \cos\theta + C_2 \cos 2\theta + \ldots + C_n \cos n\theta + \ldots] \quad (16)$$

$$\text{where } C_n = a^n/s^n \left\{ \frac{\lfloor n+1-1}{\lfloor n-1 \lfloor 1} a/s\, B_1 + \ldots + \frac{\lfloor n+k-1}{\lfloor n-1 \lfloor k} a^k/s^k A_k + \ldots \right\} \quad (17)$$

and so on. The total charge at P is

$$\frac{Q}{\pi a}\,[1/2 + L_1 \cos\theta + L_2 \cos 2\theta + \ldots + L_n \cos n\theta + \ldots] \quad (18)$$

$$\text{where} \quad L_n = A_n + B_n + C_n + \ldots \quad (19)$$

The capacitance C may be found by calculating the work done in moving a unit charge from M to L against the charge on wire A. This is

$$\frac{2Q}{\pi}\int_0^{2\pi} [1/2 + L_1\cos\theta + \ldots + L_n \cos n\theta + \ldots]$$

$$\left[\operatorname{logh}\left(\frac{s-a}{a}\right) + \cos\theta + \frac{1}{2}\cos 2\theta + \ldots + \frac{1}{n}\cos n\theta + \ldots - \frac{a}{s-a}\cos\theta - \frac{a^2}{2(s-a)^2}\cos 2\theta - \ldots - \frac{a^n}{n(s-a)^n}\cos n\theta - \ldots\right] d\theta$$

This is equal to $\frac{Q}{2C}$. Therefore,

$$1/C = 4\left[\operatorname{logh}\frac{s-a}{a} + L_1\left\{1 - \frac{a}{s-a}\right\} + \ldots + L_n/n\left\{1 - \frac{a^n}{(s-a)^n}\right\} + \ldots\right] \quad (20)$$

An alternative expression of different algebraical form can be obtained by finding the work done against the charges on both wires by carrying a unit charge to the surface of one wire from the neutral point midway between the two wires. This gives

$$1/C = 4\left[\operatorname{logh} s/a - \frac{a}{s}L_1 - \frac{a^2}{2s^2}L_2 - \ldots - \frac{a^n}{ns^n}L_n - \ldots\right] \quad (21)$$

Formulas (**20**) and (**21**) both give exactly the same numerical results as the standard formula:

$$1/C = 4 \operatorname{logh}\frac{s + \sqrt{s^2 - 4a^2}}{2a} = 4\cosh^{-1}\frac{s}{2a} \;* \quad (22)$$

EXAMPLE OF SINGLE-PHASE OVERHEAD LINE

Let $\quad s/a = 10$

Then $1/C = 9.16972$ by formulas (20), (21) and (22), in absolute units.

TWO-CONDUCTOR SHEATHED CABLE (CAPACITANCE OF THE SHEATH AGAINST THE TWO CONDUCTORS)

Let the radius of the conductors of the cable be a cm. and let the inside radius of the sheath be c cm. Then, as is well known in connection with calculations of capacitance, image conductors can be assumed at a distance s and of radius a', which will carry charges equal and opposite to those of the cable conductors. The inner surface of the sheath can be considered as a

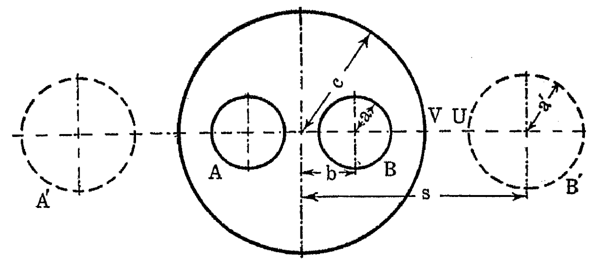

FIG. 3—TWO-CONDUCTOR SHEATHED CABLE

surface of zero potential, carrying no charges. The dimensions a' and s are given by

$$a' = \frac{a\,c^2}{b^2 - a^2} \quad (23)$$

and

$$s = \frac{b\,c^2}{b^2 - a^2} \;** \quad (24)$$

The first additional density of charge at any point of the surface of conductor B, due to uniformly distributed charges on the other three conductors may be calculated in a manner similar to that used for an overhead single-phase circuit. The angle θ is used for the conductor to the right of B and the angle $(\theta - \pi)$ is used for the conductors to the left. The first additional density on B is

$$\frac{Q}{\pi a}\sum_{n=1}^{n=\infty} A_n \cos n\theta \quad (25)$$

*For the derivation of formula (22) see "Transmission Line Formulas" by H. B. Dwight, 1st edition, Chapter XIII, or other books on alternating-current theory.

**"Elements of the Mathematical Theory of Electricity and Magnetism," by J. J. Thomson, fourth edition, pages 149 and 176.

$$\text{where } A_n = \left(\frac{a}{s-b}\right)^n - \left(\frac{-a}{2b}\right)^n + \left(\frac{-a}{s+b}\right)^n \tag{26}$$

The first additional density on B' is

$$\frac{Q}{\pi a'} \sum_{n=1}^{n=\infty} F_n \cos n\gamma \tag{27}$$

$$\text{where } F_n = -\left(\frac{a'}{s-b}\right)^n + \left(\frac{a'}{2s}\right)^n - \left(\frac{a'}{s+b}\right)^n \tag{28}$$

The second additional density on B is

$$\frac{Q}{\pi a} \sum_{n=1}^{n=\infty} B_n \cos n\theta \tag{29}$$

where $B_n =$

$$\begin{aligned} &-\left(\frac{a}{s-b}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{a'}{s-b}\right)^k F_k \\ &-\left(\frac{-a}{2b}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{-a}{2b}\right)^k A_k \\ &-\left(\frac{-a}{s+b}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{a'}{s+b}\right)^k F_k \end{aligned} \tag{30}$$

The second additional density on B' is

$$\frac{Q}{\pi a'} \sum_{n=1}^{n=\infty} G_n \cos n\gamma \tag{31}$$

where $G_n =$

$$\begin{aligned} &-\left(\frac{a'}{s-b}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{a}{s-b}\right)^k A_k \\ &-\left(\frac{a'}{2s}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{a'}{2s}\right)^k F_k \\ &-\left(\frac{a'}{s+b}\right)^n \sum_{k=1}^{k=\infty} \frac{\underline{|n+k-1}}{\underline{|n-1}\,\underline{|k}} \left(\frac{-a}{s+b}\right)^k A_k \end{aligned} \tag{32}$$

For C_n and H_n use the same formulas as for B_n and G_n except change A to B and F to G. Then for D_n and I_n change B to C and G to H, and so on.

The total density on B is

$$\frac{Q}{\pi a}\left[1/2 + \sum_{n=1}^{n=\infty} L_n \cos n\theta\right] \tag{33}$$

$$\text{where} \quad L_n = A_n + B_n + C_n + \ldots \tag{34}$$

The total density on B' is

$$\frac{Q}{\pi a'}\left[-1/2 + \sum_{n=1}^{n=\infty} M_n \cos n\gamma\right] \tag{35}$$

$$\text{where} \quad M_n = F_n + G_n + H_n + \ldots \tag{36}$$

It is now necessary to calculate the work done against all the charges, when carrying a unit charge from the surface of an image conductor to the surface of one of the conductors of the cable. This quantity of work is twice the potential between the grounded sheath and the two conductors which are taken connected in parallel in this calculation. Therefore,

$$\text{Work} = \frac{4Q}{C}$$

where C is the capacitance of the sheath on one side and the two conductors on the other. The amount of the work is calculated by using equation (1) of this paper, and the following result is obtained:

$$\begin{aligned} 1/C = {} & \operatorname{logh} \frac{(s-b-a')(s-b-a)(s+b-a')(s+b+a)}{a a'(2b+a)(2s-a')} \\ & + \sum_{n=1}^{n=\infty} L_n/n \left[1 - \left(\frac{a}{s-b-a'}\right)^n - \left(\frac{-a}{s+b-a'}\right)^n + \left(\frac{-a}{2b+a}\right)^n\right] - \sum_{n=1}^{n=\infty} M_n/n \Bigg[1 \\ & - \left(\frac{a'}{s-b-a}\right)^n - \left(\frac{a'}{s+b+a}\right)^n + \left(\frac{a'}{2s-a'}\right)^n\Bigg] \end{aligned} \tag{37}$$

Equation (37), in connection with (23), (24), (26), (28), (30), (32), (34) and (36), is used in calculating numerical values of capacitance.

Example, Two-Conductor Cable. $a = 1, b = 2, c = 5$ Then $s = 50/3$ and $a' = 25/3$.

This corresponds to $t/T = 1$ and $\frac{T+t}{d} = 1$ in Mr. Simons' paper previously referred to, Table I, and the calculation gives a geometric factor of 1.730 to compare with 1.718 given by the graphical method. The difference in this case is less than one per cent.

The geometric factor suggested by D. M. Simons, for capacitance of an n-conductor cable, between the sheath on one side and the n conductors on the other, is

$$G_1 = \frac{k\,n}{2C}$$

where k is the permittivity of the dielectric, and C is the capacitance per unit length for the above connection. The geometric factor can also be used in formulas for thermal resistance.

Three-Conductor Sheathed Cable, (Capacitance of the Sheath against the Three Conductors)

The size and location of the image conductors are given by the following equations which are similar to (23) and (24) of the calculation for a two-conductor cable:

$$a' = \frac{c^2 a}{b^2 - a^2} \tag{38}$$

$$s + b = \frac{c^2 b}{b^2 - a^2} \tag{39}$$

The first additional density on A, due to uniform density of charge on all the other conductors is

$$\frac{Q}{\pi a}\sum_{n=1}^{n=\infty} A_n \cos n\,\theta \qquad (40)$$

where $A_n = \dfrac{a^n}{s^n} - \dfrac{2\,a^n}{t^n}\cos n\,\delta + \dfrac{2\,a^n}{u^n}\cos n\,\sigma \qquad (41)$

where Q is the electric charge per centimeter on each conductor, and where the various dimensions and angles are indicated in Fig. 4.

The first additional density on A' is

$$\frac{Q}{\pi a'}\sum_{n=1}^{n=\infty} F_n \cos n\,\gamma \qquad (42)$$

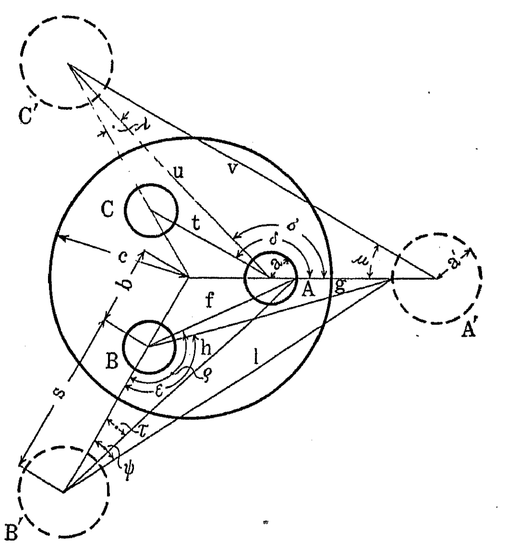

FIG. 4—THREE CONDUCTOR SHEATHED CABLE

where

$$F_n = -\frac{a'^n}{s^n} - \frac{2\,a'^n}{u^n}\cos n\,\lambda + \frac{2\,a'^n}{v^n}\cos n\,\mu \qquad (43)$$

The second additional density on A is

$$\frac{Q}{\pi a}\sum_{n=1}^{n=\infty} B_n \cos n\,\theta \qquad (44)$$

$$\text{where } B_n = -\,a^n/s^n \sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a'^k}{s^k}F_k$$

$$-\frac{2\,a^n}{t^n}\cos n\,\delta\sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a^k}{t^k}A_k\cos k\,\delta$$

$$-\frac{2\,a^n}{u^n}\cos n\,\sigma\sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a'^k}{u^k}F_k\cos k\,\lambda \qquad (45)$$

The second additional density on A' is

$$\frac{Q}{\pi a'}\sum_{n=1}^{n=\infty} G_n \cos n\,\gamma \qquad (46)$$

$$\text{where } G_n = -\,a'^n/s^n \sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a^k}{s^k}A_k$$

$$-\frac{2\,a'^n}{u^n}\cos n\,\lambda\sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a^k}{u^k}A_k\cos k\,\sigma$$

$$-\frac{2\,a'^n}{v^n}\cos n\,\mu\sum_{k=1}^{k=\infty}\frac{|\underline{n+k-1}}{|\underline{n-1}\,|\underline{k}}\,\frac{a'^k}{v^k}F_k\cos k\,\mu \qquad (47)$$

For C_n and H_n use the same formulas as for B_n and G_n except change A to B and F to G. Then for D_n and I_n change B to C and G to H, and so on.

The total density on A is

$$\frac{Q}{\pi a}\left[1/2 + \sum_{n=1}^{n=\infty} L_n \cos n\,\theta\right] \qquad (48)$$

where $\quad L_n = A_n + B_n + C_n + \ldots \qquad (49)$

The total density on A' is

$$\frac{Q}{\pi a'}\left[-\,1/2 + \sum_{n=1}^{n=\infty} M_n \cos n\,\gamma\right] \qquad (50)$$

where $\quad M_n = F_n + G_n + H_n + \ldots \qquad (51)$

The work done in carrying a unit charge from the surface of conductor A' to the surface of conductor A, along the line joining their centers, is equal to

$$\frac{6\,Q}{C}$$

where C is the capacitance of the condenser consisting of the sheath on one side and the three conductors on the other.

The result of integrating the work, due to all the charges is

$$1/C = 1/3\,\mathrm{logh}\,\frac{(s-a')\,(s-a)}{a\,a'} + 2/3\,\mathrm{logh}\,\frac{g\,h}{f\,l}$$

$$+\,1/3\sum_{n=1}^{n=\infty} L_n/n\left[1-\left(\frac{a}{s-a'}\right)^n\right.$$

$$\left.+\,2\,(a/f)^n\cos n\,\rho - 2\,(a/g)^n\cos n\,\epsilon\right]$$

$$-\,1/3\sum_{n=1}^{n=\infty} M_n/n\left[1-\left(\frac{a'}{s-a}\right)^n\right.$$

$$\left.-\,2\,(a'/h)^n\cos n\,\tau + 2\,(a'/l)^n\cos n\,\psi\right] \qquad (52)$$

EXAMPLE, THREE-CONDUCTOR CABLE

$$a = 1,\quad b = \sqrt{3},\quad c = 2+\sqrt{3}$$

This corresponds to $t/T = 1$ and $\dfrac{T+t}{d} = 1/2$ in Mr. Simons' paper previously referred to, Table I. The calculation gives a geometric factor of 1.465 to compare with 1.455 obtained by the graphical method. The difference is less than one per cent.

Discussion

D. M. Simons: I would like to emphasize Mr. Dwight's statement that while his solution is in terms of capacity, in so far as the geometric relationships are concerned, his work is immediately applicable to the calculation of thermal resistance, electrical resistance, dielectric loss, etc. His paper is especially valuable inasmuch as it makes possible a rigid calculation of thermal resistance between conductors and sheath, which calculation is believed to be the most usual calculation where the geometric relationship between the three conductors as one electrode and the sheath as the other electrode are involved.

I would like to point out also that Mr. Dwight's formula is really merely a guide to a long and difficult mathematical process. It will be found that its application is by no means similar to the use of a simple formula involving one or two slide-rule operations, but that it is really a laborious computation. It is to be hoped that someone will have an opportunity of making a large series of such computations so as to make the exact data available throughout the range of the usual proportions of three-conductor cables.

Vladimir Karapetoff: Mr. Dwight's paper is certainly a bold attempt to treat the problem in a somewhat novel manner, and I hope that the method outlined is not only correct but is the simplest method possible for this particular problem. I mean that while we cannot solve this problem by the so-called method of inversion, yet there is another method which gives splendid results for two spheres.[2] This latter method would be of no use if it were not for two facts: first, that all the fictitious charges are concentrated between the center of each sphere and its periphery on the center line; and, secondly, that all consecutive charges decrease in magnitude. Therefore, by putting an infinite number of charges along both center lines, a new electrical system is created such that, for that system, both spheres are equipotential surfaces. According to a general theory of electrostatics, if a possible distribution of electricity in equilibrium has been found, then this is the only possible distribution. Thus, having found a solution, we know that it is the solution.

It seems to me that Mr. Dwight goes to an unnecessary complication by not limiting himself to linear charges by taking charges distributed upon cylinders, and I wish to suggest that he try the same method as used with spheres.

S. E. Pero: (by letter): The final results in Mr. Dwight's paper seem to admit of simplification by a continuation of the analysis. At least in the case of the single-phase overhead-line formula which is the one I have examined particularly, the solution of the series equation by the method of successive substitutions will reduce the formula to the usual form by which Mr. Dwight checked his result numerically. This method of solution was applied by Mr. John R. Carson in his paper "Wave Propagation over Parallel Wires: The Proximity Effect," *Phil. Mag.* April, 1921, and in allied investigations. In fact, in 1920, we obtained a solution for the capacity in the case of two wires enclosed in a sheath, of which the single-phase circuit was treated as a special case.

Mr. Dwight's analysis of the latter problem may be continued in the following way. Denoting by λ, the ratio a/s where a is the radius of the conductors and s the interaxial separation, the capacity c between the wires of a single-phase overhead line, is, by formulas (13), (15), (17), (19) and (21) of the paper

$$\frac{1}{C} = 4\left[\log\frac{1}{\lambda} - \lambda L_1 - \frac{\lambda^2}{2} L_2 - \ldots \frac{\lambda^n}{n} L_n - \ldots\right] \quad (1)$$

where

$$L_n = A_n + B_n + C_n + \ldots \quad (2)$$

$$A_n = \lambda^n$$

$$B_n = \lambda^n \left[\frac{n}{1\,!}\lambda A_1 + \frac{n\,(n+1)}{2\,!}\lambda^2 A_2 + \ldots\right] \quad (3)$$

$$C_n = \lambda^n \left[\frac{n}{1\,!}\lambda B_1 + \frac{n\,(n+1)}{2\,!}\lambda^2 B_2 + \ldots\right]$$

Consequently, by equations (2) and (3),

$$L_n = \lambda^n \left[1 + \Sigma_1^k \frac{(n+k-1)\,!}{(n-1)\,!\,k\,!}\lambda^k L_k\right] \quad (4)$$

$$= \lambda^n t_n \quad (5)$$

where

$$t_n = 1 + n\,\lambda^2 t_1 + \frac{n\,(n+1)}{2\,!}\lambda^4 t_2 + \ldots \quad (6)$$

Equation (6) is identical in form with equation (35) of Mr. Carson's paper on proximity effect. The solution may be obtained as explained in that paper, or may be derived by successive substitutions. By the latter method, the solution of the set of equations (6) is given by the limit of the sequence $t_n^{(0)}\, t_n^{(1)} \ldots t_n^{(n)} \ldots$ where

$$t_n^{(0)} = 1$$

$$t_n^{(1)} = \left(\frac{1}{1-\lambda^2}\right)^n$$

$$t_n^{(2)} = \left(\frac{1}{1-\dfrac{\lambda^2}{1-\lambda^2}}\right)^n$$

or, finally, t_1 is given by the continued fraction

$$t_1 = \cfrac{1}{1-\cfrac{\lambda^2}{1-\cfrac{\lambda^2}{1-\lambda^2 \ldots}}}$$

$$= t = 2\,\frac{1-\sqrt{1-(2\,\lambda)^2}}{(2\,\lambda)^2} \quad (7)$$

and

$$t_n = t^n \quad (8)$$

From equations (5) and (8),

$$\lambda^n L_n = \lambda^{2n} t^n \quad (9)$$

and substituting this, (1) becomes

$$\frac{1}{C} = 4\left[\log\frac{1}{\lambda} + \log\,(1-\lambda^2 t)\right]$$

$$= 4\log\frac{1+\sqrt{1-4\,\lambda^2}}{2\,\lambda}$$

$$= 4\log\frac{s+\sqrt{s^2-4\,a^2}}{2\,a} \quad (10)$$

which is formula (22) of the paper, the usual expression for the capacity in this case.

While the succeeding formulas are considerably more complicated it is possible that the foregoing method is applicable to them also.

Formulas (10) and (11) are credited to Mr. Curtis, As a matter of fact, these formulas are very old and they, or their equivalents, are found in such standard works as Hobson "Plane Trigonometry" 2nd edition, p. 261, Bromwich "Theory of Infinite Series" pp. 158-159 and Webster "The Dynamics of Particles and of Rigid, Elastic and Fluid Bodies," p. 391.

H. B. Dwight: The mathematical derivation by Miss Pero of the standard formula for capacitance of two overhead wires, from series (21) of my paper, is a very interesting and useful

2 A. Russell, "Alt. Currents," Vol. I, Chap. 8

result. The simplification obtained in this way in the expression for capacitance is considerable, and if, as she suggests, a similar simplification can be made in the three-conductor formula (52), it would be a great advantage.

A check on the use of inverse surfaces or image surfaces for calculation of capacitance, as employed in my paper, can be made by using this method to calculate the capacitance of a sheathed cable with one eccentric conductor. The result is exactly the same algebraical expression as given by Alexander Russell, in "Treatise on the Theory of Alternating Currents," Edition of 1914, page 165, although his result was obtained without using images.

The fact that the three discussions of this paper suggest that it would be desirable to have a mathematical investigation of considerable length undertaken, shows that in electrical engineering, the same as in the science of physics, research cannot be carried on entirely by laboratory experiments, but a definite place must be given to research by calculation.

The JOURNAL of the A. I. E. E., by publishing papers which give the results of electrical engineering research by calculation, has done a great deal to make this type of research possible. This support should be continued. In spite of the demand which is sometimes expressed that all papers published should be interesting reading, research papers should be judged according to the criterion of whether they constitute a step in the solution of a problem in electrical engineering.

Mr. Simons is quite right about the length of the calculation in the paper which I presented. In fact, I would have hesitated to have written this up as a paper and sent it in if the cable people had not assured me (this applies particularly to the three-conductor calculation, which is extra long) that in spite of the length they wanted to use it.

There are very large opportunities, especially in this calculation of shortening the work for the people using the calculations. That is a long, tedious work but is quite worth while.

Dielectric Field in an Electric Power Cable-II.

BY R. W. ATKINSON
Member, A. I. E. E.
Standard Underground Cable Company, Perth Amboy, N. J.

I. Introduction

THERE are certain properties of multiconductor cables, the solution of which up to the present time has been made mathematically in approximate form only. These problems are, however, capable of satisfactory solution experimentally. The writer presents herewith an experimental solution of some of these problems, this work being a continuation of data presented in a paper[1] before the Institute in 1919. Determination is made of dielectric stresses in three-conductor cables and of the geometric properties affecting the calculation of capacity, dielectric losses, etc., in such cables.

The nature of these problems is best illustrated by considering the case of a single-conductor cable where the determination of the capacitance, in terms of the specific inductive capacity of the material and of the dimensions, reduces to a problem of plane geometry and of simple calculus, the solution having been given by many authors. Thermal resistance or conduction and insulation resistance, etc. are also calculated by the same type of formula. Furthermore, by similar means, the electrostatic stress at any portion of the dielectric may be determined. The present investigation results in making available a considerable amount of similar information for three-conductor cables. In the 1919 work, cable models were prepared consisting of three symmetrically spaced tubes representing the three conductors, surrounded by a fourth tube representing the sheath, all immersed in an electrically conducting liquid (electrolyte). Electrical resistance measurements and difference of potential for stress measurements made on these cable models result in a solution of the geometric problem for the dimensions of the models used and the properties determined from these models are exactly those for actual cables having cross sections which are similar figures geometrically. In making this application, it is assumed that the capacities and stresses of an actual cable are but little affected by the spiralling effect, that is, the twisting or cabling together of the conductors.

During 1920 and 1921, a further series of similar experiments was performed using a different type of model. The models in this series of tests consisted of sheets of tinfoil on which were soldered three copper rings to represent the conductors, surrounded by a fourth larger ring to represent the sheath. The earlier article gave data on three-conductor cables with round conductors only. The new series covers part of the range of the earlier article, but has extreme cases in addition, and also includes the case of sector-shaped conductors. Furthermore, data are given on round duplex cables.

It seems worthwhile, therefore, to supplement the previous paper by these new data, not only to check and enlarge the previous data, but because up to the present time no data of this type have been published on sector-shaped conductors.

Furthermore, while data have been presented confirming part of those published in 1919, some data recently published are not in entire agreement with the writer's early work and it is desirable to point out that additional data obtained are confirmatory of our earlier work.

Sacchetto[1] performed a series of experiments with cable models made of electrodes in a tub of electrolyte as in our early work, and obtained curves from which the geometric relations used in the calculation of capacity, temperature rise, dielectric loss, etc., can be calculated. He did not investigate the stresses. Sacchetto's results agree very closely with the earlier work for the case of three-phase operation, but depart from it somewhat for the case of three conductors as one electrode, against the sheath as the other. Fortunately, additional data are available on this subject, since a recent paper by Simons points out that this problem is capable of graphical solution for the case of three conductors against the sheath. His results check the earlier work of the writer throughout the entire range of that work, to an accuracy of 2 per cent, which is believed to be a very satisfactory check. Furthermore, Simons showed that while exact mathematical calculation has not been possible, an approximate mathematically-derived formula of Mie gives results which are definitely in error in a certain direction. For example, the capacity calculated from this formula is always greater than the true capacity. In the range where Sacchetto's data depart materially from those of the writer, capacities still greater than those determined from Mie's formula are shown. Sacchetto's data are therefore in error at least by the amount of the difference between his data and Mie's formula, whereas the writer's data are consistent with Mie's formula and agree with Simons' graphical solution. This phase of the matter therefore seems to be sufficiently answered without further reference.

Shortly after Sachetto's paper, an article was published by Emanueli on the subject of stress in three-conductor cables, the method of measurement being also based on cable models composed of tubes in a tank of electrolyte. Emanueli's results differ from the writer's results by as much as 12 per cent.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

1. See bibliography at end of paper for all articles cited.

In an article written in 1922 by Middleton, Dawes, and Davis, dielectric strength tests of single and three-conductor cables were reported and, based on an assumption that the breakdown voltage would be dependent upon the maximum stress, a formula or method of calculation of maximum stress was suggested. The method they advocate gives values of stress more than 30 per cent higher for the cases mentioned than the values herein given.

The present paper is therefore written not only to extend the range of the data already published, but to analyze these discrepancies and to establish the true values of the stresses in three-conductor cables. It is worthy of emphasis at this point that it is no part of the present paper to discuss the effect of distribution of stress upon the breakdown voltage, or the allowable working voltage of a given cable.

II. Description of Cable Models

The cable models of the later series were prepared in the following manner. From a roll of tinfoil 15 in. wide, strips 15 in. and 4 in. were cut alternately, the square pieces being used for cable models and the 4-in. strips for resistivity measurements. The foil was 0.0035 in. thick. A copper strip 0.450 by 0.096 in. was bent around a wooden form with a 14.5-in. diameter. The two ends were held together with about ¼ in. overlap and were brazed together with silver solder. The ends were then beveled off smooth. Both edges of the ring were carefully tinned. The ring was then laid on one of the square sheets of tinfoil and a soldering iron run around the upper edge. This soldered the lower edge to the tinfoil. It took a considerable amount of preliminary work to do this accurately, but in the final models the foil was connected to the ring at all points, with very little solder extending out over the foil from the ring. This ring represents the sheath.

The round conductors were obtained by cutting bands ¾ in. wide from copper tubes of the desired diameter. These were then trued up on a lathe to about ⅝ in. wide. Three of these rings were soldered to the tinfoil in the same manner as the sheath at predetermined locations to represent the three conductors of the cable with given proportions of insulation. The sector conductors were prepared as follows: A sector cross-section was drawn in full scale on a sheet of paper, and inside of this was drawn another sector differing from the first by the thickness of the copper strip used for the sheath. A wooden form was then prepared to fit exactly the inner sector, and a copper strip was carefully bent around this form, soldered together, and soldered to the tinfoil exactly as in the case of the sheath.

To the sheath and to each of the conductors were soldered three copper leads, the three leads to each electrode being made carefully of the same length. With this means of introducing the current to each electrode at different points, the electrode surfaces approach more nearly equipotential surfaces, and indeed any practical difference of potential between different points of the surface of one electrode is eliminated.

In addition to the tinfoil cable models, seven sector cable models of the electrolyte tank type were measured for geometric properties in 1918. These data were not given in the 1919 paper, and will therefore be included here. Table I gives the dimensions of all the models used.

TABLE I
DIMENSIONS OF CABLE MODELS IN INCHES

Cable Model		Conductors			Insulation		D
No.	Type	No.	d	Shape	T	t	
10	Tinfoil	1	4.00	Round	5.25	..	14.50

35	Electrolyte	3	2.29*	Sector *D*	1.25	1.25	11.80

d = Conductor diameter.
T = Conductor insulation thickness.
t = Belt insulation thickness.
D = Diameter under sheath.
*d for sector is diameter of round conductor of same cross-section.

Three different forms of sector were used for the tinfoil "cables," the main dimensions and shapes being given in Fig. 1. Sectors *A* and *B* are similar to those used in the cables manufactured by the company with which the writer is associated. Sector *C* was designed as an extreme sector with sharp curvature at the various points. We might add that the major and minor axes of the sectors are the following: for sector *A*, 4.75 in., 2.92 in.; for Sector *B*, 2.38 in., 1.46 in.; for Sector *C*, 6.06 in., 3.02 in. The shape of sector used with the electrolytic tank models Nos. 29 to 35 which we will call Sector *D*, is similar in general characteristics to sectors *A* and *B*. The radius of curvature at the three sharper tips was ⅝ in., and the radius of curvature of the outer surface was 4 in. The major axis was 2.97 in. and the minor axis 1.84 in. Fig. 2 shows the four sector cables of tinfoil form on which measurements of stress were made, and is offered to assist in visualizing the proportions of these cables.

Alexander Russell, in one of his articles, suggested the solution of these geometric problems by means of models using metal foil in the manner above described. We had in mind several purposes in adopting this method for a further series of measurements, in-

stead of the one previously used. The method removed all doubt as to the possibility of polarization. A method was devised by which it was possible to use, in connection with the foil models, a null method for measuring the stress at a given point. A null method was considered to have certain possible advantages from the standpoint of insuring reliability of the measurement, as compared with a deflection method. Other incidental advantages of the foil models are that it is easier to locate definitely the position of the finder

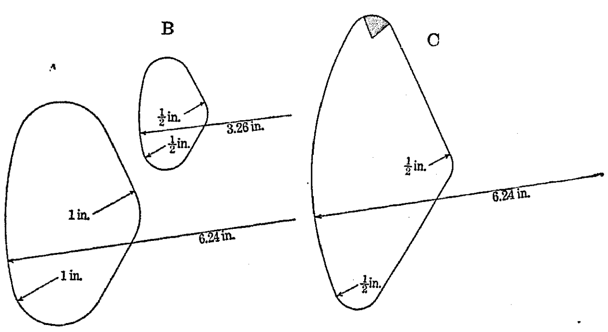

Fig. 1

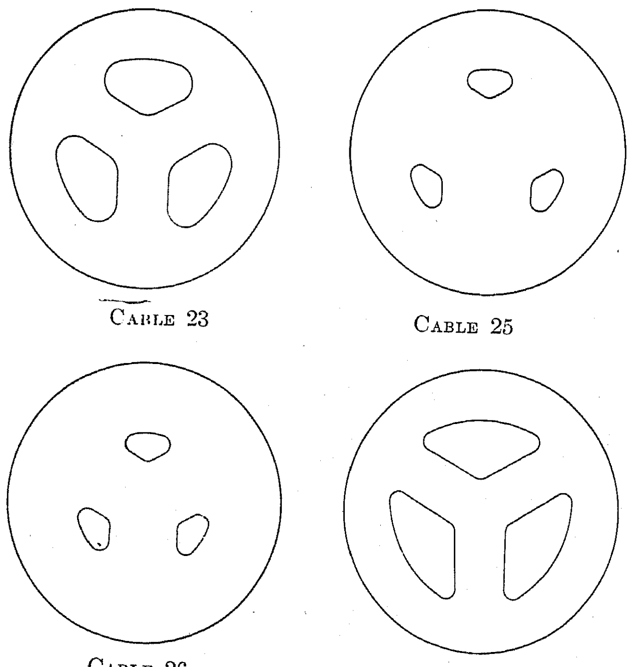

Fig. 2

in the stress measurement; the models are permanent, and after they have been prepared they are always available and check measurements can be made at a later time, both in regard to electrical measurements and measurements of the model dimensions. The electrolytic models have, of course, advantages also, which may be mentioned as follows: There is definite assurance that the medium which represents the insulation is uniform and homogeneous, while there is always danger of variations in foil thickness and the possibility of an accumulation of solder near the conductor surface in the tinfoil models; it is easier to assemble the models, though this advantage is offset by the fact that as soon as a measurement is finished and a new arrangement set up, the original model is lost. Speaking now from experience in using one method and then the other, it is believed that on the whole it is possible to obtain, with a given degree of care and skill, a higher degree of accuracy with the electrolytic type models. The particular value of the measurement with the foil models lies in the greatly added weight that is given the experimental results by the agreement between two sets of measurements carried on under such widely different conditions.

III. Geometric Factor

In the earlier work, the writer published a figure from which the charging current in any connection could be determined for three-conductor cables with round conductors, and it was pointed out how dielectric losses, temperature rise, capacity and insulation resistance could be determined from these data. Sacchetto gave his data in terms of capacity. The data might, of course, just as well have been given in terms of temperature rise or insulation resistance, and Simons has suggested that it is probably more logical to give the data, not in terms of any of these quantities, but as a numerical factor which he calls the "geometric factor" from which all of these quantities may be determined. The advantage of this method of presentation is that the formula for the various quantities is presented directly in terms of fundamentals, instead of in terms of charging current or capacity or in whatever form the data are given. The writer has adopted this notation for the new data.

The definition and meaning of the geometric factor are given by Simons and need not be repeated here, except to state that in general the geometric factor is merely a number which can be substituted for the logarithm which appears in the usual approximate formulas. He also gives formulas in terms of the geometric factor and the specific properties of the insulation, from which insulation resistance, capacity, charging current, temperature rise, and dielectric loss can be directly obtained. G_1 is defined as the geometric factor for the three conductors as one electrode against the sheath as the other, and if it is substituted in the formulas, the properties of the cable will be obtained for that connection. G_2 is the geometric factor under three-phase operation. The geometric factor for any other connection can be obtained from G_1 and G_2 from formulas given by Simons, or can be derived directly from Russell's relationships.

The method used was to measure the resistance between the rings representing the conductors and the ring representing the sheath in the desired connections, and from these measurements to calculate the geometric factors. In order to determine G_1, the resistance was

measured between the three conductors as one electrode, against the sheath as the other. G_2 could be determined by measuring the resistance to neutral with three-phase voltage impressed on the conductors. It has been shown, however, that the resistance to neutral under three-phase pressure is exactly one-half the resistance between any two conductors, if the third conductor and the sheath are insulated. The resistance between two conductors, pair by pair, was measured, and the resistance to neutral was calculated by dividing the average measured value by two. The method used with the electrolyte models has been described in the earlier paper. For the foil models, a standard Kelvin double bridge was used. The three leads connected to each electrode as previously mentioned formed one of the pairs of leads to that electrode, the potential point being separately attached by means of a clip. The measurements were made at whatever room temperature existed at the time and the resistances were corrected to a standard temperature, 25 deg. cent. being chosen, by the following formula:

$$R_{25} = R_t [1 + 0.0042 (25 - t)] \tag{1}$$

In order to calculate the geometric factors from resistance measurements, it is necessary to eliminate the foil thickness and resistivity. This was accomplished as follows: As mentioned in the description of the models, alternate strips of foil, 4 and 15 inches wide respectively, were cut from a 15-in. roll. The square piece was used for a model, and the 4-in. strips were used for a specific resistance measurement. A piece of copper strip was soldered to each end of the 4-in. pieces of foil, and the resistance measured between the strips. From this measurement it was possible to calculate the resistance between opposite edges of a square of foil. Such a resistance depends only on the foil thickness and resistivity and is independent of the length of the side of the square. The average of the two values from the strips originally on each side of a model and corrected to 25 deg. cent. is a constant, characteristic of the model, which will be called K. It may be remarked that a test was made to determine if the resistance of the foil might be different in the direction of the roll as compared with the width of the roll. For this purpose, some special samples were cut with the length parallel to the length of the roll and measurement of resistance made for comparison with the resistance measurement of the strip cut crosswise. The resistivity in the two directions was found to be the same.

The geometric factors may be calculated from the resistance measurements as follows: The insulation resistance of a cable may be expressed by the following standard formula, G being substituted for the usual logarithm:

$$R = \frac{\rho\, G}{2\, n\, \pi} \tag{2}$$

where

R = the resistance in ohms per centimeter length of cable.

ρ = resistivity of the insulation ohm-cm. units.

G = geometric factor for the connection used.

n = number of conductors in cable.

The resistance of the foil, of course, corresponds to the insulation resistance of a cable. If the foil thickness is t centimeters, then the model may be considered as a cable t centimeters long, and the resistance of the foil of the model R is equal to $\rho\, G/2\, n\, \pi\, t$ ohms. The resistance K is equal to ρ/t. If ρ from this be substituted in the equation for the resistance of the model, both ρ and t are eliminated, and we have the following final equation for the geometric factor.

$$G = \frac{2\, n\, \pi\, R}{K} \tag{3}$$

G_1 is obtained by substituting the measured resistance between three conductors and the sheath in (3), and G_2 by substituting the resistance to neutral under three-phase pressure.

For the models composed of tubes in an electrolytic tank, the length and resistivity must also be eliminated. This was done by removing the three electrodes used as the conductors and inserting one circular electrode with a diameter of 2.5 in. concentric with the sheath, and measuring the resistance between the conductor and the sheath. This is equivalent to a single-conductor cable model and is mathematically calculable. From this measurement a constant K suitable for substitution in equation (3) can be calculated. K in this case is not actually the resistance between opposite edges of a square, but is equal to the resistance between the conductor and the sheath multiplied by $2\,\pi$ and divided by $\log_e (R/r)$.

The following Table II gives the values of the resistances at 25 deg. cent. in the two connections considered, the value of K, and the values of the geometric factors as calculated by formula (3). The table also shows the geometric factors for the different cable models as determined by the data from the 1919 paper and also from the paper by Simons, and shows the per cent deviation of the new values from the older ones. For cable 11, the geometric factors are beyond the range of either data, and G_1 and G_2 are compared with values calculated by Russell's formulas, since Simons shows that these formulas are closely correct for such a large value of the ratio $(T + t)/d$. For the case of sector cables, the geometric factor is compared with its value for cables with the same insulation thicknesses, but with round conductors of the same cross-section.

The values of the geometric factor for cables with round conductors are in satisfactory agreement with the earlier determinations, the check being almost perfect in most cases. The check is particularly significant when it is considered how different the three methods are. The present data for round conductor

*Calculated by ordinary logarithmic formula.
†Calculated by Russell's formula.

cables may therefore be considered merely as a confirmation of the earlier data. The maximum deviation occurs in the case of cable 19. This may be explained in part at least by the fact that the graphical method is least accurate in this range of dimensions, and also that the experimental method is least accurate for extreme dimensions. Thus in cable 19, a very small absolute variation in the spacing is a large proportion of the insulation thickness, producing a correspondingly large error.

The data for sector-shaped conductors are believed to be the first published data on this subject with the exception of three short paragraphs in the writer's 1919 paper and for some data on one sector cable model mentioned by W. A. Del Mar in a discussion at the same meeting, and some experimental measurements in connection with thermal resistance published in Appendix VII of the Second Report on the Research on the Heating of Buried Cables. Simons suggested that the geometric factors for the sector cable might be obtained in approximate form by diminishing the geometric factor for the corresponding round conductor cable by 10 per cent. The present data make it possible to obtain a more accurate answer. The geometric factor for sector cables may be obtained by finding the geometric factor for a cable with round conductors with the same insulation thicknesses and the same size of conductor from any of the available data, and then decreasing this by a percentage read from Fig. 3. This method will reproduce the data of Table II quite closely. G_2 of cable 24 seems erratic. Neglecting this one value, the average deviation of Fig. 3 from the data of Table II regardless of sign is 2.3 per cent, the maximum deviation being—

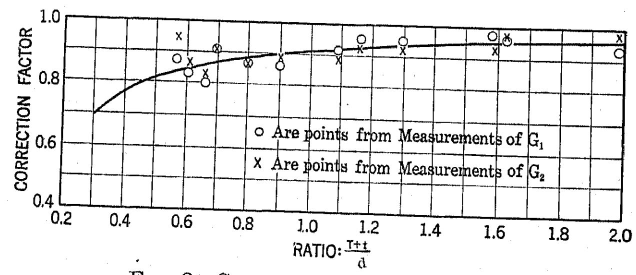

FIG. 3—SECTOR CORRECTION FACTOR

6.0 per cent for G_2 of cable 28 which has the sharp sectors. The correction curve of Fig. 3 is actually a curve whose equation is $y = 1 - 0.093/x$. For round conductor cables Simons has given formulas for G_1 and G_2 which express accurately these values as determined by previous experimental work and by his calculation. Corresponding empirical formulas for sector cables can

therefore be obtained by multiplying his values by

$$1 - \frac{0.093}{(T + t)/d}$$

It seems not improbable that if the shape of the sectors had been designed on an exactly uniform mathematical basis, a more consistent curve for the correction factor might have been obtained. Also if results were of sufficient precision, a different curve could, of course, be drawn for each value of the ratio t/T and there would be different values for G_1 and G_2. It was not deemed that the present data justified more than the single curve as shown. Results of precision will not be obtainable except for approximately a given shape of sector until added numbers of points are obtained for different shapes. We might add, however, that the accuracy which can be reached for sector cables by the use of Fig. 3 is undoubtedly greater than that usually obtained for the case of round conductor cables by means of the approximate formulas which were in ordinary use up to a few years ago.

We have mentioned above two experimental determinations of the geometric factor and one graphical solution. In addition to this work, H. B. Dwight has presented a rigid solution for G_1 for a two-conductor cable, that is, his formula contains a series of converging series, so that any required degree of accuracy can be obtained. He stated that he had also developed a formula for G_1 of a three-conductor cable with round conductors and when this is presented, this phase of the matter will be finally settled.

The Second Report on the Research on the Heating of Buried Cables contained in its appendix two more determinations, not in terms of geometric factor, but in terms of quantities from which the geometric factor can be obtained. In Appendix IV Wedmore shows a graphical solution of this problem which is entirely different in method from Simons', but we are unable to compare the results because the scale on which Wedmore's data are plotted in the published article is such that no accuracy of reading is possible.

In Appendix III of this report some measurements were shown for cable models still different from either of the types mentioned in this paper. Three models were made, each composed of three cylinders surrounded by a fourth cylinder, in the form of an air condenser. It was possible to measure the various capacities of this cable model. We are unable, however, to compare our data with the results of the measurements on these three air-insulated cable models for the following reason: While in a cable model composed of three electrodes surrounded by a fourth electrode, the three "conductors" can be located anywhere inside the "sheath," providing they are symmetrically arranged, this is not the case with an actual cable formed by applying insulation to each of the three conductors, with a belt insulation around the three, where there are certain definite limitations. For instance, half the distance between adjacent conductors is the conductor insulation thickness. The distance between conductor and sheath is the conductor insulation plus the belt insulation thickness. It is obvious that the conductors cannot be nearer the sheath than half the distance between conductors, this condition being the case of a cable with no belt. The first two air-insulated cable models violated this principle, as the conductors are considerably nearer the sheath than half the distance between conductors, and are therefore impossible practical cables. Stated differently, if the circles representing the conductors and the circle representing the sheath are drawn and it is attempted to draw circles representing the boundary of the conductor insulation, such circles will extend outside of the cable. The third model was not impossible, but was an improbable cable according to American practise, in that the electrodes were so located that it corresponded to a cable with a belt insulation two and one-half times greater than the conductor insulation. Our data do not, of course, cover any of these cases.

Electrostatic Stresses

In recent years there has been considerable discussion and by no means entire agreement on the maximum permissible stresses in cables. Whatever these limits may be and whatever the importance of the limits, they cannot be applied or determined unless the stresses can be calculated. It therefore seems well worthwhile to enlarge the scope of the previous data, to check further the accuracy of the work, and to give new data for sector cables.

The geometric factor of all cables which are similar geometric figures is exactly the same, regardless of the absolute dimensions of the cables. The stresses, however, depend not only upon the geometric configuration but upon absolute dimensions and upon the voltage applied. We may say, however, that the stresses will be the same in cables which are similar geometrically if the applied voltages are proportional to the size of the cables. What amounts to the same thing is that the ratio of maximum (or any other stress) to the average stress in a certain part of the cable is a constant for cables which are geometrically similar. The problem is therefore solved for a particular cable model, if the maximum (or other) stress and the average stress through any region are determined, and the ratio of the two is given.

In the earlier work, it was experimentally determined that the maximum stress and other stresses in the part of the cable toward the center were independent of the belt insulation thickness. The stresses vary according to the ratio of conductor insulation thickness to conductor diameter, and may be completely determined if we plot the ratio of stress to average stress as a function of the ratio of conductor insulation thickness to conductor diameter.

The stress of greatest interest is undoubtedly the

maximum stress. If the conductors are very close together, that is, if the conductor insulation is very thin, the maximum stress will occur at the conductor surface on a line joining conductor centers. This is obvious if we go to the limit and imagine the conductor insulation as approaching zero. In this case the stress between conductors will approach infinity, while all other stresses will be finite. With the more usual proportions of insulation thickness and conductor diameter, however, it was shown in the previous work that the maximum stress occurs at the surface of the conductor and towards the axis of the cable, that is, on a line joining the conductor center and the cable center. For very thin insulations, where the maximum stress is at the surface of the conductor and toward an adjacent conductor, it can be calculated by a formula given by Russell. As the insulation thickness is increased, the maximum stress is towards the center, and at an intermediate point the stress all along the surface of the conductor between these two points is approximately the same. Indeed, with the usual thicknesses of insulation, the stress at the surface of the conductor on the line joining conductor centers is very nearly as great as the stress on the surface of the conductor nearest the center of the cable. So far no one has calculated the maximum stress when it occurs in the usual position toward the cable center; hence the need of an experimental determination. The complete curve for maximum stress as a ratio to average stress will therefore consist of two parts; when the insulation is thin we may use a curve obtained by Russell's formula, and for thicker insulations, use experimental data, joining the two curves for a short intermediate section by a curve tangent to the two.

The experimental method of determining stress is the following (described in full with an example in Appendices A and C). A finder was made by fixing two needle points exactly one-quarter inch apart. Half way between the two was a pointer. The pointer is placed at any point on a tinfoil cable model, and the voltage between the two points is measured; this voltage will be a measure of the average stress throughout this quarter inch, or to within about one per cent, the actual stress at the pointer. The voltage between the two points was measured as described in the appendix, being balanced against a voltage adjustable in magnitude and phase angle using a sensitive a-c. galvanometer to detect balance.

Fig. 4 shows a drawing in terms of which the measurements can be most easily explained. The stress was measured along the 180-deg. line in order to determine the true maximum stress, as well as the stress at the center of the cable and the stress at the edge of the fillers. It was measured also at various points along the zero-deg. line, in order to determine the maximum stress towards the sheath. The stress was then measured in a radial and also a tangential direction on various circles around each conductor, in order to be able to find stresses at other points. This procedure was carried out completely except for the case of some of the sector models. By "stress" in this paragraph, we mean potentiometer readings which are proportional to the stress. Though it was possible to determine actual voltages as will be shown, this was not necessary.

We will now describe in detail how the data of the stress measurements were put into useful form. We will begin with the determination for the stress at the surface of the conductor at the 180-deg. line, that is, across the center of the cable, which is normally the point of maximum stress. As stated above, the stress was measured along the 180-deg. line at frequent intervals, starting with ¼ in. from the surface of the conductor. The stress could then be plotted as a function of the distance from the conductor surface along the 180-deg. line, from the conductor surface to the cable

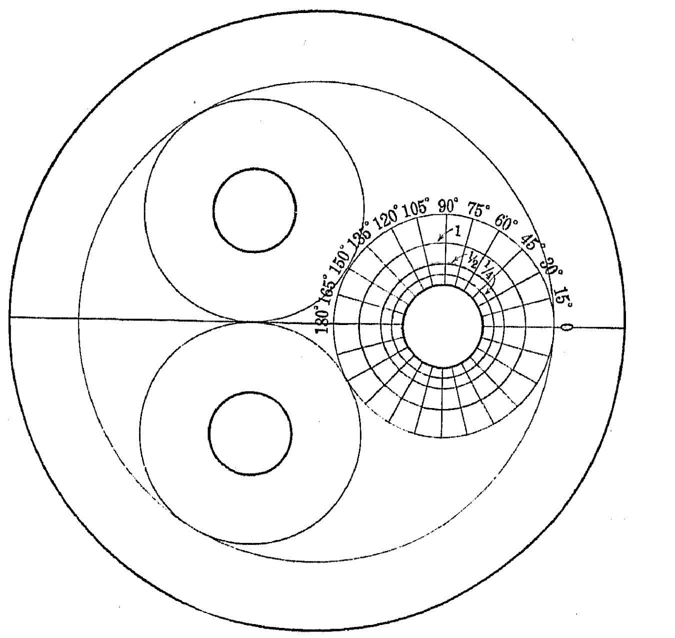

FIG. 4

center. The actual stress at the conductor surface, the maximum stress, is not measured directly, though it might be determined roughly by extrapolating this curve towards the conductor surface.

The maximum stress, however, is much more accurately determinable than this. In a single-conductor cable, the stress varies throughout the field according to a very simple law, that is, it is inversely proportional to the distance from the conductor center. In a multi-conductor cable, no matter what law of variation may be effective at points remote from the conductor surface, the law of variation of stress approaches the same simple law of inverse stress proportionality to the distance from the conductor center, as the surface of the conductor is approached. If the conductor is not round, then instead of conductor center, the statement applies to the center of curvature of the adjacent surface of the con-

ductor. This follows directly from the fact that the lines of electric stress must be normal to a conducting surface, at that surface. If for a single-conductor cable we plot the reciprocal of the stress along a line perpendicular to the surface of the conductor, we obtain a straight line which, if produced, will pass through zero at the center of the conductor. Thus, if data showing the stress at a very few points are plotted, it becomes a simple matter to determine quite accurately in this way the stress at the conductor surface. If the same method of plotting, that is, reciprocal of stress versus distance from the conductor surface, be used for a three-conductor cable, it is found that the data can be represented quite accurately by a straight line which makes extrapolation to zero distance, that is, conductor surface, relatively easy and exact. For round conductor cable, these curves remain straight lines (and pointing in the direction of zero at the conductor center) for a long distance from the conductor surface and the extrapolation is as easy and as accurate as for single-conductor cable. For sector-conductor cable the lines are straight from the nearest point to the surface measured and remain so for a long distance. At the outer tips they point to zero very nearly at the center of curvature of the arc at the tip. At the center they point to zero well beyond this point. They must therefore change direction nearer the surface. We have, however, continued them as straight lines, which means that the values given for the stress at this point are too low by a very small amount. At the surface toward the sheath the line points toward zero at a point much nearer than the center of curvature. As these also were continued as straight lines, the stress determined at this point is very slightly too high.

The maximum stress thus determined is plotted on the stress curve, thus completing the curve from the conductor surface to the cable center along the 180 deg. line. The average ordinate of this curve is the average stress along this line, and this value is found by measuring the area by a planimeter and dividing the area by the distance between conductor surface and cable center. Another way of looking at this is that since the curve has stress as ordinates and distance as abscissas, the area is the voltage between the cable center and the conductor surface in the arbitrary units. This voltage divided by the distance will, of course, give the average stress.

For purposes of ready numerical calculation, the average stress between conductor surface and cable center is awkward to calculate. It therefore seems better as a matter of convenience to find the average stress between conductors, and express the other stresses in terms of this. For this purpose, by the average stress between conductors, we mean the numerical average obtained by dividing the voltage between conductors by the distance between them.

We now have the maximum stress, the average stress between conductors, and stresses at various parts of the cable cross-section obtained by direct measurement. They are all expressed in arbitrary units. Dividing all these values, however, by the average stress expressed in the same units, we obtain a value which is a characteristic of the cable, and the final results are given in this form.

In addition to the maximum stress and various stresses in the fillers, the stress at the conductor surface and toward the sheath is sometimes of interest, that is, the stress at the conductor surface on the zero deg. line. This can be obtained by plotting the reciprocals of stress as measured along the zero deg. line against distance from conductor center exactly as the maximum stress toward the center was obtained. This stress is, of course, a function not only of the conductor insulation thickness, but also of the belt, and it must therefore be expressed not in terms of the average stress between conductors but of the average stress between a conductor and the sheath. This determination makes possible an incidental check. As stated before, the

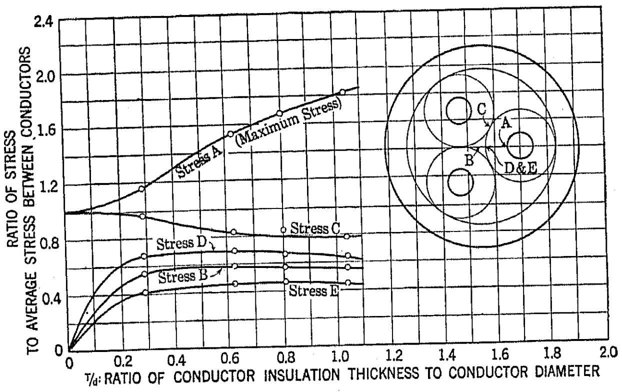

FIG. 5—STRESSES IN THREE-CONDUCTOR CABLES WITH ROUND CONDUCTORS

area of a curve of stress plotted against distance is equal to voltage. The voltage from conductor surface to cable center along the 180-deg. line and the voltage from conductor surface to sheath along the zero-deg. line are equal. The areas under the two curves, therefore, should be equal. A satisfactory check in this regard was obtained, the areas usually being equal to within a few per cent.

Fig. 5 shows the ratio of stress at certain points to average stress between conductors as a function of the ratio of conductor insulation thickness to conductor diameter, for round conductor cables. The points corresponding to the lower two values of the ratio are repeated from the 1919 data, while the other two are from cables 12 and 21, a complete curve thus being obtained and the new data being apparently entirely consistent with the early data, though covering a different range so that exact comparison is not possible.

Sector Stresses

Fig. 6 gives the same data for such sector cables for which stress measurements were made in the present series.

Since the stress was measured along various lines radiating from about the center of the conductor, as shown in Fig. 4, for the round conductor cables, it is possible to find the stress at the surface of the conductor

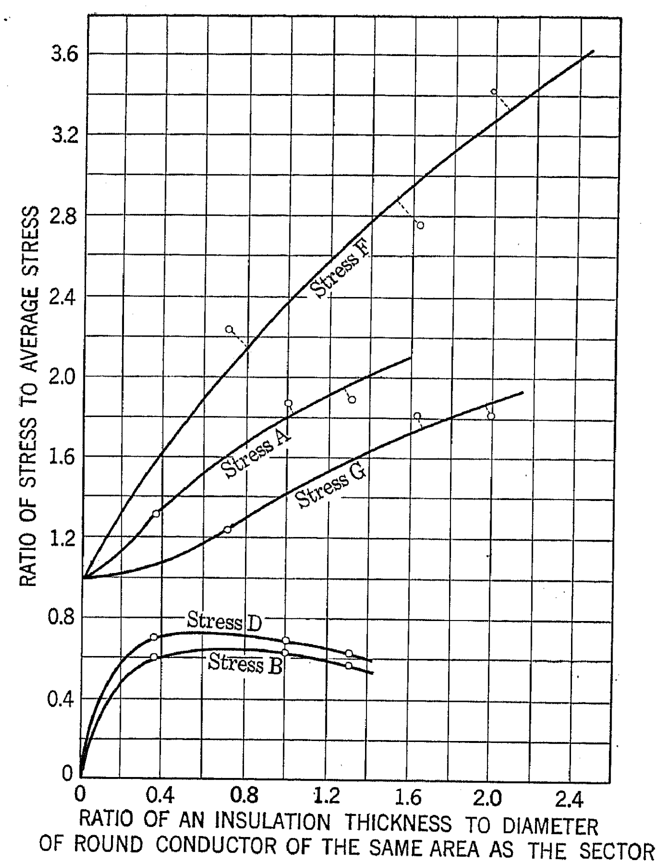

Fig. 6—Stresses in Three-Conductor Cables with Sector Conductors

The stresses are described in Table III and some of them are shown graphically in Fig. 5.

Note: The stresses A, B and D are given as a ratio in terms of the average stress between conductors, and are plotted against the ratio of conductor insulation thickness to conductor diameter.

Stresses F and G are however toward the sheath, and are therefore plotted in terms of the average stress between a conductor and the sheath; and plotted against the ratio of total insulation thickness between conductor and sheath to conductor diameter.

No direct comparison should be made on this figure between the former and the latter stresses, as the scales are not comparable.

along any of these lines by a similar method. The point of greatest interest in regard to the stresses in sector cables is that it has been found that with only one exception the maximum stress occurred not at the point toward the center of the cable but at the outer tip of the sector and in the general direction of the sheath. This maximum stress is practically constant along a short arc at the outer tips of the sector, this arc being indicated in the shaded portion of Fig. 1. It is also of interest to note that the stress toward the cable center, which is the region of maximum stress in round-conductor cables, is only very slightly greater for sector cables than for round.

The stress F next the tips of the sector conductor toward the sheath, which is often the maximum stress in the cable, is best defined in terms of the average stress toward the sheath, just as in the case of stress along the zero-deg. line. The stresses F and G are thus expressed in terms of the average stress between conductor and sheath, as shown in Fig. 6, but in Table III, they are also expressed for the particular models investigated in terms of the average stress between conductors in order that they may be compared with the other stresses.

The curve F, showing the stress next the tip of the sector conductor, is not of as general application as the curve for stress of round conductor cable or even the curve showing other stresses in the sector cables because the value of the stress depends so greatly upon the radius of curvature at the tip. For instance, the maximum of cable 28 with sharp cornered sectors is considerably above this curve. The various curves however for sector cable will make it possible to obtain a close approximation of the stress at several points including the maximum stress, where the sector conductors are of reasonably normal shape.

In the chart showing stresses in sector cable, no curves are shown for the stresses at C and E as in the case of a chart for stresses of round conductor cable, as these measurements were omitted in the measurement of the sector models.

IV. Check of Accuracy of Method

Up to the present time, no one has derived an accurate method of calculating the actual maximum stress in a three-conductor cable with round conductor, or any of the stresses where the conductors are sector-shaped. Our experimental method may however, be searchingly tested, since there are other stresses which can be calculated. To begin with, the maximum stress can be exactly calculated for single-conductor cables. This can be expressed as a ratio of maximum to average stress. The identical process above described in detail was performed with two single-conductor models, cables 10 and 27, and the ratio of maximum and minimum stress to average stress as determined experimentally can be compared with the calculated values.

Furthermore, there are two stresses in a three-conductor cable with round conductors which can be calculated accurately. Russell has given a rigid formula for the calculation of maximum and minimum stress between two eccentric cylinders. The stress at the conductor surface and at the sheath along the shortest line between conductor and sheath (*i. e.*, along the zero-deg. line) could therefore be calculated by Russell's formula if it was proved that these stresses were uninfluenced to an extent of practical importance by the presence of the

TABLE III

TABULATION OF RESULTS OF STRESS MEASUREMENTS ON THREE-CONDUCTOR CABLES

All Stresses are Expressed as a Ratio in Terms of an Average Stress

Cable Number	Conductor Shape	Stress: In Terms of Average between Conductors A	B	C	D	E	F	G	In Terms of Average between a Conductor and the Sheath F	G
*	Round	1.16	0.55	0.96	0.67	0.42	..	..	..	..
*	Round	1.54	0.59	0.83	0.69	0.46	..	..	..	..
12	Round	1.67	0.57	0.84	0.66	0.47	..	1.17	..	2.21
21	Round	1.81	0.55	0.77	0.63	0.44	..	1.68	..	1.95
23	Sector	1.31	0.60	0.47	0.70	..	1.28	0.70	2.24	1.23
25	Sector	1.87	0.63	..	0.68	..	2.10	1.10	3.44	1.81
26	Sector	1.89	0.57	..	0.64	..	2.54	1.67	2.76	1.81
28	Sector	1.44	0.64	..	0.73	..	1.60	0.67	2.77	1.17

*These are the 1919 data transformed to the present basis; the two models have ratios, T/d, of 0.288 and 0.625 respectively.

A = stress at conductor surface and toward cable center.
B = stress at cable center.
C = stress midway between conductors on line between their centers and in the direction of this line.
D = stress at outer edge of conductor insulation on line joining conductor and cable centers.
E = ditto, but normal to this line.
F = maximum stress at outer tip of sector conductor.
G = stress at conductor surface and toward the sheath.

other two conductors. This was definitely proved for cables of the forms tested and described in the 1919 article, and it may therefore be concluded that these two stresses can be determined experimentally and mathematically, and give another check of the data. Table IV gives the ratio of maximum stress to average stress for the two single-conductor cables, and the two above-mentioned stresses for the case of the two three-conductor cables with round conductors. It also gives the calculated values, and the per cent error.

TABLE IV

CHECK OF EXPERIMENTAL METHOD

For the Three-Conductor Cables, the Stresses are Along the Shortest Line from Conductor to Sheath, *i. e.*, the Zero-Deg. Line

Cable	Type	Ratio of Stress to Average Stress: Maximum Stress: Measured	Calculated	Per Cent Error	Minimum Stress: Measured	Calculated	Per Cent Error
No. 10	1-Condr.	2.04	2.04	0%	0.563	0.563	0%
27	1-Condr.	4.35	4.33	+0.4	0.375	0.373	+0.5
12	3-Condr.	2.21	2.07	+6.7	0.614	0.614	0
21	3-Condr.	1.95	1.90	+2.5	0.654	0.681	−4.1

The agreement of measured values with the calculated is well within the expected accuracy of the measurements, especially for cable 27.

The great difficulty with the method of tinfoil models is the danger of irregularities in the thickness and composition of the foil. It is believed, however, that the fact that all the stresses were measured and calculated separately for each of the three conductors, and that each of the final values is thus the average of three, would indicate that the errors are probably averaged out. We believe therefore that the present data are probably correct to within 4 per cent, and that undoubtedly a large amount of it is even more accurate.

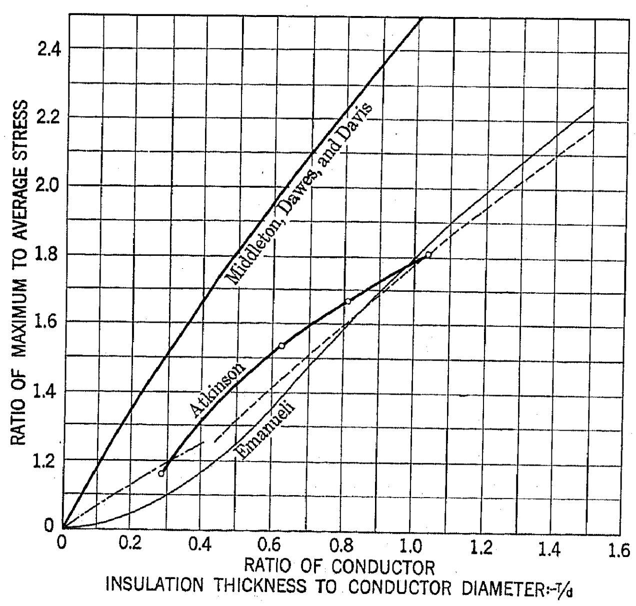
V. Comparison with Other Data

The difference between our own results and those of Emanueli will now be considered, the remarks being limited to a comparison of the values of maximum stress only. As stated before, the maximum stress in its usual location cannot be calculated. Starting with the data available as to geometric factor we have derived an equation by which the average stresses around the entire circumference of the conductor may be determined. This derivation is given in Appendix B. Obviously, the true maximum stress must be greater than the average of the stresses around the conductor surface, and from this equation we have a *lower limit* to the value of maximum stress. In the case of cables with thin belts, the stress toward the sheath is very close to the maximum stress toward the center, and the difference between average and maximum stress at the surface of the conductor is reduced to a minimum. In Fig. 7 is plotted our experimental curve for maximum stress in terms of average, Emanueli's data for the same quantity, and another curve calculated by the method advocated by Middleton, Davis and Dawes. In addition, the curve calculated by equation (7) of Appendix B is shown, this curve having been calculated on the basis of three-conductor cables with no belt, so that the stress toward the sheath would be about the same as that toward the center. We know, therefore, definitely that the true maximum stress must lie above this curve and also that it is probably not very far above it for cables with thick insulation (large T/d).

By inspection of Fig. 7, we see immediately that much of Emanueli's curve for maximum stress is lower than the average of the stresses around the conductor surface, and therefore must be too low, at least by the amount of the difference. For small values of T/d the maximum stress occurs at the surface of the conductor toward an adjacent conductor, as stated before,

and this can be calculated by Russell's formula. One can see that Emanueli's curve is incorrect for this range and by a large amount.

Emanueli gave very little of his experimental results, most of his data being shown merely in the final curve form. For that reason, there is little opportunity to analyze his results and to suggest a possible explanation for the extent of the error of parts of his curves. It seems not unlikely, however, that the explanation lies in the inherent difficulty of accurate determination by his method. He used a tank of electrolyte as did we, but in our method we have determined stresses at various points *by direct measurement of stresses* and the results should be as accurate as the measurement made. Emanueli, on the other hand did not determine stresses directly but used a single-point finder and plotted equipotentials. From this data he was able to plot



—·—·—·— from Russell's formula for maximum stress between cylinders.
- - - - - - - - from formula 6, Appendix B. Limiting minimum value.

Fig. 7—A Comparison between Various Determinations of Maximum Stress in Three-Conductor Cables

the voltage curve in various directions, and from his voltage curve he derives the stress curve. Any inaccuracy in the measurement of potentials is very greatly magnified in the determination therefrom of the stresses. The stresses are virtually the difference in potential between successive points on the potential curve, so that small errors in measurement are greatly magnified. This explanation is partly discounted by the fact that Emanueli also applied his method to the determination of stress in single-conductor cables and was able to check the calculated values to within 2 per cent, though no further details of this check were published. The difficulty with his method, which is described above, is somewhat less serious with a single-conductor cable for the same outside diameter of model than for three-conductor cables as the distances are greater and a given inaccuracy in point of distance in the setting of the finder would produce a smaller percentage error in the final result. Others have used a similar method of determining and plotting equipotential lines for the purpose of determining stresses and, while such diagrams are very instructive and help one to visualize the condition of the field, the method inherently is rather unsatisfactory for the obtaining of exact mathematical data.

A brief statement of the experimental data quoted by Middleton, Dawes, and Davis, will show that it is not a suitable basis for determination of stresses. They experimentally determined the breakdown strength of a series of triplex cables and single-conductor cables with similar insulating material. They calculated the maximum stress at breakdown of their single-conductor cables by the rigid formula for this, and of the three-conductor cables by the writer's 1919 data and also by a method of their own. They found that the maximum stress at breakdown in the three-conductor cable calculated by their method was somewhat more nearly equal to the maximum stress at breakdown in the single-conductor cables than was the value calculated by the writer's method. From this they concluded that their method was more accurate than the writer's, the difference between the two being quite large.

In view of the demonstrated accuracy of our method, their logic is not very convincing. In the first place, they assume that cables of different proportions have a constant value of maximum stress at breakdown and that three-conductor cables and single-conductor cables break down at the same value of maximum stress, both of these assumptions being unproved. We believe that the result of their experiments proves the fallacy of these assumptions for the samples tested, rather than proving a basis for calculating maximum stress.

It is worth repeating that no attempt is made here to draw conclusions as to the importance of maximum stress in determining breakdown strength, or allowable operating voltage of any given cable. A mathematical tool is furnished which will be useful in correlating experimental or practical data bearing on breakdown strength or allowable operating voltage of different cables. As far as concerns the present paper, the data contained herein may as well be used to prove, that the ratio of maximum stress to average stress is unimportant as it is to prove that the breakdown strength is dependent upon the maximum stress.

In this investigation, account has not been taken of the effect of stranding, though some data on that were given in the previous paper, and no account has been taken of the effect of spiralling or cabling of the conductors. In addition to extending the scope of the data now available, future work should be done on these things, in particular to determine the effect of stranding on the sector conductor.

TABLE V
DETERMINATION OF MAXIMUM STRESSES IN CABLE MODEL 25 ON ZERO-DEG. AND 180-DEG. LINES

Distance from Conductor	Stress toward Cable Center (180-deg. Line)						Stress toward Sheath (Zero-deg. Line)					
	Conductor 1		Conductor 2		Conductor 3		Conductor 1		Conductor 2		Conductor 3

VI. Conclusions

The satisfactory check between the old and new data for the geometric factor, together with their check with Simons' graphical method, leads to the belief that this phase of the matter has had a satisfactory solution, and that any of the data may be used confidently, including the new data for sector-shaped conductors.

We believe that our own determination of stress as opposed to that of Emanueli is quite completely vindicated for the following three reasons:

1. The measurement of the stresses which could also be calculated gave a very close check as indicated in Table V.

2. The new data fall directly in line with the earlier data, in spite of the fact that the earlier cable models were tanks of electrolyte and the present models foil sheets.

3. Direct measurement of stress, which is the method we used, is inherently capable of a higher degree of accuracy than a determination of stress from voltage curves.

One of the most important conclusions to be derived from the present data is believed to be the fact that the maximum stress in cables with sector conductors may occur at the outer tips of the sector rather than toward the cable center, and that this stress may be somewhat greater than that in a cable with round conductors. No generalizations of this feature can be made, however, inasmuch as the maximum stress in round conductor cables depends upon the conductor insulation thickness and the diameter only, while the belt thickness is a determinant in the case of sector stresses.

Appendix A

The electrical connections used in measuring stresses with the foil model are shown in Fig. 8. At the left of the diagram is shown the cable model with the exploring device, and above it are shown the transformers and circuits for supplying the three-phase current to the conductors of the model. In the center of the figure is shown the device used for producing an e. m. f. variable in amount and phase. At the right is shown the detecting galvanometer and related circuits.

The three-phase 220-volt supply is stepped down by three transformers A, each single-phase transformer being 220 volts primary to 1 volt secondary, the three primaries being connected in delta and the secondaries in star. Current is led from each phase of the secondary circuit to one of the condensers, through a non-inductive, zero temperature coefficient resistance of value 1/15 ohms. The neutral of the transformer is connected to the sheath of the cable model and this circuit is grounded.

Two transformers B and C, shown in the middle of the diagram, are used to furnish potential of varying amount and phase. Transformer B is 110 volts primary with 4-volt secondary with taps at one, two, and three volts. Transformer C is 95.5 volts primary to 4 volts secondary. Except for the difference in the primary turns, the two transformers are identical. Across one part of each secondary is connected a resistance R_1 of about 25 ohms. This resistance is made up of 150 turns wound on a non-metallic cylinder. A slider is arranged to connect to any one of these. This resistance serves to divide the one volt into 150 units and the resistance is low enough in amount in proportion to the 100,000-ohm resistance which is in series with the meter circuits so that the potential is not affected by the current drawn. By an arrangement of switches shown, the secondaries of transformers B and C are connected in series and any proportion of the voltage of either may be used in units of 1/150 volt. The current from this point is led through a 100,000-ohm resistance box and through a fixed resistance of 100 ohms.

On the right is shown the alternating galvanometer, a special shunt on the moving coil and means for supplying potential to the field coil. By means of two Scott-connected transformers, B and E, two secondary voltages are available, at right angles to each other in phase. With a double throw switch, the field of the galvanometer may be excited from either one or the other of these transformers. By means of the adjustable resistance shunting the condenser, the phase of the voltage across the field may be varied.

The shunt used on the moving coil circuit of the galvanometer is similar in purpose to the usual galvanometer shunt and similar in arrangement except that a special connection is attached and arrangement is

made so that a 100-ohm resistance is connected across the galvanometer terminals when the shunt is in any position except the most sensitive. In general, with an a-c. galvanometer, variation of the resistance across the moving coil will cause a shift in the electrical zero, which is decidedly inconvenient and is avoided by the adjustment shown.

The deflection of an a-c. galvanometer for a given current through its moving coil is dependent upon the phase of that current with respect to the phase of the field current. In the use of the arrangement shown, the field of the galvanometer was first adjusted so that the galvanometer would have zero sensitivity for current in phase with the potential of one of the secondaries of the transformers A. When the field is supplied from the other of its two transformers, the sensitivities for current of the same phase would conversely be a maximum.

In order to measure the stress at any point, the exploring device is put in the desired position, with the two points in contact with the surface of the foil, the switch at P is closed, and current is supplied to the cable model by closing the switch for the primary circuits of transformers A. The other two primary switches are closed and the voltage supplied from the secondaries of the transformers B and C is varied until a balance is obtained on the galvanometer, thus signifying that the voltage across the 100 ohms as produced by transformers B and C, is equal to the voltage on the exploring device, both in amount and phase. With the adjustment of the field circuit of the galvanometers already men-tioned, it will be found that the galvanometer is sensi-tive to variation in the voltage supplied by transfor-mer B when the field is excited from one source, and sensi-tive to voltage from transformer C when the field is supplied from the other source, and that a considerable amount of variation in voltage of either transformer can be made without greatly affecting the galvanometer when the source for the field is not in a position which gives the maximum sensitivity. Thus the process of balancing can be carried on quickly, usually an approxi-mate adjustment of one transformer circuit being made, then an accurate adjustment of the second trans-former, and finally an accurate adjustment of the fi

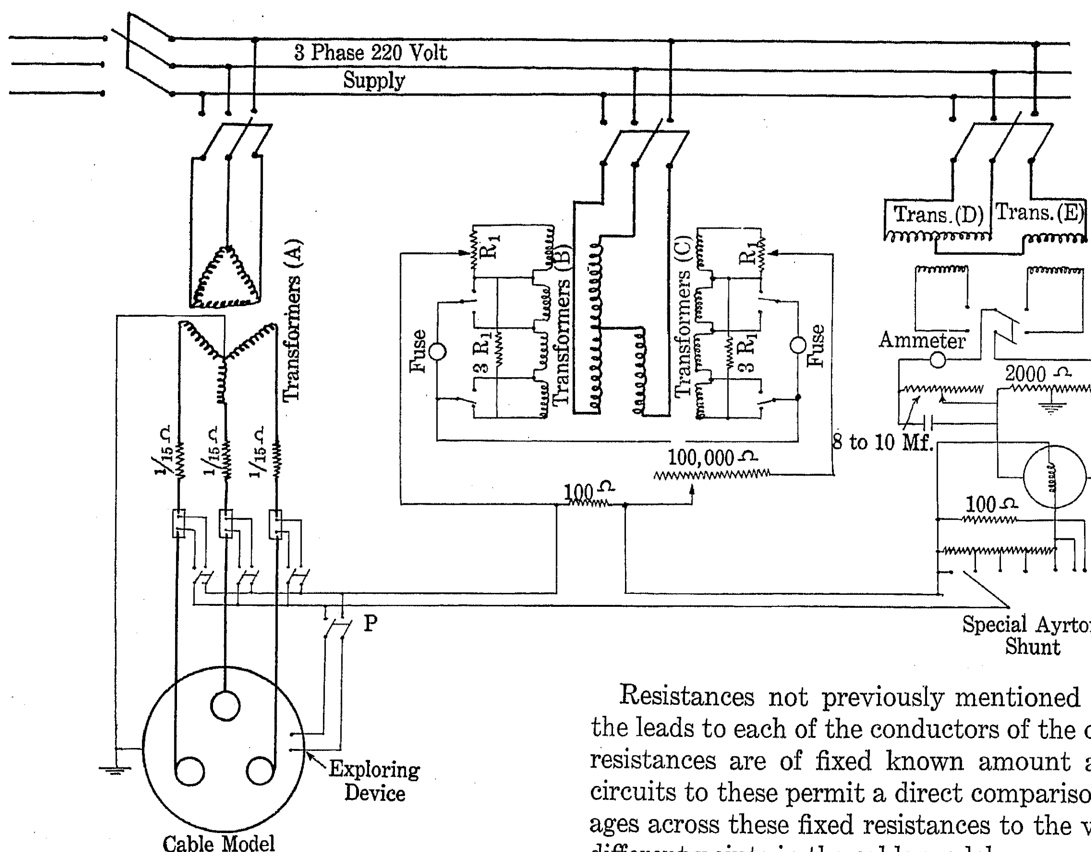

Fig. 8

Resistances not previously mentioned are shown in the leads to each of the conductors of the cable. These resistances are of fixed known amount and potential circuits to these permit a direct comparison of the volt-ages across these fixed resistances to the voltage across different points in the cable model.

The arrangement is independent of variations in primary voltage because voltage on transformers A will vary in the same ratio as voltage on transformers B and C and therefore the adjustment obtained will be the same through large variation of primary supply voltage which therefore does not need to be taken into account.

Appendix B

Derivation of Formula for Limiting Value of Maximum Stress in Triplex Cables

The experimental work with cable models has shown that while the maximum stress occurs at the surface of the conductor in a direction toward the cable axis, for small sizes of conductor and with thick insulation thick-nesses, the maximum stress is not very much greater than the stresses practically all around the circumference of a conductor. That is, the stresses at the conduct

surface are quite uniform for small conductor cables. If a cable has a thick belt, as compared with the conductor insulation, the stress toward the outside will be less than the maximum. If a cable is chosen with a thin belt or no belt, then the stress toward the outside can be made the same as the maximum stress, and in such a cable the stresses around the entire circumference of a conductor are still more uniform.

If the stresses around the surface of the conductor are absolutely uniform, then the equipotential lines near the surface of the conductor would be circles, or speaking in terms of a cable model of unit length, the equipotential surfaces would be cylinders. If the stresses are not absolutely uniform around the entire surface, the introduction of a metallic cylinder in the insulation but close to the conductor surface will make the stresses uniform, and will therefore tend to reduce the maximum stress and raise the stresses which are the lowest, the stresses in this case being very close to an average of the stresses which would exist around the conductor surface without the cylinder.

Let us consider a cable of unit length, with a belt so thin that the stress toward the sheath is practically equal to the stress at the surface of the conductor toward the center, or in other words, so that the cable will have quite uniform stresses around the surface. Let us assume that a metallic cylinder is inserted in the insulation and fairly close to the surface of the conductor.

Let C_{10} = capacity of conductor to neutral
C_{20} = capacity of cylinder to neutral
C_{12} = capacity between conductor and cylinder
Let E_{10} = voltage of conductor to neutral
E_{12} = voltage impressed between the conductor and the cylinder

Let the conductor radius equal r_1 and the cylinder radius equal r_2. We may now calculate the maximum stress at the surface of the conductor, considering only the condenser made up of the cylinder and the conductor by the ordinary single-conductor formula as follows:

$$\text{Maximum stress} = \frac{E_{12}}{r_1 \log \frac{r_2}{r_1}} \qquad (1)$$

We know that

$$C_{10} = \frac{3\,K}{2\,G_2} \qquad (2)$$

where K = the permittivity or self-inductive capacity of the insulation
and G_2 = the geometric factor

and
$$C_{12} = \frac{K}{2 \log \frac{r_2}{r_1}} \qquad (3)$$

We have expressed the maximum stress at the surface of the conductor in terms of the voltage between the conductor and the cylinder, while we, of course, desire to express it in terms of the voltage between conductor and neutral. We have, however, expressions for the capacities C_{10} and C_{12}. Inasmuch as in a series circuit voltage is inversely proportional to the capacity, we may write directly

$$\frac{E_{12}}{E_{10}} = \frac{C_{10}}{C_{12}} \qquad (4)$$

Substituting the values of C_{10} and C_{12} from (2) and (3) in (4), we obtain

$$E_{12} = E_{10} \times \frac{3 \log \frac{r_2}{r_1}}{G_2} \qquad (5)$$

If this value of E_{12} is substituted in equation (1) we obtain

$$\text{Maximum stress} = \frac{3\,E_{10}}{r_1\,G_2} \qquad (6)$$

We thus have an expression for the maximum stress in a three-conductor cable in terms of known quantities, and have eliminated the cylinder which we imagined to have been inserted in the insulation. The derivation, however, hinges on the fact that the cylinder was present, and therefore this equation gives not the true maximum stress in a given cable, but the average of the maximum stresses around the surface of the conductor. We know that the maximum stress must be close to this value for very small conductors, and that for the case of a cable with a thin belt of such thickness that the stress toward the outside is equal to the stress toward the center, the maximum stress will not be very far different from this value even for larger sizes of conductor. We know definitely that in all cases the true maximum stress will be greater than the maximum stress from this formula.

The average stress between conductors is equal to $\sqrt{3}\,E/2\,T$. We therefore have directly that the ratio of maximum stress to average stress equals

$$\frac{4\sqrt{3}}{G_2} \times \frac{T}{d} \qquad (7)$$

and the broken line curve of Fig. 8 has been plotted by this formula.

Appendix C

EXAMPLE OF ACTUAL DETERMINATION OF STRESS

As an example we will take sector cable model 25. Various potentiometer readings were obtained and these readings which are proportional to stress will be referred to as "stresses" in this appendix. The stresses measured along the zero-deg. line and the 180-deg. line are shown in Table V, while some of the more important stresses at various points in the fillers will be found in Table VI.

Referring to Table V, it will be noted that the measured stress S and its reciprocal are shown for each conductor on both the zero-deg. line and the 180-deg. line, the various stresses being taken at various dis-

tances from the conductor surface. All the stresses shown are measured values except the stress at zero distance from the conductor surface, the maximum stress along that line, which is what must be determined. This may be found as follows. The reciprocals of all the stresses are obtained and are plotted against distance from conductor surface for each conductor and for both the lines under investigation. It will be found that the reciprocals of the points nearest the conductor surface, as mentioned in the text, fall on a straight line, which line passes through the center of the conductor of a round conductor cable. No figure is given of this because the construction is so obvious. In many cases the points fell on perfectly straight lines, and in all cases there was very little doubt as to a close determination of the line. From this curve, therefore, it is possible to read the reciprocal of stress at distance zero from the conductor surface, or, in other words, the reciprocal of the maximum stress on the line. The reciprocals of stress at distance zero shown in Table V were obtained by this means, and the reciprocal of these values is, of course, the stress at the surface of the conductor.

Having obtained the stresses at the surface of the conductor by this means, a curve was drawn both for the zero-deg. and 180-deg. lines, plotting stress against distance from conductor surface. For the zero-deg. line this goes out to the sheath, and for the 180-deg. line this stress is carried out along the line from the conductor surface to the center or axis of the cable. The area under these curves is now found by means of a planimeter, and the figures being stress plotted against the distance, the areas will be proportional to voltage, or, in other words, we obtain numbers proportional to the voltage between the conductor and center and the conductor and sheath, namely, the voltage to neutral. Dividing this by the distance from conductor to center and conductor to sheath respectively, we obtain numbers proportional to the average stress between these points.

Reference will now be made to Table VI. In Table VI we show the area under the curve of stress versus distance, both toward cable center and toward sheath, and the temperature. At the right we show these areas proportional to voltage, corrected for temperature, and the average. The two averages being proportional to voltage should be equal, and it will be noted in this case that there is a 2 per cent variation. To illustrate the consistency of the results, the greatest deviation in this respect was in cable 21 where the difference was 7.8 per cent. Having obtained these various areas proportional to the voltage, we divide them by the distance, and obtain in lines 4 and 13 respectively the numbers proportional to the average stress, which are corrected for the temperature.

The temperature correction is necessary because a 1/15-ohm resistance of zero temperature coefficient was connected in series with each of the conductors of the model. In Appendix A we have shown that the effect is as though the applied voltage was strictly constant, and therefore the voltage on the cable model itself and the measured stresses depended on the distribution of voltage between the external resistance and the resistance of the model, the latter having a decided temperature coefficient; in fact the temperature coefficient shown in formula (1). This necessitates correcting all the values to a standard temperature which was taken as 25 deg. This temperature has no bearing whatsoever on practical stresses, as our final results are all in terms of ratios; it was necessary, however, to have both the stresses from which the ratio was obtained corrected to the same temperature.

The data in this paper are given, however, in terms not of average stress toward the center but of average stress between conductors, and the average of the average stresses toward the center, namely, 300, is transformed to the average stress between conductors by multiplying it by the square root of 3, and the distance from conductor surface to cable center, and dividing this by the distance between conductors, obtaining the value 288, in terms of which most of the data are to be expressed. The stress at the surface of the conductor A, as obtained as shown in Table V is again given in

TABLE VI
DETERMINATION OF AVERAGE STRESSES AND CORRECTIONS FOR TEMPERATURE AND DATA FROM WHICH FINAL STRESS RATIOS WERE OBTAINED FOR CABLE MODEL 25

line 6 of Table VI and is corrected for temperature, as well as averaged. The stress, as stated before, was measured in many other places of the cable cross-section, including stresses at frequent intervals all around the conductor and at various distances from the conductor surface. The stress at the cable center was obtained three times, in measuring along the 180-deg. line for each of the three conductors. These values are shown in line 7, where they are corrected for temperature and averaged. The stress C was not measured in this cable, the stress D was measured and is shown; the stress E was not measured in this cable. The stress F, namely, the stress at the surface of the conductor at the sector tips, was obtained exactly as the stresses A and B were obtained; that is, the stresses were measured on various lines around the conductor at different distances from the surface. The stresses on any radial line could be determined, and by plotting the reciprocals of stress, it is possible to obtain the reciprocal of stress at the conductor surface, and therefore obtain the actual stress at the conductor surface. By this means not only were the stresses A and G obtained as described, but stresses all the way round the surface of the conductor, which in some cases turned out to be higher at the tips of a sector and in a general direction toward the sheath. These are shown in line 11, the two values being for the two tips of each conductor, all corrected for temperature and averaged.

From the values shown as the average at 25 deg. cent., the final values of stress ratio shown in Table III were obtained directly, that is, the A, B and D stress ratios in Table III were obtained by dividing the averaged stresses 539, 180, and 196 respectively by the average stress of line 5 or 288. The stress ratios F and were obtained by dividing 606 and 318 respectively by the average stress toward the sheath from line 13, namely, 176.

It is interesting to compare the determinations of stresses for the three individual conductors with the average of the three to determine the uniformity of the models and of the foil thickness. Cable model 25 shows results possibly a little more uniform than others, but all the results were much more uniform than had been originally feared. For instance, the maximum deviation of the stress A for any one conductor from the average for the three conductors of a model is 4 per cent for model 21. Only two cases worse than that were found, namely a deviation from average of 8 per cent in stress F of cable model 25 shown in line 11 of Table VI.

Appendix D

Example of Application of Stress Data

To illustrate the use of the data on stresses in a practical way, the stresses will be calculated for the case of a three-conductor cable 350,000 cm. in cross-section, insulated with 10/32 in. on each conductor and 5/32 in. belt for 33,000 volts working pressure.

We will first consider that the conductors are round. The average stress on which Fig. 5 is based is the average stress between conductors. Ordinarily, stresses are expressed in terms of kilovolts per centimeter, and therefore the average stress must be obtained in those units. With 10/32 in. insulation on each conductor, the separation between conductors is 20/32 in. The voltage is 33 kv., and if 33 is divided by 20/32 and again divided by 2.54 to change into centimeters, we find that the average stress is 20.8 kv. per cm. In Fig. 5 the abscissas are in terms of T/d, which in this case is $0.3125/0.681 = 0.46$. Referring to Fig. 5, we can obtain a series of multipliers corresponding to the abscissa 0.46 of 1.37, 0.58, 0.88, 0.69, and 0.44, corresponding to the A, B, C, D, and E stresses. Multiplying these values by the average stress, 20.8, we obtain 28.5, 12.1, 18.3, 14.4, 9.2 kv. per cm. respectively for the above-mentioned stresses.

If the conductors of the above cable are sector in shape, our data is to be obtained from Fig. 6. Stresses A, B, and D are expressed in terms of the average stress between conductors and plotted against T/d exactly as in the case of Fig. 5. The average stress is 20.8 kv. as before and T/d has the same value. We find the following multipliers from Fig. 6; 1.41, 0.63, and 0.72, and multiplying them by the average stress 20.8, we obtain 29.3, 13.1, and 15.0 kv. per cm. for the A, B, and D stresses respectively. The F and G stresses being toward the sheath, are plotted in terms of average stress between conductor and sheath, the abscissas of the figure being $(T + t)/d$. The average stress is obtained by dividing the voltage to ground, namely, 33 divided by the square root of three, or 19.0 by the distance between conductor and sheath in centimeters, or 15/32 in. times 2.54. This gives 16.0 kv. per cm. as the average stress to ground. $(T + t)/d$ is equal to $0.469/0.681 = 0.69$. Finding the multipliers from Fig. 6 corresponding to this abscissa, namely 2.02 and 1.23, and multiplying these by the average stress 16.0, we obtain 32.3 and 19.7 kv. per cm. for the F and G stresses respectively. In this particular case the F stress is the greatest, the stress at the tips of the sector, this being 10 per cent higher than the A stress in the sector cable, or 13 per cent higher than the maximum stress in the corresponding round conductor cable.

Potential Gradient and Flux Density
Their Measurement by an Improved Method in Irregular Electrostatic and Magnetic Fields

BY J. F. H. DOUGLAS

Review of the Subject.—*The safety of electric power cables is dependent in part upon the maximum electrostatic flux density in the dielectric. The core loss in revolving machinery is, in part, a pole-face loss, dependent on variations in the magnetic flux density. Alternators work best in parallel, and give less interference with communication circuits, if of a good wave form, of flux density. These fields of electrostatic and magnetic flux are often too irregular to lend themselves to an accurate computation, and hence experimental methods of study are needed. The writers have improved a method suggested by F. W. Carter, and the results obtained give promise of a field for useful study. The method itself may be briefly described as measuring an electric model of the field to be studied cut out of sheet metal. By the use of a contact-making device, with two contacts, held at a fixed distance apart, but movable to any part of the edge of the metal sheet, voltage gradients may be measured upon a galvanometer. From these measurements, the flux densities may be calculated. The paper describes the method in detail and also gives some results of study on the three problems mentioned. It is shown how this method of test can be used to improve pole-shoe design. The importance of pole-shoe design is pointed out. An appendix is included, showing that correct pole-shoe design is needed to eliminate the so-called "tooth ripples."*

ONE of the authors published in the A. I. E. E. PROCEEDINGS some time ago, a paper on the "Reluctance of Some Irregular Magnetic Fields."[1] Some of the results were applicable to electrostatic fields, and some of the measurements gave an indication of flux density variation. The latter, however, were crude, and lately the experiments were resumed with a view to improving this feature. These new experiments, like the old, are based on a method of test suggested by F. W. Carter.[2] This method is based upon the following principles. (1) The electric, the electrostatic, and the magnetic fields follow the same equation, that of LaPlace. (2) Models of the electrostatic and the magnetic fields can be made out of conducting material if (a) the boundaries are of the same shape, (b) if the electrodes are fastened in similar places. (3) An electric current passed through the specimen will cause effects similar to the magnetic or electrostatic fields desired to be studied. Namely, by the use of a voltmeter, the equipotential surfaces may be traced and the resistance of the field measured.[3] (4) In two-dimensional distributions of flux, the equipotential lines and the flux lines are conjugate, *i. e.*, mutually interchangeable, if the equipotential portions of the boundary are interchanged with the insulated portions. In the papers cited, this principle was not utilized; in fact, would have been impracticable. Messrs. Fortescue and Farnesworth, and Mr. Rice were studying fields which were surfaces of rotation, and not two-dimensional fields. For these no conjugate field exists. Mr. Atkinson used polyphase currents, which would have made the use of conjugate fields too difficult. So far as we know the only use of this last principle other than our own is by C. H. Smoot.[4]

Some attempt was made in the previous paper to obtain the potential gradient by taking differential readings. Thus in Fig. 1, current was passed through the specimen, and through a slide wire in parallel, and points of zero deflection were obtained on the slide wire for different points on the specimen. If the balance points on the slide wire corresponding to the points X and X' on the specimen are V and V', then the gradient at a point midway between X and X' may be taken as,

$$G = \frac{(V' - V)}{(X' - X)}$$

This method of procedure was inaccurate because: (a) the millivoltmeter was insensitive; (b) the distance X could not be read accurately; (c) slide wire reading V was inaccurate because of limited length; (d) there was lack of uniformity of the slide wire; (e) there was variation in the relative strengths of current in the wire and in the specimen. This criticism applies also to all cases where the gradient is judged from the closeness of equipotential surfaces in a map of a field, as in Mr. Rice's paper.[5]

The problem of measurement of flux density and

potential gradient was felt to be of considerable importance, and that improvement in the method of measurement was desirable. To mention only two such cases, we may refer to the problem of the wave form of flux density in an alternator, and the gradient in a power cable with three conductors. The specimen in Fig. 1 may be taken to represent the air-gap of an alternator. Surface 1 is the pole shoe, surface 2 is the armature surface, 3 is a neutral surface between the poles, 4 and 5 are lines of force. The flux density at X is desired as a function of X. It will be observed that in Fig. 1, the conjugate character of the potential

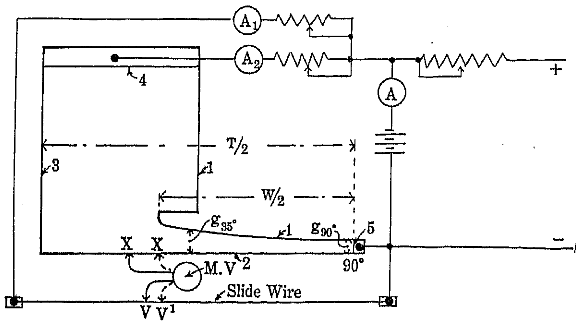

FIG. 1—FLUX-DENSITY TEST FOR ALTERNATOR

and flux lines is utilized. The flux lines 4 and 5 are made electrodes, and the magnetically equipotential surfaces 1, 2 and 3 are left insulated. By measuring the electric potential gradient at X, namely $\left(\frac{d\,V}{d\,X}\right)$ the density in the magnetically equivalent and conjugate case is obtained.

We may note here in connection with Fig. 1 some of the advantages of testing the conjugate field with a metal sheet. (1) In most cases the electrodes used may be short in length, straight or of slight curvature, easily soldered to the sheet, and easily kept at a uniform potential throughout. (2) Smaller currents were required and more sensitive indications were obtainable. (3) The places of most interest for determining the density or gradient were by this means transferred to the free edge of the sheet, where contacts were most easily made. (4) In modifying proportions of the specimen, instead of resoldering electrodes, the free edge of the sheet was trimmed. This saved a great deal of material and time.

Another case of some interest, the voltage gradient in a cable, is illustrated in Fig. 2. It seemed to us that the insulation strain was greatest at the surface of the conductors and at that instant of time when one of the three conductors was charged positively, one negatively, and one at zero potential. We made our tests accordingly. However, a more recent study of Mr. Atkinson's paper indicates that further tests corresponding to other instants of time would be desirable.[6] Only one half of the cable is shown in the figure, there being a line of symmetry along a diameter. Conductor A is positive. Conductor B, the sheath and the diameter are neutral. Owing to the convergence of the electrostatic lines of force upon the conductor, the gradient at the surface of the conductor is of most interest. The gradient is proportional to the dielectric flux density, and the latter was the quantity actually measured. The electrodes are fastened so as to make the field conjugate to the electrostatic field in the cable. The electrodes 4 and 5 are soldered to flux lines. The insulated edges 1 and 2 are the equipotential surfaces in the cable. By measuring the gradient at X the dielectric flux density in the conjugate electrostatic case is obtained.

Our improved method of test may be illustrated by Fig. 2. Current was taken from a six-volt storage battery on account of its steadiness; and, this was kept on a slight charge. The current was regulated by means of a German silver ribbon resistance capable of continuous adjustment, and kept at a constant value with a Weston ammeter. The gradient at the point X was measured by the direct deflection of a sensitive Leeds and Northrup galvanometer, which was connected to two terminals 6 and 7 located approximately one centimeter apart, but held at a constant distance by a wooden spacing member. A resistance box R was included for the purpose of regulating the maximum deflection of the voltmeter, usually to 5 or 10 cm. The contacts were of brass, the same as the test sheets, in order to reduce thermal effects. The switch S was opened after each reading, and the "zero" thus obtained was used to correct the readings. It is hoped that this procedure eliminated residual thermal effects, usually of the order of one millimeter. Contacts

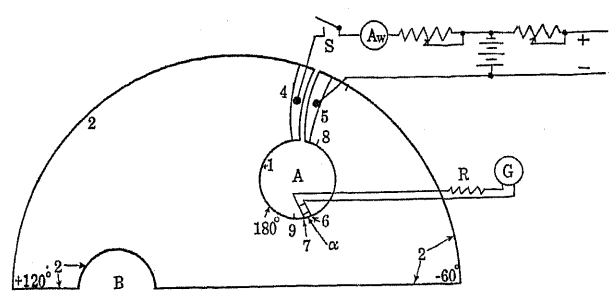

FIG. 2—FLUX-DENSITY TEST IN A THREE-PHASE CABLE

6 and 7 were pivoted to a yoke and held against the edge of the sheet by a spring. The other end of the spring was attached to a block, which was clamped to the edge of the sheet. In this manner an intimate contact was secured, which was flexible, easily adjusted, and movable from place to place. Credit must be given to R. W. Atkinson for the use of a double-contact electrode, for use in measurement of gradient with electrolytes and in the non-conjugate field, and with alternating currents.[7]

6. *Loc. cit.*, p. 991.

7. *Loc. cit.*, p. 983.

It is to be noted that when a double contact is to be used at the boundaries of a field, the electrodes should be oriented parallel to the edge of the sheet, if this is a line of flow; on the other hand, if the boundary tested is equipotential, the electrodes must be oriented perpendicular to the same. This is another advantage for the conjugate method of test, since the orienting of the electrodes is automatic. A single measurement will also suffice on the edge of the sheet. In Mr. Atkinson's paper, the gradient was measured at a point 1/16 in. from the boundary of the conductor, and by several measurements was extrapolated for the boundary itself.[8] It is no criticism of the accuracy of Mr. Atkinson's results to state that the method of

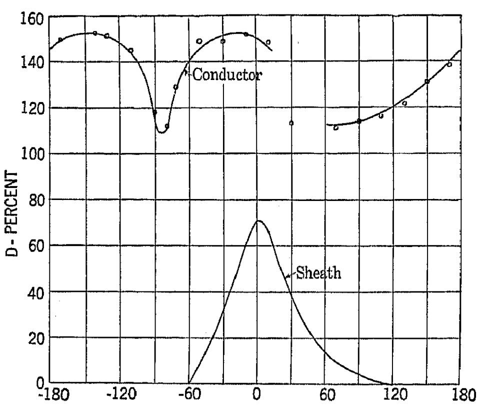

FIG. 3—GRADIENT IN A THREE-PHASE CABLE

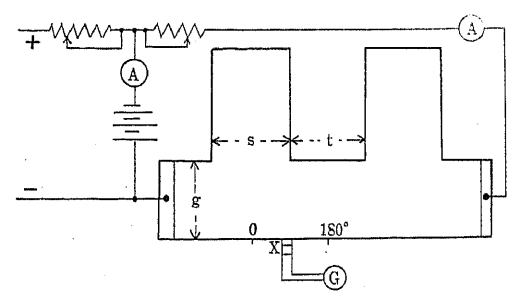

FIG. 4—FLUX-DENSITY TEST FOR A SLOTTED ARMATURE

testing the conjugate field gives superior rapidity of test at the boundary of the field. For points on the interior of the field, the electrodes should be oriented so as to secure a maximum deflection, if the true gradient at these points is desired. This is best done by trial. We understand that in most cases Mr. Atkinson oriented his contacts so as to be radial with the conductor. On this account we venture to question the accuracy of his results as far as they refer to the field on the interior of the three-phase cable. For instance, in his Fig. 8 at the point E-90 deg. the electrodes were radial. On the other hand, from Wm. A. Del Mar's discussion and Fig. 1, the field, at one instant at least, is some 45 deg. from the radial position. We do not understand, however, that Mr. Atkinson claimed entire accuracy for these results, nor do we stress it as an important point.

8. *Loc. cit.*, p. 987.

The sheets out of which our specimens were cut were of 20 or 24-gage sheet brass, one ft. in width, and of length varying from 24 to 32 in. Currents of approximately 10 amperes were used through these sheets. We calibrated our galvanometer by the use of a rectangular sheet taken from the same stock.

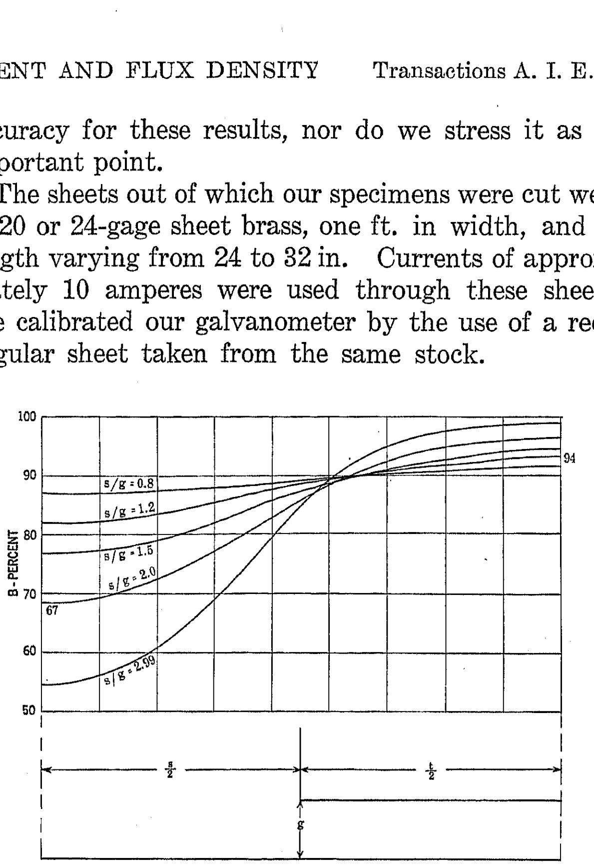

FIG. 5—POLE-SHOE DENSITY WITH SLOTTED ARMATURE

At first we attempted to use a null method; but the simplicity of the direct deflection method, the rapidity with which it was possible to get readings, and the consistency of the results (when corrected for thermal effects) convinced us that the null method was not necessary. In this we find that Mr. Atkinson supports our conclusion.[9]

Some question might be raised as to whether contacts

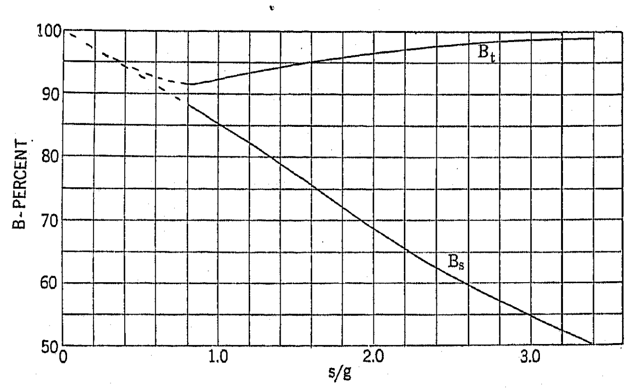

FIG. 6—MAXIMUM AND MINIMUM POLE-FACE DENSITY

one centimeter apart would give a good approximation to the actual gradient at the mid-point. We arrived at the following conclusion, with reference to the problem of alternator wave form: If the base in Fig. 1 be 90 cm., a contactor with one centimeter spacing would measure the flux density far more accurately than necessary. The 19th harmonic would be determined to ½ per cent, and the 41st harmonic to two

9. *Loc. cit.*, p. 988.

per cent, and others in proportion. We feel, therefore, that this error does not enter to any appreciable extent.

The results of our test on the cable are shown in Fig. 3. The angles θ are measured from the point where the density is the greatest, namely point 8 in Fig. 2. It will be noted that the densities are greatest at the points 8 and 9 where the conductor approaches a neutral electric surface. The gradient obtained with a uniform strip, of width equal to the minimum dielectric thickness, is taken as 100 per cent. It may be

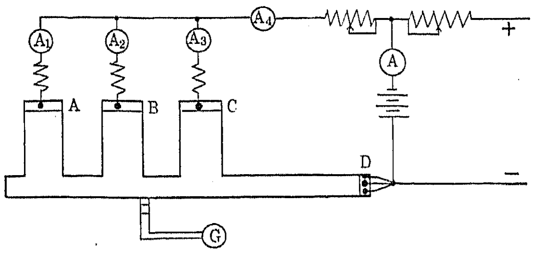

FIG. 7—FLUX-DENSITY TEST FOR TURBO-ALTERNATOR

concluded that, owing to the curvature of the lines of force, the gradient in cables is larger than the value computed on a simple volt per mil basis. This is in no respect a novel conclusion. To advance the knowledge of cable stresses our tests would have to be very considerably expanded. We feel, however, that we have shown that our method will be of considerable utility.

We suggest two series of tests. The first series would be with sheets with electrodes attached as in

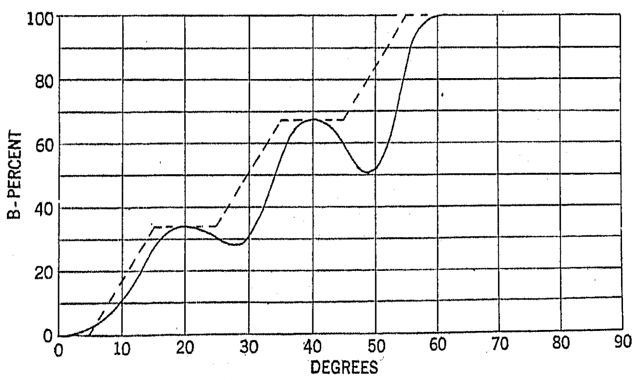

FIG. 8—FLUX-DENSITY WAVE IN TURBO-ALTERNATOR

Fig. 2; the second series would naturally be with electrodes attached to imitate conditions at 90 deg. time phase later. In each series several sheets would have to be used, each with a certain amount of belt insulation. Each sheet would require trimming and testing several times, to correspond with several conductor sizes. Professor Karapetoff, in his "Electric Circuit,"[10] gives a method of superposing fields in equilibrium, which would enable one to obtain, from these two tests, the gradient in the cable at any instant of time phase.

In Fig. 4 is shown a model of an air-gap with a slotted armature surface, the teeth and the slots being equal in width. The flux density was measured for various proportions of slot and air-gap; our results are plotted in Fig. 5. The abscissas represent positions on the pole face, the ordinates represent the flux density in the pole face, expressed as a percentage of that obtaining with a smooth core armature. The maximum and minimum values of density are plotted in Fig. 6 as a function of the ratio of the slot width S to the air-gap G. The curve B_t represents the density opposite the tooth center, the curve B_s represents the density opposite the slot center. These waves are nearly sinusoidal. The two curves of B_t and B_s indicate the amount of pole face loss that may be

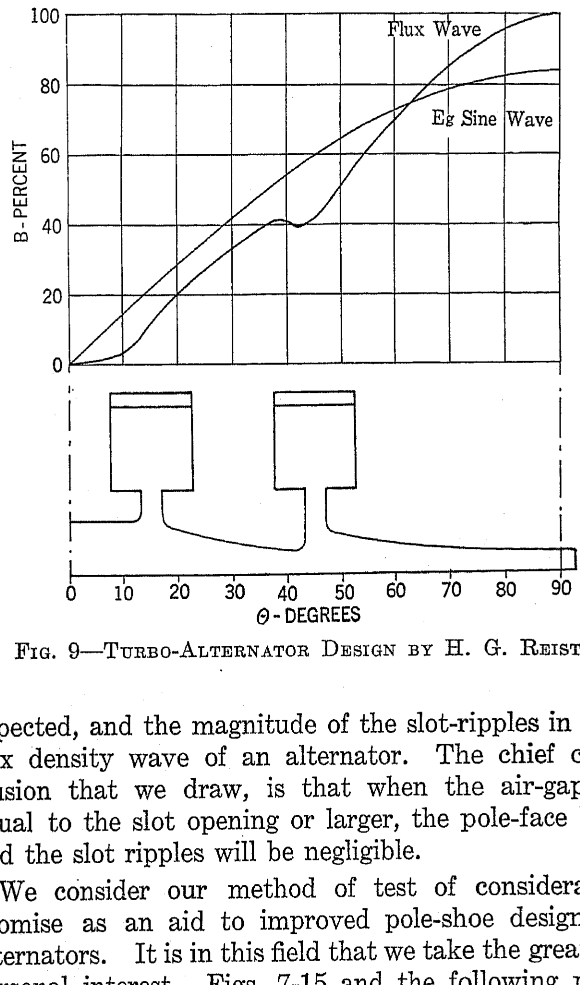

FIG. 9—TURBO-ALTERNATOR DESIGN BY H. G. REIST

expected, and the magnitude of the slot-ripples in the flux density wave of an alternator. The chief conclusion that we draw, is that when the air-gap is equal to the slot opening or larger, the pole-face loss and the slot ripples will be negligible.

We consider our method of test of considerable promise as an aid to improved pole-shoe design in alternators. It is in this field that we take the greatest personal interest. Figs. 7-15 and the following part of the paper are devoted to this one topic. In Fig. 7 is shown a specimen for testing the flux distribution in the air-gap of a turbo-alternator. The stepwise variation of the m. m. f. of the field winding was imitated, by causing the test current to enter the sheet in three different places by electrodes A, B and C, and to leave by the electrode D. These currents were adjusted for equality to correspond with the

10. Page 176.

practical case of an equal number of ampere-turns in each slot. The different electrodes were made of copper to equalize the potential, and wherever needed, as at *D*, several wires were soldered to the electrodes to achieve this end. By adjusting the relative length

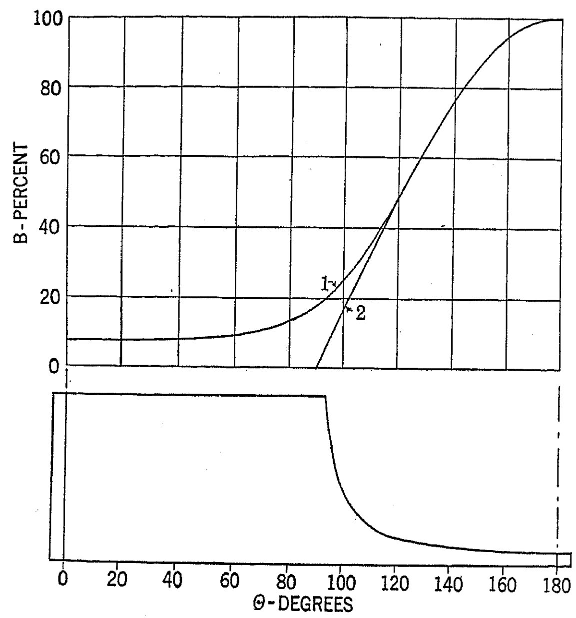

FIG. 10—INDUCTOR ALTERNATOR DESIGN BY J. F. KELLEY

of these wires, the edge of the copper electrode, adjacent to the equipotential boundary of the field, could be kept accurately in an equipotential condition. The measured flux density wave is shown in Fig. 8, together with the wave shown by Gray[11] as applying to this

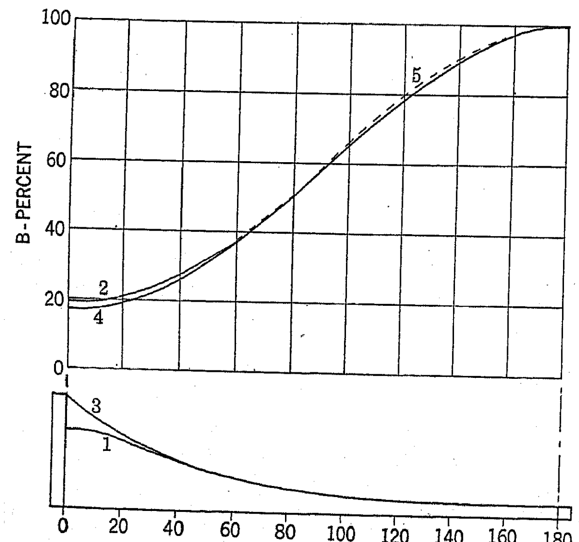

FIG. 11—IMPROVED INDUCTOR ALTERNATOR DESIGN

case. It is seen that the wave form with a uniform gap, and open slots is very poor in form, giving a large deviation and containing apparently a large 17th and 19th harmonic.

In Fig. 9 is shown a turbo-alternator pole-shoe shape given by H. G. Reist,[12] together with the results of a test made by us upon a specimen cut to this shape. It will be seen by a comparison with Fig. 8 what a great improvement in wave form was secured by using (a) a central member diverging from the armature surface, (b) side members diverging at a greater angle, and (c) unequal air-gaps on either side of the slots separating the central from the side members. Fig. 9 also shows a sine wave for the purpose of comparison. By advancing the pole shoe toward the armature surface where the flux density is too low and *vice*

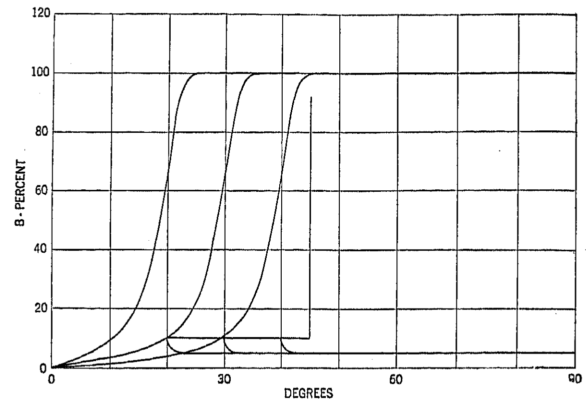

FIG. 12—FLUX-DENSITY WAVES WITH SALIENT POLE ALTERNATOR WITH UNIFORM AIR-GAP

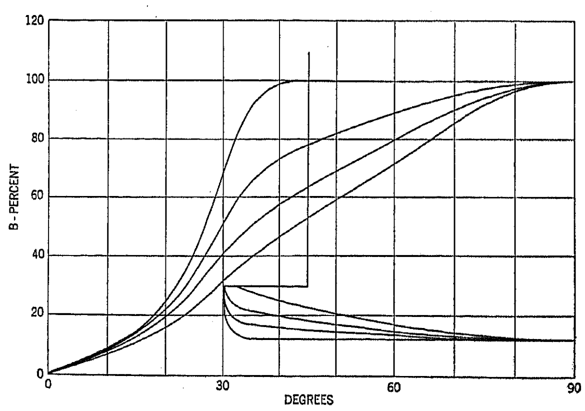

FIG. 13—FLUX-DENSITY WAVES WITH SALIENT POLE ALTERNATOR WITH 67 PER CENT POLE ENCLOSURE AND CURVED POLE FACE

versa, the wave of flux density should be further improved.

In Fig. 10 is shown the shape of the pole face of an inductor alternator disclosed by J. F. Kelley.[13] This pole face was shaped to an inverse sinusoidal curve, which theoretically should have given a good wave form of flux density. Fig. 10 also gives (1) the wave as measured by us, and (2) a wave computed on the basis of radial lines of force, *i. e.*, disregarding their curvature and convergence. It will be readily seen that a purely theoretical formula, which does not take

11. Electric Machine Design, p. 288.

12. U. S. Patent, No. 1,008,561.
13. U. S. Patent, No. 529,918.

into account these phenomena, is open to considerable error.

Fig. 11 represents an attempt upon our part to improve the shape of the pole shoe of an inductor alternator. The line 1 represents the shape of the pole face computed on the basis of radial lines of force, to produce the sine wave 5. Curve 2 represents the measured wave of flux density obtained with a specimen shaped like Curve 1. This density is somewhat too high at points where it should be lowest. A second trial was made using the shape given by Curve 3, which increased the gap where the density was too high. Curve 4 is the result of a test made on this specimen. This curve is so close to 5, the sine wave, that the latter is shown as dotted only where the two deviate from each other. We conclude that our method of test should be able to give more nearly ideal shapes of alternator pole shoes.

With reference to the wave form of salient pole alternators, with poles of alternating polarity, we have tested specimens of the general form shown in Fig. 1, but with differing proportions. One series of tests was made with a uniform air-gap 6 per cent of the pole pitch, but with various ratios of (W/T), that is, differing pole enclosures. The results of these tests are shown in Fig. 12. A second series of tests was made with specimens of 67 per cent pole enclosure, but with varying degrees of pole face curvature. The results of this series of tests is shown in Fig. 13.

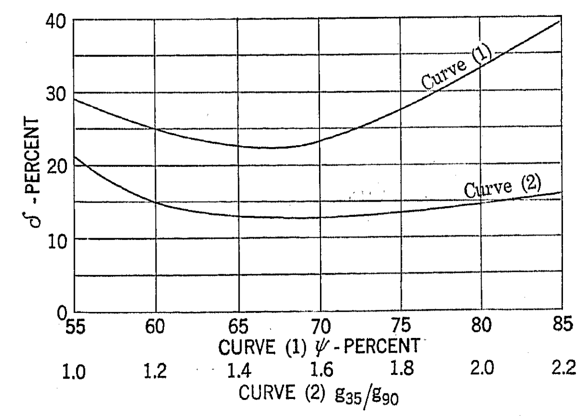

Fig. 14—Deviation Factor of Flux Wave of a Salient Pole Alternator vs. Per Cent Pole Enclosure and Pole Face Curvature

The deviation factors of all these waves were computed and are plotted in Fig. 14. Curve 1 shows the variation of the deviation factor δ with the pole enclosure ψ. Curve 2 shows the variation of δ with the pole face curvature as represented by the ratio of the air-gap at 35 deg. to the air-gap at the center of the pole. These curves show a minimum deviation from the sine wave when the pole enclosure is approximately 67 per cent and when the gap at the 35-deg. position is approximately 1.5 times the minimum gap. The results tend to justify present practise. However, further improvement can be made, since the wave forms disclosed in Figs. 12 and 13 are still far from a sine wave. The investigation reported upon here is incomplete, in that pole faces of only simple curvature were considered. The results would be more useful if harmonic analyses had been included or at least, the telephone interference factor had been shown. We hope to have further results at a later date.

We wish to state here our reasons for believing that the elimination of telephone interference and other

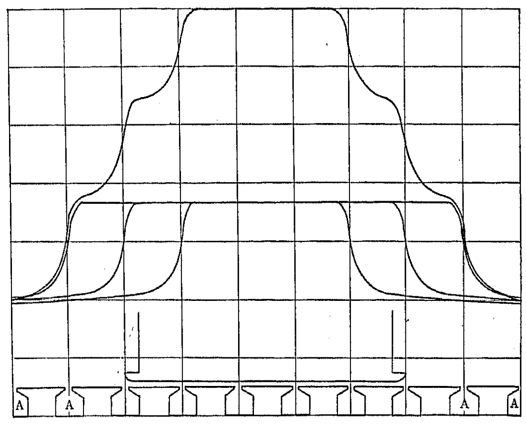

Fig. 15—Voltage Wave showing "Slot Ripples" Due to Poor Pole-Shoe Design

harmful effects of poor wave form, is in large measure dependent upon improvements in pole-shoe design. In the first place, with the alleged exception of tooth ripples, a good pole-shoe design goes to the root of the matter and removes harmonics at their source. In the second place, other remedies are palliative and partial only. For example, the use of distributed and short chord windings eliminates some harmonics in the wave of voltage, but not all. What is more, the ones that are eliminated may easily make the others more apparent. For example, in Fig. 15 is shown a wave of e. m. f. built up of three waves like one of those in Fig. 12 displaced in phase 20 deg. It corresponds to the voltage induced in one phase of a three-phase machine, with 9 slots per pole, the slots almost closed, and in which variations in air gap reluctance would not occur. The resultant wave, instead of being more nearly a sine wave, shows a pronounced 17th and 19th harmonic. The fact of the matter is the original smooth wave contained those prominent 17th and 19th harmonics, as well as many others which concealed them. However, the distribution factor of the winding is such that harmonics other than the 17th and 19th are eliminated in large measure, while these two are not eliminated and so stand revealed. It is to be noted that these harmonics are of the so-called tooth-ripple frequency, and the ripples in the wave might be attributed to variations in the air-gap reluctance caused by the teeth. It is a fact that in every case the distribution factor of a winding is such

as to eliminate partially harmonics of other than tooth-ripple frequency, but not the harmonics of tooth-ripple frequency. We conclude that harmonics of tooth-ripple frequency may not be due to the teeth at all, but may represent harmonics present in the original flux wave, because of poor pole-shoe design.

We add an appendix containing a proof that tooth ripples occur only with pole shoes giving a wave of flux density which in itself contains harmonics of tooth-ripple frequency.

Appendix

A Proof that Slot Ripples are Due to Incorrect Pole-Shoe Design

In Fig. 16, let A represent a smooth core armature surface and B the pole shoe designed so that every harmonic except the nth has been eliminated. Let the magnitude of this harmonic in terms of the fundamental be a. Let C be center lines of symmetry located midway between the poles. Let X be any point on the armature surfaces at which the flux density is desired expressed in electrical radians from the eutral axis. Let G be the equivalent air-gap from the armature at this point to the pole face; that

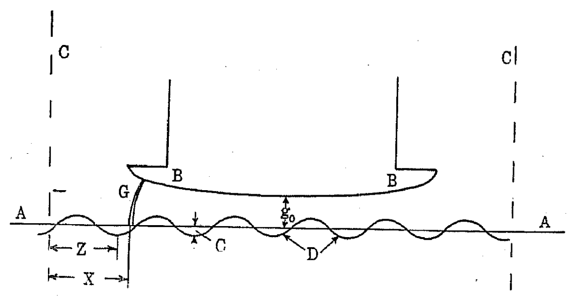

Fig. 16—Construction Used in Proof that Slot Ripples Are Due to Poor Pole-Shoe Design

is, G is the curved distance shown corrected for the tapering of the tube of force. Let G_0 be the gap at the center of the pole which would yield the peak of the fundamental sine wave. The distance G may be defined by equation,

$$G = \frac{G_0}{(\operatorname{Sin} X + a \operatorname{Sin} n X)} \tag{1}$$

Let D be the equivalent armature surface of a toothed armature in its first approximation—a sine wave. Let the point Z be the location of a slot center. Let c be the deviation of this equivalent armature surface from that of the smooth core armature. Let the ratio of (c/G_0) be designated by b. Let there be m slots per pole.

The effect of the slotted armature surface is to increase to effective gap by an amount $\operatorname{Cos}(2m)(X - Z)$. The equivalent air-gap with the slotted armature is, therefore,

$$G = \frac{G_o}{(\operatorname{Sin} X + a \operatorname{Sin} n X)} + c \operatorname{Cos}(2m)(X - Z) \tag{2}$$

The flux density in the air-gap may be expected to decrease in the ratio that the gap is increased, or if B_1 is the maximum value of the fundamental component of flux density, and B is the density at the point X in the slotted armature, we have the equation,

$$\frac{B}{B_1} = \frac{G_0}{G} = \frac{(\operatorname{Sin} X + a \operatorname{Sin} n X)}{[1 + (c/G_0) \operatorname{Sin} X \operatorname{Cos} 2m (X - Z) + a (c/G_0) \operatorname{Sin} n X \operatorname{Cos} 2m (X - Z)]} \tag{3}$$

Upon expanding this expression by polynomial division we obtain

$$\begin{aligned}(B/B_1) = {} & \operatorname{Sin} X + a \operatorname{Sin} n X \\ & - b \operatorname{Sin}^2 X \operatorname{Cos} 2m (X - Z) \\ & - 2ab \operatorname{Sin} n X \operatorname{Sin} X \operatorname{Cos} 2m (X - Z) \\ & - b^2 \operatorname{Sin}^3 X \operatorname{Cos}^2 2m (X - Z) + \ldots\end{aligned} \tag{4}$$

The total flux ϕ expressed as a fraction of the fundamental component ϕ_1 is obtained by an integration from $X = O$ to $X = P i$. That is

$$\phi/\phi_1 = (1/2) \int_0^\pi (B/B_1)\, d X \tag{5}$$

Equation (4) was substituted into equation (5) and was finally integrated be the use of trigonometric reduction formulas. In case $n \neq (2m \pm 1)$

$$\phi/\phi_1 = 1 + (a/n) + (2/3) b^2 + 3 b^2 \operatorname{Cos} 4m\ c/(16 m^2 - 9)(16 m^2 - 1)$$

The last term is extremely small and moreover of double-tooth frequency. We conclude, if the pole shoe does not contain a harmonic of tooth-ripple frequency, there will be no material fluctuation in the magnetic flux of a pulsating nature.

In case $n = (2m \pm 1)$ we get the following result (omitting the last three terms above), namely

$$\phi/\phi_1 = 1 \mp (\ /4)\, a b \operatorname{Cos} 2 m Z \tag{7}$$

This is a flux that pulsates with a frequency $2m$ and which will cause in the armature winding harmonics of frequency $(2m + 1)$ and $(2m - 1)$. This means that in addition to the harmonics of tooth ripple frequency, due to the pole shoe itself, the interaction of pole shoe and slotted armature surface tends to increase the result.

Discussion

DIELECTRIC FIELD IN AN ELECTRIC POWER CABLE—II

(Atkinson)

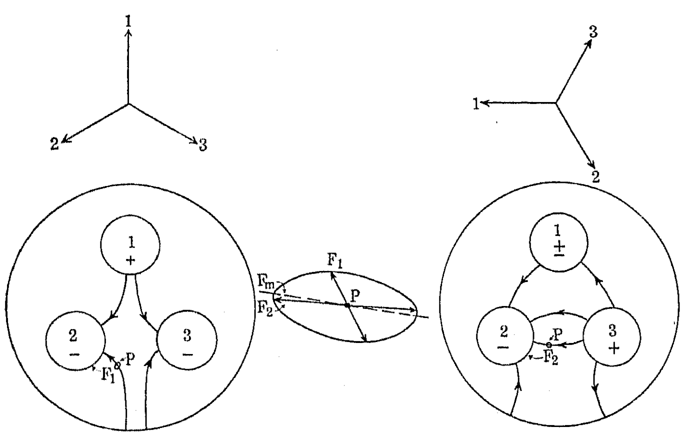
POTENTIAL GRADIENT AND FLUX DENSITY

(Douglas and Kane)

D. M. Simons: The paper by Messrs. Douglas and Kane is of great interest and I think their method can be applied to cable work advantageously.

They have possibly been more interested in the method than in the results of their test, and have so stated. One of their results in regard to cables might cause a slight confusion. Referring to Fig. 3, they mention in the text that they have discovered that the point of maximum stress in their three-conductor cable model was at the surface of the conductor and at the point nearest to the outer sheath, while most observers have found it toward the center of the cable. Mr. Atkinson has pointed out in his previous paper that the stress toward the

sheath depends not only on the conductor insulation but also on the belt insulation and that if the thickness of the belt is reduced, the maximum stress swings around from the center or axis of the cable to the direction of the sheath. As far as I can tell from rough measurements of Fig. 2, the authors have apparently dealt with a cable which had all the insulation on the conductors, but no belt insulation. Their experimental results are therefore correct, but they do not disprove, and I am sure are not intended to disprove, the general statement that in practise cables normally having an appreciable thickness of belt, the maximum stress is toward the center or axis of the cable.



H. Halperin: In regard to Mr. Atkinson's paper, it has been our experience in test and service failures that a large percentage of the failures in three-conductor, 33-kv., sector cables were at the outer corners of the sectors. According to the author, the maximum dielectric stress is at these corners.

E. W. Kane: In regard to Mr. Simons' remarks in relation to Fig. 2, he is correct in stating that in our particular test we made no belt insulation, and we agree with his conclusion; referring to Fig. 3, it may be noted that part of the curve will be lower at the right-hand side when the belt insulation is used.

In regard to Mr. Atkinson's paper on the gradient in three-phase cables, it is perhaps ungracious to attack the accuracy of his results on the basis of a single test; however, a theoretical point of some importance in involved. The electrostatic field in any three-phase cable is, in certain places a pulsating field, but in other places it is a rotating electrostatic field.

In Fig. 1 at the left, is shown the field at an instant when the charge on the conductor 1 is a maximum, the field shown at the right is ninety degrees time phase later, when the charge on conductor 1 is zero.

Considering the field at the point P at the instant of time shown in the left-hand figure, the field is upward, to the left and rather small. At the instant of time phase shown in the right-hand figure, the field is nearly horizontal and much larger. At other instants of time these components are present in different degrees. The elipse in the center shows the locus of the force F at the point P at various intervals of time. It is a rotating electrostatic field.

The electrodes measuring maximum gradient should be oriented along the axis of maximum F, that is F_m and not radially to the conductor. At the surface of the conductor, the field is always radial and there is no criticism of Mr. Atkinson's results here. We contend merely that our method has advantages in the line of speed for these conditions.

A three-phase field can be split up in two single-phase fields which can be combined geometrically at all points and algebraically where they are in the same direction, as at the conductor surface.

R. W. Atkinson: I am going to refer to the paper of Messrs. Douglas and Kane wherein they mention to some of my work. They speak of the fact that the field is not radial at all points. Just in a word, the point that they make does not affect the accuracy of the data which has been given. It is possible for stress to be greater in some other direction. The stress, though, has all been given in either radial stress at the surface of the conductor which is correct as given, or it has been given as stress at some other part of the insulation and in a certain direction. Usually the radial stress approaches very nearly the maximum stress that can exist at a point in any direction.

Some Notes on Street Lighting

BY PRESTON S. MILLAR
Member, A. I. E E.
Genl. Mgr. and Secy., Electrical Testing Laboratories, New York, N. Y.

Review of the Subject.—*This paper, after discussing the criterion of street lighting effectiveness, presents comments upon certain of the variables of street lighting.*

Test data are presented upon certain sizes and types of incandescent lamps for street lighting. An attempt is made to indicate something of the present status of street lighting, including the presentation of a selected list of modern lamp posts and lighting equipments. The paper concludes with data to show the character of installations now recommended by experts for the lighting of various classes of streets, and the advance in recent years in ideas of desirable levels of street illumination.

* * * * *

A GOOD way to begin any activity is to define the purpose in view. The purposes of street lighting have been defined variously. Starting thus from different premises, writers on the subject have naturally arrived at divergent conclusions. In consequence there is uncertainty as to the principles which should guide in the design of street illumination.

The Purposes of Street Lighting. Reduced to lowest terms it is believed that the purposes of street illumination are:—first to reveal, and second to embellish.

Protection against the hazard of criminal violence and collision; security in avoiding obstacles and inequalities in roadway; facility in finding one's way about, all require that the light which is provided shall reveal what it is important to see on or about the street. No system of street lighting is effective which fails to achieve this purpose. Any system of street lighting is effective largely in proportion as it serves this purpose.

Of secondary importance, to be weighed with respect to the type of street involved, is the extent to which a street lighting system, by reason of the design and location of lamp supports and equipment, promotes the good appearance of the street in the daytime, and by virtue of these things and its characteristic of light distribution, promotes the good appearance of the street at night.

Subsidiary purposes which street lighting systems have been designed to serve are advertising of the locality, attracting trade, etc. These more properly fall in the category of advertising display, but are sometimes combined with street lighting for reasons of expediency.

Among diverse requirements for a successful street lighting system which have been put forward, the following may be noted:

"The problem of street illumination is to produce a uniform low intensity."

* * * * "I recognize that a moderate diversity (of illumination) is much more satisfactory."

* * * * "Avoidance of glare is the most important factor in street lighting."

It is submitted that any of these and other alleged major requirements to be served by street lighting may be tested fairly by ascertaining to what extent they contribute to the revealing power of the street lighting system and to the embellishment of the street. It would perhaps be desirable to sacrifice other features to secure a "uniform low intensity" if by doing so the revealing power of the lighting would be greater, but until such has been demonstrated to be the case, the writer for one is unwilling to subscribe to this statement. The test of whether uniform distribution of light along the street or a "moderate diversity" is better lies in a determination of revealing power of the two kinds of lighting. That "avoidance of glare" is not the "most important factor" is evidenced by the obvious fact that this can be accomplished by extinguishing street lamps, which would not at all contribute to the revealing power of the lighting system.

In this country the history of the street lighting art records the prevalence for a period of years of first the "2000 candlepower" criterion and subsequently the candlepower delivered 10 deg. below the horizontal as measures of street lighting effectiveness. The causes contributing to the adoption of these two criteria are now well understood. Neither could have come into use had revealing power been recognized as the principal test of street lighting.

Effectiveness in Street Lighting

There is at this time no generally accepted criterion of effectiveness in street lighting. It is customary to decide between competing street lighting systems by any means which best commend themselves to those responsible and to stipulate in contracts the lamps, equipment and service which together constitute the street lighting system. Among the means availed of in choosing a system are usually inspection, observation, and tests of the lighting units in a laboratory or on the street or both. Actual attempts to determine relative revealing power of various systems are rarely if ever, made in practise.

Effectiveness in a street lighting system like personal charm is recognized when encountered, but is difficult to define. It depends upon the right combination of several qualities, some of which are perhaps intangible. However, when a street lighting system attains to thorough effectiveness, the illuminants will be found to be located and spaced suitably, to be mounted at a

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

desirable height and to be enclosed or equipped in such a way as to present to the eye a desirable combination of candlepower and brightness for the lighting unit and of distribution of light along the street and upon buildings. Suitability and desirability in these particulars sometimes hinge upon the local conditions peculiar to the installations. A few comments of general applicability may, however, be in order at this point of the discussion.

Location of Lamps. For effectiveness in illuminating streets there is no location quite so favorable as directly over the driveway. Where the lamps are few and far between and of small size, and where the pavement is of asphalt or other material which tends to take a polish from motor traffic, the advantages of locating the lamps over the driveway are greatest. Thus, guy wire suspension and mast-arm post mountings possess advantage in such installations. When the lamps are numerous and of large size, and the street illumination is of higher intensity, precise location of the lamps is of less importance since the greatest revealing effectiveness does not have to be obtained from them. This point is well illustrated in Fig. 1 in which a modern twin lamp installation supersedes an earlier mast-arm installation. The new installation is effective in spite of a location which makes for much lower effectiveness per unit of light. When a relatively great amount of light is produced, effectiveness of utilization may be sacrificed somewhat to secure improved appearance. With the lesser quantity of light afforded by the earlier installation, the location of lamps over the street was essential in order to utilize with fair efficiency the relatively small amount of light which was produced.

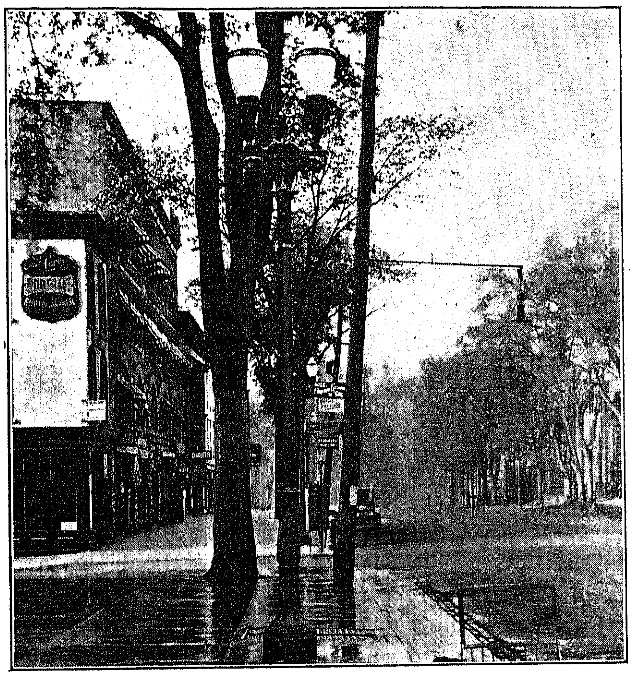


FIG. 1

In the old system, but little light being available, the lamps were located over the roadway for greatest effectiveness. The more adequate modern lighting permits location of lamps for pleasing effect.

Spacing of Lamps. Evidently spacing intervals should be small enough to avoid dark areas between lamps. On the other hand, the writer's experience has indicated that it is not desirable to incur large expense through reducing spacing intervals in an attempt to approximate uniformity of illumination along the street. Discernment in the street at night is largely dependent on contrasts of light and shadow. Studies of revealing power made for the joint street lighting committees of the National Electric Light Association and the Association of Edison Illuminating Companies 1914-1915, indicated that when uniformity is attained through multiplicity of small illuminants, contrasts are diminished through the elimination or reduction of shadows, so that objects on the street and depressions or holes in the street surface are not seen so well as they are when lighted from fewer, larger lamps. These, through failing to provide uniformity of illumination, do produce relatively strong shadows which are an aid to visibility.

Mounting Height. In connection with the control of light for street lighting purposes, much planning and design have been influenced by a desire to approximate uniformity of illumination along the street. Attention in this connection has been focused upon illumination intensity curves such as those shown in Fig. 2. Other aspects of street lighting effectiveness have sometimes been sacrificed to secure a considerable percentage increase, but a small absolute increase in

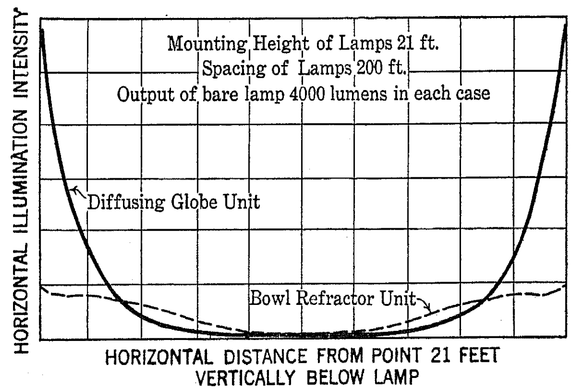

FIG. 2

The desire to approach uniformity of illumination along the street has influenced street lighting design quite generally.

illumination midway between lamps. Such improvement in midpoint illumination can be had, of course, only at the expense of largely increased candlepower just below the horizontal. To avoid glare as a consequence of such light distribution, the units have sometimes been mounted high. The resultant effect upon the illumination curve has been thought to be good.

It must not be forgotten, however, that as lamps of symmetrical horizontal distribution are mounted higher, the proportion of light flux delivered upon the street

surface is diminished. This effect is increased if the candlepower just below the horizontal is made large to reinforce the illumination midway between lamps. In Fig. 3 curves are shown to illustrate the relations that are here involved. Considering the total light produced, a smaller part is delivered below the horizontal from a diffusing globe unit than from a bowl refractor. With low mountings of the bowl refractor, the advantage in the proportion of light delivered upon the street is quite large. At 43 ft. mounting height, which, of course, is higher than may be considered practicable when lamp posts are employed, the proportion of light delivered upon the street is the same for the two types of distribution. If, however, some light is desired above the horizontal, and the lower hemispherical light flux alone is considered in this relationship, the relative proportions delivered upon the street surface are shown in the two lower curves,

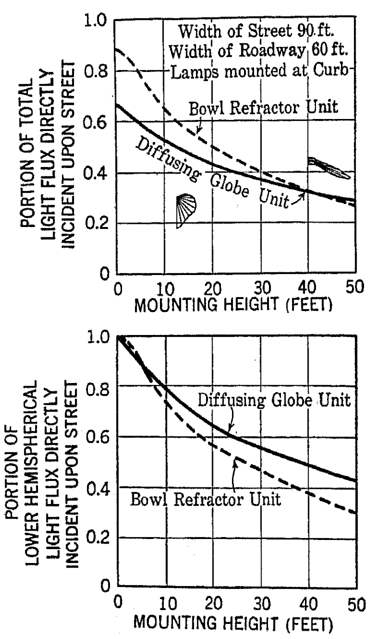

FIG. 3

With increased mounting heights, the proportion of light flux delivered directly to the street surface becomes smaller.

the bowl refractor delivering a smaller proportion of flux from all practicable mounting heights.

This consideration apparently has entered into the design of two-way and four-way refractors, described later, which are intended to deliver larger proportions of the light along the streets by utilizing the light which otherwise in some installations would be wasted or used to poor advantage in other directions.

Characteristics of Equipment and Illumination. The avoidance of undue glare is important to street lighting effectiveness. Glare depends largely upon the brightness and candlepower of the lighting unit within the field of vision and is modified by the brightness and extent of other illuminated areas likewise within the field of vision. It is modified also as the source is removed from the center of the field of vision.

The relationship between candlepower and brightness of source, and the relationship of these to location and background in street lighting are not well understood. The writer has been unable to accept the indications of his own and other attempts to measure and evaluate such effects. In none of them has the subjective element been eliminated or brought under adequate control. No way has been found to reproduce for test purposes the conditions of attention which obtain in the ordinary use of the street by drivers and pedestrians, nor have means been found to evaluate the feeling of satisfaction and contentment with one lighting system which may not be experienced with another lighting system, when the latter cannot be said to produce serious glare which can be measured in visual tests, but is still unsatisfactory as to brightness or candlepower in the direction of the eye. Considerable pioneer work has been done along these lines and street lighting systems have been designed with reference to the results of such investigations. The writer's experience in the conduct of investigations in this field and his observation of designs, based upon such investigations, lead him to feel that the answer has not been found by such means.

The problem resolves itself in the main, into a means of delivering sufficient light upon a street without producing serious glare. The usual means employed are to mount illuminants at a moderate height and employ sufficiently large globes to keep the brightness below the point which produces serious glare, or else to mount the lamps high with a view to removing them from the center of the field of vision, employing some means of directing the light downward upon the street.

An interesting comparison of these two methods has been afforded through demonstration installations in Columbus, Ohio during the spring of 1924. These installations have covered too short a length of street to make the demonstrations entirely convincing, but the contrast between the two systems was displayed in so striking a fashion as to occasion surprise that, after years of effort along the lines of improvement in street lighting, leaders in the art could entertain such diverse views as to means of accomplishing the desired ends.

One more comment on the desirability of uniformity in street illumination should be made. When lamps of moderate or large size are mounted at relatively large spacing intervals, the only way to approach uniformity of lighting is to redirect the light along the street with a large excess at angles slightly below the horizontal, in order to deliver enough light midway between lamps to render the illumination in such areas comparable with that nearer the lamps. This can be accomplished only at the expense of such high candlepower and brightness at angles slightly below the horizontal as to occasion serious glare at any practicable mounting heights. The superiority of substantially uniform illumination along the street over a moderate

diversity, resulting from more natural light distribution characteristics, is usually insufficient to compensate for the attendant condition of glare.

Uniform illumination of moonlight is excellent. But uniform illumination achieved by many small illuminants staggered along both curbs or by means of candlepower distribution curves, having an excess just below the horizontal, imposes damaging visual handicaps and, in the writer's opinion, is not be to desired. Observation and experience indicate that in street lighting moderation is generally desirable. Moderate size lamps, equipped so as to modify light distribution somewhat in the direction of uniformity of illumination, moderately bright, moderately spaced and at moderate heights, lend themselves to successful street illumination in the generality of cases. Departures toward either extreme in any particular may be justifiable and may be desirable, but in general, moderation is the best rule of practise.

It appears to be indicated that in proportion as little light is available for streets, it is important to employ equipment which is designed to direct it along the street to the exclusion of the side of the street. Conversely, when ample light is available, unnatural and dissymmetrical light distributions become unnecessary and buildings along the street may be lighted as well as the street surface with advantage to visibility conditions and to the appearance of the street.

In the interesting and useful demonstration of street lighting systems made available last winter, through the cooperation of the National Lamp Works of the General Electric Company, The Cleveland Electric Illuminating Company and the Cleveland Municipal Department of Light and Heat, comparison was made between lamps of a given size, spaced at equal intervals but mounted at respectively 16½, 21 and 26 ft. above the street level, the highest mounting being out over the street and the lowest mounting being over the curb. The lowest mounting resulted in the greatest amount of light being delivered upon the street with some appreciable glare. The highest mounting resulted in a smaller quantity of light being delivered upon the street and less glare. The writer's independent judgment favored the medium mounting height as producing the largest effectiveness under the particular conditions which prevailed, and he was advised subsequently that this judgment tallied with that of most observers. This verdict was applicable, of course, only to the particular conditions of these trial installations. But the incident illustrates the fact that the most desirable mounting height in any case can best be determined by trial in the street.

Some years ago in New York City, in order to ascertain the best location and arrangement of lamps for lighting a boulevard, lamp posts were mounted in rock ballasted barrels which were shifted about to secure best practicable locations. The result was excellent utilization of the light from the lamps. Some such method of experiment in the street is to be recommended wherever it is practicable to apply it.

Illuminants

Rating Accuracy of Tungsten Filament Lamps. Like all illuminants which are employed in street lighting, tungsten filament lamps differ individually in light output and efficiency when new, and vary somewhat as they are operated. It is not possible to present any tests of rating or of life performance which may be regarded as representative of all tungsten lamp products or of any one product at all times. In Figs. 4 and 5, however, there are shown ratings and life performance data of Mazda lamps of the street series and multiple types which are perhaps as nearly representative as any that might be chosen.

The tests of rating represented in Fig. 4 in the form of target diagrams bring together samples of various Mazda products selected over a number of months.

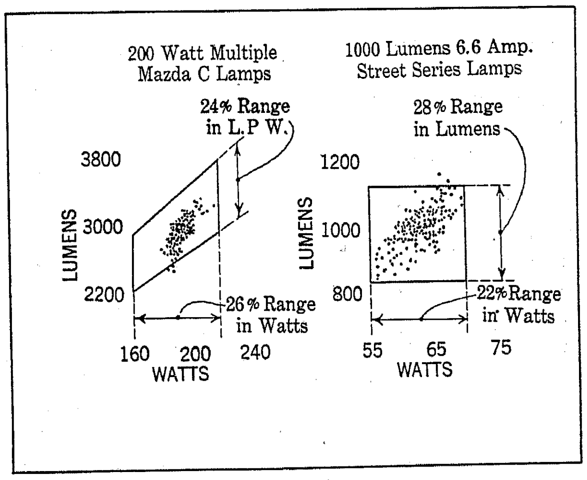

Fig. 4
Rating accuracy of incandescent lamps for street lighting.

It is to be expected that a similar number of lamps of some one product produced at one time would display somewhat more consistency than is here shown, but such a group would be less representative than the group chosen. The trapezoid and the rectangle represent the tolerances of standard lamp specifications, and each dot indicates by its location on the diagram the lumens and watts of a lamp. In the sample ratings illustrated, a range of ± 14 per cent in lumens for series lamps and of ± 12 per cent in lumens per watt for multiple lamps is indicated for new lamps by the standard specification tolerances.

It is understood that there are in existence some street lighting specifications which call for closer conformity to rated lumens on the part of individual lamps than has been attained by the most progressive lamp manufacturers. Such provisions, if complied with, occasion undue expense in the selection of lamps and accomplish little, if anything, of advantage to the public. If not complied with, they introduce possi-

bilities of trouble which are undesirable from every point of view. It is submitted that street lighting specifications ought not to prescribe closer adherence to rating on the part of the illuminants than best practise permits, unless it is understood that such closer adherence involves increased cost which must be met at public expense.

Laboratory performance throughout life with respect to light output and efficiency is indicated in Fig. 5 for samples of series and multiple Mazda lamps of the type illustrated.[1] These performance characteristics are perhaps as representative as any that might be chosen. The performance characteristics of other sizes, types and makes of lamps may be materially different from those illustrated. The better lumen maintenance of the series lamps as compared with the multiple lamps is the natural result of the increased watts expended in the lamp as the filament resistance increases throughout life. The lumen maintenance of the multiple lamp, though not so good as that of the

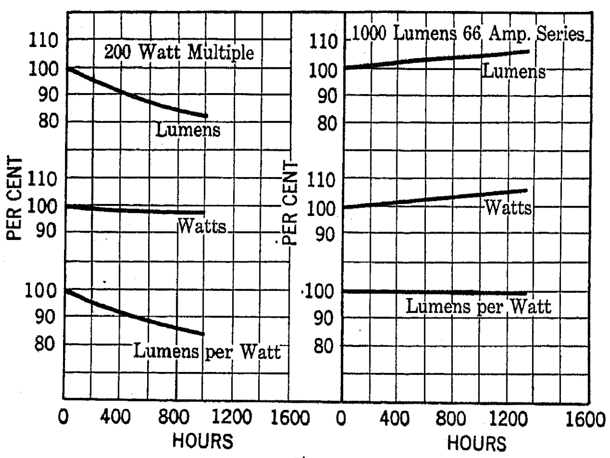

FIG. 5

Life performance of certain sizes of incandescent lamps for street lighting.

series lamp, is excellent as compared with earlier types of incandescent lamps.

These changes in light output throughout the lives of lamps do not take into account losses due to dust or discoloration of reflectors or globes.

No statistics are available to the writer to show the change in light output of modern magnetite arc lamps throughout the period of electrode life and between cleaning and trim periods.

Multiple Lamps. With the development of a successful system of remote control[2] and of reliable time switches, the multiple incandescent lamp operated from commercial service mains has come into much greater favor than it formerly enjoyed for street lighting purposes.

1. Lamp test statistics are available through the courtesy of the Lamp Committee of the Association of Edison Illuminating Companies.

2. Remote Control of Multiple Street Lighting—W. T. Dempsey, JOURNAL A. I. E. E., October 1923, page 1106.

Arc Lamps. The arc lamp has now been very largely superseded by the incandescent lamp for utilitarian lighting of secondary streets. In its more powerful form, however, employed with diffusing globes, the magnetite lamp is a very lively factor in lighting the most important and distinctive streets of many cities.

PRESENT STATUS OF STREET LIGHTING IN THIS COUNTRY

Municipal Expenditures. Cities ordinarily spend about 75 cents per capita per annum for street lighting. It seems to be the general feeling of those, who after study of the subject have expressed themselves in the technical literature, that about twice this amount should be spent on the average for street lighting, in order to provide illumination which is adequate to meet the requirements of modern congestion of high speed traffic. Differences in local conditions may double or halve the sum required in a given community to afford street lighting of the desired effectiveness.

Unity of Design. Street lighting systems in most American cities suffer from lack of uniformity and style, having been designed at different times by people whose ideas as to the requirements differed. For the most part, systems have grown from small beginnings, according to the seeming expediency of the hour and without any coherent principle as a basis upon which to develop a homogeneous system expressive of the city's character and reflecting favorably upon its management. Few, indeed, of the larger cities have attempted, as St. Louis is now doing, to introduce an entirely new street lighting system designed with unity of purpose to serve present needs and to be capable of expansion for future requirements without sacrifice of unity of design.

Lamp Posts. In lamp mountings, independent posts for one or more lamps or brackets on trolley line poles are in general use. The cluster of five lamps, more or less, in diffusing globes mounted low is passé. The columnar post for one lamp, the bracket post for lantern type of housing, and the modern multiple lamp post are illustrated by a variety of samples in Figs. 6 and 7. The inclusion of transformers in the bases of lamp posts has had an undesirable influence in making the diameter larger than is consonant with the purpose of the post, often robbing it of grace. In this respect, the posts for multiple lamps have possessed an advantage. Recent transformer types of smaller dimensions have mitigated this difficulty.

To a considerable extent the leading manufacturers of lamp posts, lamps and lamp equipment have influenced the type of street lighting installations, particularly in the smaller cities. For the most part, new street lighting systems which have been installed have been superior to existing systems. In street lighting the tendency to passing styles has not exceeded the bounds of moderation because innovations have had to justify themselves in the eyes of the purchasers

and users who have generally inquired rather carefully into their merits before committing themselves to the large expenditures involved.

ATMOSPHERE AND TRADITION IN STREET LIGHTING

Economy dictates, at least for smaller installations, the choice of standard lamp posts and equipments. Such choice, however, loses distinctive qualities for the installation. There are some communities which are perhaps so characterless and colorless as to possess no traditions and to afford to the observer no distinctive features. When, however, a community is of distinctive character, it would seem that lamp post and lamp equipment design afford an excellent opportunity for the exhibition of atmosphere and traditions which ought to be availed of where practicable. Two illustrative installations occur in this connection. Some of the street lighting of Riverside, California was until recently provided from concrete posts the heads of which represented the archway of a Mission belfry, while a bell-shaped lamp shade represented the Mission Bell, the whole embodying the romantic Mission traditions of the neighborhood. Another instance is offered by the historic lighting of Independence Square, Philadelphia, in which the modern lamp posts and lanterns are designed to preserve the traditions through faithful reproduction of the oil lamp lighting of the Square which is said to have been designed by Benjamin Franklin. In neither case did the lighting achieve high effectiveness from the point of view of utilitarian street lighting. Both designs, however, are notable as worthy attempts at preservation of traditions in street lighting design and as illustrations of attempts to obtain a logically distinctive lighting system.

Lamp Equipments. Perhaps no phase of the street lighting problem is mooted so generally as is the question of equipment of the lamps. Preference for urban street lighting ranges from a diffusing ball, largely lacking in directive qualities, to optical equipments which afford maximum opportunity for directing the light as desired. Among intermediate equipments some combination of a slightly diffusing outer globe of large area with an internal refractor appears to meet with rather general approval. These combine a measure of control of the light with a reduction in brightness, achieving a satisfactory degree of effectiveness for many street lighting purposes. Lighting equipments of these types are illustrated in Fig. 8.

Notable advances have been made in recent years in the adaptation of prismatic glassware to street lighting. The prismatic refractor as a complete globe for street lighting units has proved very effective in redirecting light as desired. In its original form, limited apparently by cost considerations to relatively small size, its brightness was rather high and, in particular when used with the larger lamps, was too high for many purposes. A more recent development of the refractor in a larger size (16¾ in. upright inverted) has mitigated this difficulty.

More recently the prismatic refractor has found an interesting field of usefulness as an internal directing element of a street lighting fixture employed with a larger outer globe, usually more or less diffusive in character. Such directing refractors employ horizontal prisms to direct the light upward or downward, or vertical prisms to direct the light along the street, diverting it from the side of the street. Some illustrations of refractors employed in this way appear in Fig. 8.

Another recent development of the refractor, which is designed to form a complete lighting equipment,

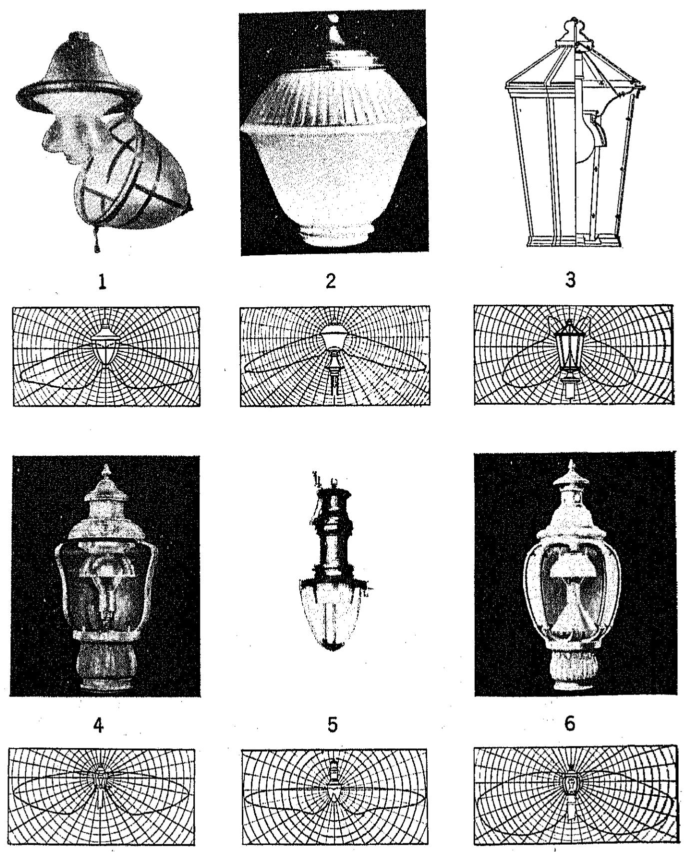

FIG. 8—PRISMATIC GLASS FOR LIGHT CONTROL

employs a system of prisms, designed to direct much of the light in two directions up and down the street, or in four directions at rectangular street intersections. The horizontal distribution of candlepower for such refractors shows either two or four pronounced lobes. Where accurate setting of such equipment can be assured, and where the high brightness is not objectionable, these two and four-way refractors may be found useful. They are not intended ordinarily to be applied chiefly in "ornamental" lighting systems; *i. e.*, with underground distribution and ornate posts and housings.

Still another application of prismatic glassware is in

the form of panels of a lantern type of street units as illustrated in Fig. 7.

Highway Lighting Units

A feature of modern development in street lighting is the lighting of highways. This is very desirable as a contribution toward the construction of pole lines in rural communities and toward the solution of the difficult automobile headlighting problem, in addition to the direct advantages of street lighting which apply to highways as well as to city streets. In the lighting of highways spacing intervals must of necessity be great and the design of equipment must be such as to utilize to the utmost the available light flux for delivery along a narrow strip of highway. A concentration of light up and down the road with a generous flux of light on the street below the lamp is indicated. Although some attempts in this direction were made at an earlier date, highway units were not put forward actively until the availability of the concentrated filament, gas-filled tungsten lamp made possible higher effectiveness from such devices than was formerly attainable. Three designs, with practically the same objects in view, are illustrated in Fig. 9. All accomplish more or less well the purpose of delivering the light along the highway. None is conspicuous for grace or beauty. In highway lighting units, "handsome is as handsome does."

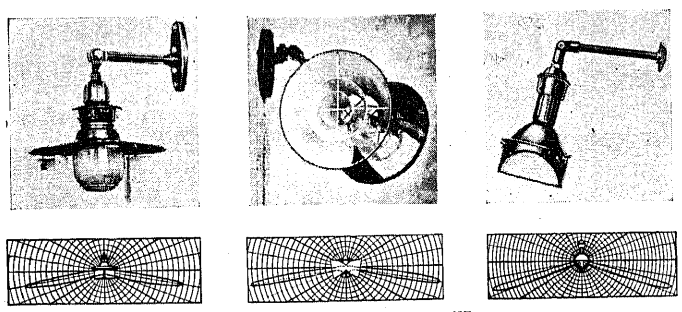

Fig. 9—Highway Lighting Units

Standards of Illumination for Various Classes of Streets

Several writers[3] on street lighting recently have classified streets and suggested ranges of illumination suitable for each. In Table I an attempt is made to combine these statements to indicate modern ideas of suitable levels of illumination. Obviously, in consolidating them certain liberties have had to be taken. The table, however, is probably fairly representative of their views as expressed. For each class of street, the range of lower limits and the range of upper limits have been shown for each particular of street lighting which has been covered by these writers.

In relating lamp lumens to illumination on the street surface, it is necessary to take into account the loss of light in the lamp equipment, the width of the street, the location and height of the lighting unit and the reflection of light from buildings.

Advancing Standards of Street Illumination

Increase in high-speed vehicular traffic and growing appreciation of the importance and value of good street lighting have brought about a rapid advance in levels of illumination advocated for street lighting. A good illustration is afforded by the comparison in Table II between illumination intensities regarded as typical of

TABLE II

ADVANCING IDEAS OF SUITABLE LEVELS OF STREET ILLUMINATION

1916 Standards			1924 St. Louis Proposal	
Class of Streets	Avg. Horiz. Illumination Intensity	Desirable Characteristic	Zone	Average Ft.-candles
Important avenues and heavy traffic streets	0.5-1.0 ft. c.	Ample light on building	Downtown retail	1.68 ft. c.
			Intermediate Zone 1	1.20
Secondary business streets	0.1-0.2	Ample light on building	Intermediate Zone 2	0.7
			Intermediate Zone 3	0.47
			Major thoroughfares outside central zones	0.30
City residence streets	0.05-0.1	Subdued light on bldg. fronts	Residential heavy traffic	0.16
Suburban highways	0.02-0.04	Max. light on roadway		
Suburban residence streets	0.005-0.02	Very subdued light on building fronts	Residential outlying	0.09

practise in 1916[4], and levels of illumination intensity proposed for the new lighting of the streets of St. Louis.[5] The St. Louis proposed illumination levels are considerably in advance of the standards advocated in Table I. The writer does not know how representative they are of modern ideas, but if they are no more than the expression of convictions reached by municipal authorities after investigation, the contrast which they form with the levels regarded as typical in 1916 is a striking commentary on the advance of street lighting theory if not of practise.

It is not clear at this time how far this advance in standards of street lighting will be carried, but it is clear that large advances are being made with results that are beneficial to the public, the utility company and the manufacturer of equipment.

The author desires to thank representatives of the General Electric Company, the Holophane Glass Company and the Westinghouse Electric and Manufacturing Company for street lighting information supplied upon request, and to express appreciation to several others who have assisted in the preparation of this paper.

4. Lighting of Streets—P. S. Millar, I. E. S.—U. of P. Lecture Course, 1916.

5. Ralf Toensfeldt, Department of Public Utilities, St. Louis, *Electrical World*, Nov. 24, 1923, page 1065.

Discussion

L. A. S. Wood: Mr. Millar has preached the gospel of moderation, and, while I subscribe to that doctrine, it is rather difficult to determine just where moderation ends and intemperance begins.

I hope that Mr. Millar's remarks regarding low intensities with diversified illumination will not be taken as his recommendations for modern street-lighting practise. In another part of his paper he refers to the desirability of high intensities with uniform illumination, provided such can be obtained without undue glare, and this, in my opinion, is the best kind of illumination suitable for modern traffic conditions.

The tables on the last page showing the tendency of modern street-lighting practise toward higher intensities are very interesting, and it is gratifying to note that the standards set by the City of St. Louis are so very much higher now than those prevalent in 1916. I feel, however, that there is still a very wide margin for increased intensities of illumination before we get out of the range of moderation.

Mr. Millar refers to the control of light by prismatic refractors and the possibilities of directing the light flux in such a manner as to build up the illumination between units to higher intensities than could be obtained without such control. In this connection, I would like to refer to a prismatic refractor which was presented at the Illuminating Engineering Society last fall. This refractor bends part of the light flux from the direction of the property line and adds it to the light flux in the directions "up and down," the street producing unsymmetrical or what is sometimes called "asymmetrical distribution." I believe that the tendency from now on will be the direction of asymmetrical distribution as compared to symmetrical distribution for street illumination.

F. C. Caldwell: I would particularly emphasize the difficulty experienced in laying down practicable specifications for good street lighting. This is, of course, especially true where, with high-intensity lighting, the elements of aesthetic effect and of making the street a pleasant place in which to walk or ride are important factors. Probably an adequate illumination of the building fronts as well as of the pavement should be included in such specifications and perhaps information on the foot-candle intensities needed for this purpose may become available. Indeed, I hope we may make a small beginning along this line in connection with the Columbus demonstrations.

Apropos of this type of lighting, I am not quite so sure as Mr. Millar seems to be, about the place of the refractor. With him I would question whether any refractor now available is suited to this case, but might not one be made that would give just the illumination desired. While a rather uneven or spotted illumination on the pavement is not objectionable, should not the illumination on the buildings be as uniform as practicable. Would it not be in order then to design a refractor which would redirect that part of the light, perhaps 30 to 40 per cent, which now falls upon the adjacent buildings, on the same side of the street. This makes a bright spot opposite the light and is otherwise ineffectively used because of the small angle at which it strikes the walls. Again there is all the flux that escapes to the sky from a diffusing globe.

If without attempting to increase the illumination on the pavement or to make it more uniform, most of the light in these two zones, that is the flux which does not fall upon the sidewalks, the pavement or the opposite buildings, could be redirected by a refractor and thrown across the street onto the building fronts, a refractor might well justify itself even in high-intensity and ornamental lighting.

It is almost useless however to throw light onto dark-faced buildings. If the illumination of the walls as well as the floor of the street is accepted as important and the city is to spend money to accomplish it, an organized effort, probably by educa-

tion rather than ordinance, should be made to get owners to use light-colored building material and to keep it clean. Once such a practise becomes general, a builder would hesitate to place his building at the disadvantage of being invisible at night.

From another point of view, assymmetric refractors may become important in the high intensity of business streets. The movement to eliminate poles will, if carried to its logical conclusion, result in the support of the trolley wires from the fronts of the buildings and the mounting of street lights on large brackets. A downtown street without an obstruction from end to end, is a pleasant thing to think upon. Here refractors would be almost necessary.

At another point the public should take an interest in conditions accessory to street lighting. Hitherto illumination has had to take second place to the trees on the street. With changing conditions it appears to be time for this order to be reversed. I know a street where the the trees are kept, for the most part, back to the line of the house-fronts. The effect of openess and breadth is very pleasing. Perhaps however, such an arrangement of the trees as a general policy would be too much to hope for. It is not at all unreasonable however to locate the trees on the lot line instead of at the curb and this is a requirement well within the rights of the public, for safety, if for no other reason. Again, regulations for the trimming up of trees may well be made and enforced, on the same grounds.

The testing of the Columbus demonstration will be completed next week. While for the most part the results are not yet worked out, a few points seem to have been rather clearly established. One is that four 15,000-lumen lights on a 500-ft. block give more satisfactory results than ten 6000-lumen lamps, which is the spacing hitherto used. Again our experience indicates that 150 lumens per linear foot gives very satisfactory lighting for ordinary business streets and that 300 lumens makes fine "whiteway" illumination. Also 25 to 50 lumens per foot covers very nicely the usual range of residence streets and boulevards.

The important questions of incandescent versus magnetite-arc lamps and of diffusing globes vs. refractors, symmetrical and unsymmetrical, have not had final consideration, but we hope to throw some light upon them before we are through.

Mr. Millar has spoken of character in standards. There are few expenditures involving so much money that we make with more inadequate judgment than in the purchase of lamp standards. Their selection is generally left to someone who, in other matters of art, would certainly not claim to be a qualified critic. Probably it is usually the salesman, rather than the standard which decides the matter.

The increasing emphasis which is being put upon the aesthetic aspects of city planning indicates the reference of such a selection to the best practicable commission of architects and artists. In the case of large orders, a standard specially designed by a competent artist should be used and if it can embody some feature characteristic of the city so much the better.

Finally, let me advise anyone who would conduct an extended series of tests of street lighting to arrange to close up his other affairs for the time being. Our efforts in Columbus have convinced me that the most practicable place to test street illumination is anywhere else but on the street.

G. H. Stickney: We all realize that the new thing, which is creating the need for better street lighting and more light, is the automobile. Ten or fifteen years ago the principal traffic on city streets was moving about six miles per hour. Now it has attained a speed of twenty or more miles per hour.

It is, therefore, necessary to see more clearly and further if accidents are to be avoided. Street lighting, in general, has not adapted itself to this demand which the automobile has created, and greater progress in this direction is essential to the preservation of life, limb, and property.

The question of symmetrical and asymmetrical distribution of light from street-lighting units is a very live one at the present time. It is not merely a comparison of two systems, since there are many possible characteristics of asymmetrical distributions. There are several schools of thought on the subject, and more experience is necessary before the best conclusions can be expected.

Past experience has indicated, that when such new possibilities are opened up there is a tendency to go to extremes. Having made such mistakes, I am inclined to expect the best practise to be found nearer a medial point rather than at an extreme. I believe asymmetrical distribution is here to stay, but not to the exclusion of symmetrical distribution. Nor do I think it probable that the best forms of asymmetrical distribution have yet been secured.

We should expect to find ways of utilizing light more effectively, but this one feature should not be over emphasized to the exclusion of other considerations.

There seems to be a natural tendency to think that it is desirable to put as large a portion of the light on the pavement and provide uniform illumination over this entire area. However, practically all of the tests and demonstrations have indicated that when the amount of light is limited, as is usual in street lighting, better visibility is secured where sections near the unit receive more illumination than the more distant areas, provided, of course, this is not carried too far. Such illumination often appears uniform to the eye, and seems to give better results than a similar amount of light so distributed as to give measured uniformity.

This is undoubtedly one of the factors which is bringing about the tendency toward the use of higher power units, even with incandescent lamps, in spite of availability of small sizes. It is, of course, promoted also by the superior economy of the larger lamps.

D. K. Blake (by letter): Mr. Millar, in his paper (page 994) mentions three important factors in the development of street-lighting systems which should be of considerable interest to the distribution engineers. They are first, the development of remote-control systems; second, the practise of connecting multiple incandescent lamps to the commercial service mains and, third, the increase in municipal expenditures per capita for street lighting. Because of the expenditures involved and because of the relation of the street-lighting system to the distribution system these factors are additional reasons for an intensive and extensive economic study of the distribution system as a whole.

It seems to me that the highway-lighting units mentioned on page 997 should be of considerable help in solving the problem of rural electrification. Because the highway-lighting unit increases the rural load and consequently reduces the cost of central station service to the farmer, its use should be justified on the highways where otherwise it would not be advisable to spend the money for the installation of these units.

The Flashing Characteristics of Series and Compound-Wound Motors

BY RALPH E. FERRIS
Associate, A. I. E. E.
Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*This paper, to a certain extent, is in the nature of a log covering several years' test on a line of dynamotors. The flashing characteristics of series and compound-wound motors are discussed with special reference to these tests. The principles derived from the study of these machines have, however, been applied successfully to other motors. Machines of this type are apt to have a critical flash point, depending upon the constants of the electric and magnetic circuits. The oscillograph has been used to determine the best relation of shunt to series field for a given difference of speed between full load and no load. Methods of improving the flashing characteristics of a given machine are discussed. In some cases it is shown that a damper on a series-wound motor gives better flashing characteristics. An attempt to explain the nature of a flashover on a d-c. machine is made.*

THE writer has had considerable doubt as to the best method of presenting the material contained in the following paper. First, it could be presented in a more or less abstract way giving examples to support the theoretical conclusions; second, it could be given purely as a history of a series of tests; or third, it could be conveyed as a combination of the first and second methods.

The third method was finally decided upon because it not only contains to a certain extent a narrative interest, but at the same time gives a vehicle for presenting conclusions which in the end are borne out at least in part by the tests recorded.

Some classes of motor service require the machine running continuously under a variable load from low or no load up to maximum. An occasional second requirement is that the motor be capable of withstanding full line voltage applied at any time from standstill up to normal speed. The first requirement necessitates a shunt field, while the second calls for a series field, thus giving for the combination a compound-wound machine.

The flashing characteristics of a machine of this type under the application of full or over-voltage are more or less varied and interesting. It is the purpose of this paper to discuss these, in connection with a particular example, this example being a line of dynamotors and dynamotor compressors for use on 1200 or 1500-volt railway service. A detailed description of this type of apparatus may be found in the *Electric Journal* for October, 1913.

Briefly, the dynamotor consists of two separate and distinct armature windings on the same core, each connected to its individual commutator. The two windings have a common field and therefore the generated e. m. f. per turn is the same for each winding at any given field excitation; or the voltage at each commutator is equal to some factor times the number of turns in series in the winding.

In reality, the dynamotor is a d-c. voltage transformer. If, for example, it is desired to transform from 1200 to 600 volts, the armature windings may have the same number of turns and the two connected in series externally. Current at 600 volts may then be obtained by tapping off at the middle point between the two windings. With the introduction of high-voltage direct current for railway work, when the locomotive or car is required to operate either on 1200 or 600 volts, the dynamotor presented itself as a means of generating 600 volts direct current, for lights, control, compressor and blower motors while on the 1200-volt section. This connection is shown in Fig. 1.

The dynamotor-compressor combines the dynamotor, the compressor motor, and blower motor all in one, thus materially reducing the weight and also the space required for the outfit. This is accomplished by using the dynamotor as a motor and driving the compressor thereby through a set of gears and a multiple-disk clutch.

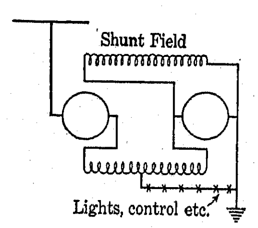

FIG. 1

If a blower is required on the car or locomotive, an extended shaft is used and the blower mounted thereon.

While the paper deals mainly with the dynamotor-compressor as an example, the fundamentals are the same for all series or compound machines and the experience obtained and principles involved have been applied to a number of other type machines with success.

The first machine built was for use on 1200 volts reducing down to 600 volts. This machine was run for several months on a very severe cycle, and appeared to be satisfactory in every way, except the capacity was somewhat low for the service to which it was to be applied. This machine will be referred to as No. 1. The next machine designed was for a commercial order, and was for use on 1500 volts reducing down to 750 volts, and will be referred to as No. 2. A large number

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

of flash tests was made on No. 2 dynamotor with the compressor both on and off. The results of these tests gave evidence that a permanent resistance should be placed in series with the dynamotor. A resistance was used and from all tests made seemed to give satisfactory conditions as regards flashing. Unfortunately, however, the very point where the dynamotor was most susceptible to flashing was missed during the flash test in the factory. After being placed in service it was found that the dynamotor flashed when the trolley came off the overhead wire, or was pulled off, and then put on again after the dynamotor had slowed down to a certain speed. In other words, No. 2 dynamotor had a critical flash point, at approximately 75 per cent of maximum speed running light.

The flashing on No. 2 dynamotor was apparently prevented by the use of a pneumatic starting switch. Arrangements were made for starting with a resistance in series and in approximately 4/5 of a second the pneumatic switch was closed, short-circuiting a portion of the resistance, leaving only a small amount permanently in circuit. As was stated above, this arrangement of permanent resistance, starting resistance, and cutout switch apparently worked O. K. on the No. 2 dynamotor, and also on the No. 3 dynamotor which had been developed for 1200-600-volt service. A fourth dynamotor, which will be called No. 4, was then developed for use on 1200-600 volts, but driving a large size compressor. On both previous machines the greatest tendency to flash was found with the dynamotor running light. On the No. 4 dynamotor, however, the heavy current drawn through the starting resistance with compressor on, so lowered the voltage applied to this machine that when this resistance was short-circuited, it was practically the equivalent of throwing line voltage on the dynamotor, thus causing a flashover.

At this point, the flashovers on the No. 4 machines began to be more thoroughly investigated than on any of the preceding dynamotors. As it is our purpose to cover progressively the trouble encountered on this type of machine, we will, at this point, discuss at some length the flashovers.

There is a number of theories concerning the nature of flashing in general, one of which is a rise in voltage as the direct cause, this theory will be discussed more fully later in connection with the oscillographs. A second theory is as follows: If any sparking occurs at the brushes, the gaps between the successive bars as they leave the brush may be bridged by small arcs. If the voltage between the bars is fairly high from any cause, this arc may be maintained until the other brush is reached. This being the case, the successive bridging arcs may form a chain of arcs from one brush to the other, thus giving practically a short circuit and complete flashover. It would seem therefore, from this theory that poor commutation is an entering wedge for a flashover. As will be shown later in connection with the oscillograph, the flashover on this particular type of machine is probably a combination of rise in voltage and low resistance path.

The No. 1, 2, 3, and 4 dynamotors were wound with a compound field, the connection being made as shown in Fig. 1, the shunt and series field coils are on the same magnetic circuit, in fact, at start they form a series transformer. Assuming the normal direction of current in shunt field to be positive, the heavy rush of current through the series coils gives a negative current in the shunt field. This negative current in the shunt, of course, opposes the series field and gives therefore a weak resultant field at start. The heavy armature current in connection with this weak field gives a highly distorted resultant field and consequent sparking at the brushes. This, in connection with the high maximum volts per bar, in all probability starts the flash. It should be noted in connection with the distorting effect of the armature that the ratio of resultant field ampere turns to armature ampere-turns is not constant, being higher at high current, due to the increased magnetizing current required as the iron becomes saturated.

The foregoing does not, however, explain why the dynamotor will flash at or around some critical speed, considerably below normal, but will not flash at standing start or with a comparatively quick opening and closing of the supply circuit. The following explanation is offered: At standing start the current is excessive and gives heavy sparking under the brushes, but the bridging arcs are not carried around at sufficient speed to give a low resistance path and consequent flashover, also as before stated, the ratio of resultant field ampere-turns to armature ampere-turns is a maximum. In other words, the small arcs bridging the bars, due to sparking at one brush, die out before reaching the other brush and by the time the peripheral speed of the commutator has reached a sufficiently high value to carry the arcs around, the sparking at the brush has ceased. When the dynamotor is thrown on the line while running between 25 and 80 per cent of normal speed, the same condition as regards weak field obtains to a certain extent, and therefore to the same extent the distorted field and sparking at brushes. In this case then, the dynamotor is sparking quite freely and at the same time is rotating at a fairly high speed, thus carrying the bridging arcs around from one brush to the other causing a continuous short circuit between bars and flashover. The flashing would seem to be, therefore, a function of the sparking at the brushes and the speed.

As stated before, the concentric shunt and series field winding form in substance a series transformer, the series winding corresponding to the primary and the shunt short-circuited through the low-tension armature, to the low-tension winding, (See Fig. 1). In any transformer the primary ampere-turn may be considered as made up of 2 parts: one element which supplies the magnetizing and core loss current and another element which supplies the working current. The working

current ampere-turns are always practically equal to the secondary ampere-turns. This being true, for every rush of current in the series coils, there will be a corresponding rush in the shunt coil, modified to a certain extent by the damping effect of the magnetic circuit. Everything else being equal, the higher the resistance of the secondary, the higher will be the voltage required to establish the secondary current, this higher voltage meaning in turn a more quickly established flux. In other words, if a variable resistance is placed in series with the secondary of a series transformer, the total flux may be varied directly by changing the resistance. This means simply, of course, that the magnetizing current of a series transformer changes directly with resistance of secondary. It would seem therefore, that in the case of a compound-wound machine, the higher the volts drop per turn of shunt coil, the stronger will be the resultant field at start. A high-volt drop per turn of shunt coil may be obtained in two ways: first, by a high resistance per turn, as before stated, and second, by a low ratio of shunt to series turns. The second method, would, of course, give a heavy current in the shunt field and consequent high-volt drop per turn, so in final effect the two methods are the same. This higher-volt drop per turn would naturally require a higher rate of change in flux and consequently a more quickly established and heavier resultant field. This point will be treated more fully when the oscillographs taken on these machines are discussed.

We will now return to the No. 4 machine. From a consideration of the foregoing points and also from oscillograph tests, the following investigations were made:—The original resistance used on the No. 4 dynamotor was 15 per cent permanent and 85 per cent starting. As before stated, the dynamotor flashed under start when the starting resistance was cut out with the compressor on, but not when it was disconnected. This indicated that too much resistance was cut out by the starting switch, and tests were made to find the best combination of permanent and starting resistance without at the same time making the permanent resistance unduly high. A large number of tests were made using different combinations of resistance and different time elements on the starting switch. It was finally found that approximately one-third permanent and two-thirds starting resistance with a 4/5 sec. time-element switch gave fairly good results. It was, however, decided to make further tests of a different nature to see if it would be possible to make the dynamotor still more safe as regards flashing.

Flash tests were made with the shunt field excited before the line switch was closed, connections being made as shown in Fig. 2. Switch B was closed first and then switch A was closed. Under these conditions very little, if any, resistance was needed to keep the dynamotor from flashing. This arrangement was not considered practicable, however, for various reasons, the chief of which was the automatic closing of switch A.

The next arrangement tried was that shown in Fig. 3. In this case A is the starting resistance, which after a short time is short-circuited by switch B which is operated by compressed air, the air valve being operated by magnet C, which is connected across the permanent resistance D. The shunt field F was connected in parallel with resistance E in series. This would, in effect, increase the volt drop per turn and so give stronger field at start. The method shown in Fig. 3 actually worked somewhat better than the original but was still thought to be too unstable for use on this machine. This method will be referred to later in

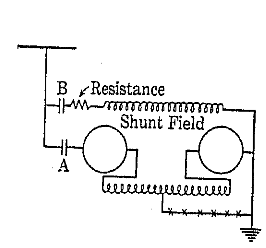

Fig. 2

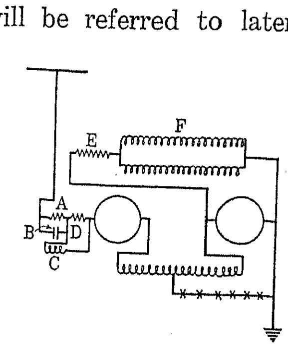

Fig. 3

connection with a machine designed for 1500-600-volt operation.

The next arrangement tried was that shown in Fig. 4. In this arrangement A is a permanent resistance, D is a switch, which not only closes the main circuit but short circuits the resistance B in series with the shunt field. The coil C was used for operating air valves to switch D. At start, therefore, the shunt field is excited before the switch D is closed. The time element of the switch D being about 4/5 sec. The above arrangement failed to work for the following reasons:—When the main circuit was opened to the dynamotor, the switch D failed to operate until the generator voltage on the machine had dropped so low that coil C would not operate the air valves.

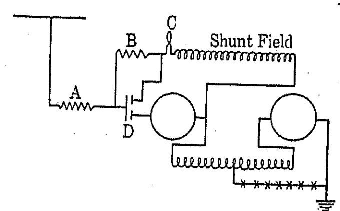

Fig. 4

After trying various other schemes in the hope to eliminate flashing and still hold the same field design, it was considered best to eliminate the shunt field on the No. 4 dynamotor entirely. On the No. 4 machine it was possible to use a straight-series winding as the equipment called for a fan to be mounted on an extended shaft, the fan giving sufficient load to hold the speed down when the dynamotor was not driving the compressor.

As the experience with this type of machine is being

given in a more or less chronological order, it will be necessary at this point to discuss a few of the oscillographs taken. Before going to this part of the subject, however, it should be stated that the flash or buck always occurred on the low-voltage armature. This is due to the fact that the winding for the low-voltage side lies in the bottom of the slot and so has a very much higher reactance voltage.

current rose to between 30 and 40 amperes, at which point the dynamotor bucked and the main current rose further to approximately 50 amperes. The oscillograph also shows that the shunt field reversed and rose to approximately 1.7 amperes. During this period, the voltage across the low-tension armature remained fairly constant up to bucking point, where it starts to fall off, due to the excess current pulled through the

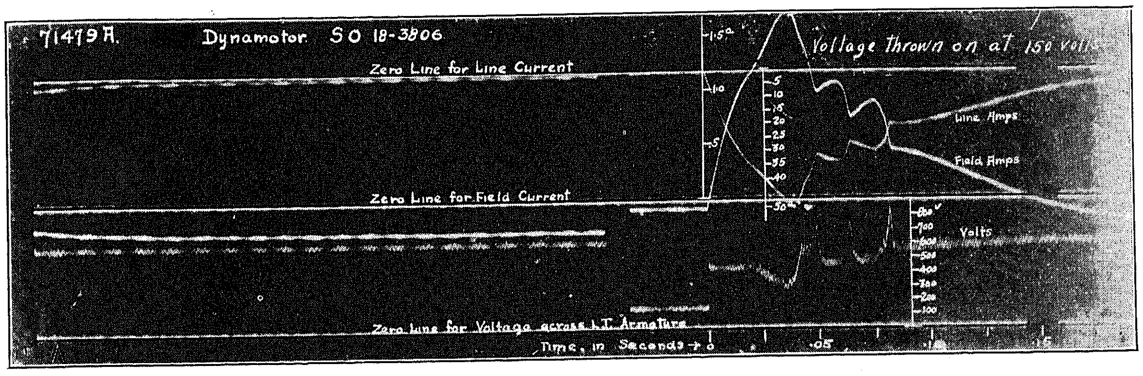

Fig. 5

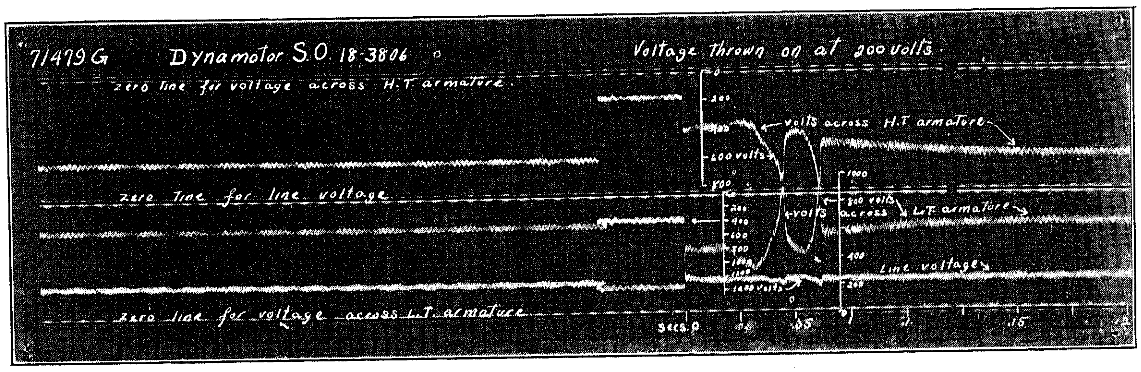

Fig. 6

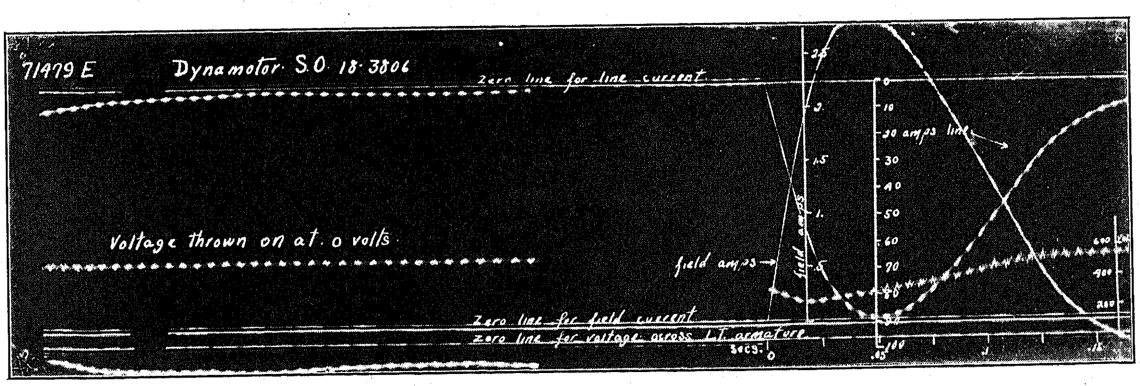

Fig. 7

The first oscillograph tests were made to determine what happened when the machine flashed. Fig. 5 shows the record made on a No. 1 dynamotor. A volt meter was placed across the low-voltage armature and the line switch opened. When the generator voltage had dropped to 150 volts, full-line voltage was thrown on again, the voltage in this case being 1200. There was no resistance in series with the machine, so the main high-tension armature and field, these two, therefore, absorbed more than their share of the line voltage. Up to this point the phenomena is fairly clear, but now the voltage across the low-tension armature starts to rise and reaches a value of approximately 800 volts, when the machine bucks again. This voltage rise is repeated three separate and distinct times, the last indicating the highest rise in voltage.

At first, it might be thought that this rise in voltage on the low-tension armature is due to its high reactance. This may be partly the case, but to a very small extent, as is clearly shown by the oscillograph of voltage on both the high-tension and low-tension armatures. See Fig. 6. This oscillograph shows the line volts as well as the volts across the high and low-voltage armatures. The maximum voltage reached on the low-voltage armature is approximately 900 volts and the maximum on the high-voltage armature is approximately 800, or a total of approximately 1700 volts, in this case 36 per cent rise over line voltage, which is approximately 1250 volts. The machine in this case bucked three times. What may be called the primary buck is due to rise in current and two secondary bucks due apparently to rise in voltage.

If reference is made to the oscillograph shown in Fig. 7, which is a record of the voltage across the low-voltage armature line amperes and shunt-field amperes when 1200 volts are thrown on the machine at standstill, it will be noted that while the main current rises to 89 amperes, twice that shown in Fig. 5, the machine does not buck. It would seem, therefore, that the theory regarding bridging sparks was probably an explanation of the primary bucks. The rise in voltage, which is the apparent cause of secondary buck, is probably due to stored energy in the field which is a result of the excess rush of current due to the primary buck.

Oscillographs were taken on the No. 2, 3 and 4 machines and in general showed the same results as those taken on No. 1.

It will be noted that in all cases the shunt field reverses from its normal direction and thus opposes the series field. As far as can be observed from the oscillographs, for example, Fig. 7, there is no observable time between the start of rise of series-field current and the reversal and rise of shunt-field current.

With the data from the foregoing tests, a method of designing compound-wound machines with given characteristics, which will have the best possible flashing characteristics, was worked out as follows: Assume for the compound-wound machine that the maximum and minimum speed limits are given, the maximum and minimum current, the maximum permissible watt loss in field, and the maximum available space for field winding. The maximum and minimum speed fixes the maximum and minimum ampere-turns with a given saturation curve.

A = Min. ampere-turns total.
I_1 = Max. load current.
I_2 = Min. load current (No load).
T = Turns of series field.
D = Ampere-turns from shunt field.
K = Ratio of max. ampere-turns to min. ampere turns

$$\therefore K A = \text{Max. ampere-turns.} \quad (1)$$

$$A = D + I_2 T \quad (2)$$

$$K A = D + I_1 T \quad (3)$$

Substituting the value for A from No. 2 in No. 3 we have

$$K (D + I_2 T) = D + I_1 T \quad (4)$$

From which

$$T = \frac{K D - D}{I_1 - K I_2} = \frac{D (K - 1)}{I_1 - K I_2} \quad (5)$$

Equation **5** gives T in terms of D as from assumption K, I_1 and I_2 are known.

The value of T so found may be substituted in terms of D in either **2** or **3** and the value of D found at once.

The value of D so found may be substituted in **2** or **3** and the value of T found. It will be noted from equation **5** that T increases directly as K, so the greater the difference between the maximum and minimun ampere-turns, the stronger the series field may be made. There are two ways of making K large, first, a large difference between the maximum and minimum speed, or second, making the machine highly saturated and working well up on the saturation curve at maximum load. As long as $K I_2$ is less than I_1 the shunt field will be accumulative with the series field, but with $K I_2$ equal to or greater than I_1 no shunt field will be required to keep the speed within the required limits. This means simply that the machine would be worked so high on the saturation curve and with so many turns on the series field that no shunt would be required to keep the machine from overspeeding, the saturation on the other hand.holding the speed up on the heavy load. Ordinarily a machine of this type, *i. e.*, with series field only, would mean an abnormal design, if at times it is required to run with no-load current only.

There is now a method of finding the maximum number of turns on series field, also the ampere-turns of shunt, but the minimum number of turns on shunt field is not yet found, and as it is desirable to have the ratio of series to shunt turns a maximum in order, as before explained, to obtain a quickly established field, the next step is to find the minimum number of shunt turns.

The minimum number of shunt turns will be limited by heating considerations only. If a shunt field with a certain number of turns and a certain resistance giving a certain number of ampere-turns is considered, the number of turns may be reduced without materially changing the number of ampere-turns, providing the mean length of turn remains approximately the same. The reason for this, is very evident, for as the number of turns is decreased, the total resistance of shunt field is reduced in the same proportion, and therefore the current is increased sufficiently to keep the value of ampere-turns approximately a constant. The heating, however, will increase, for all the heat in the shunt field is due to amperes squared times resistance, and as the resistance decreases directly, the heat will vary inversely with the number of turns.

Any theoretical method of calculating the minimum

number of shunt turns involves so many variables or assumed values that for practical purposes it is hopeless.

Perhaps the best method for the problem involved is to start with a very high value of amperes per square inch in shunt field copper and then check for heating and space. The amperes per square inch in the shunt coils of some machines designed has been run up as high as 1400 amperes per sq. in. This, of course,

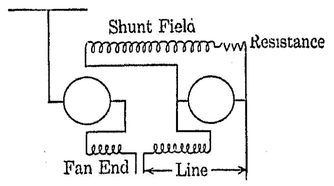

Fig. 8

depends a great deal upon type of machine, shape of coil, etc., and no rule can be given.

A No. 5 machine was designed for use on 1200 volts, driving a fan and using a series field, also a No. 6 designed in the same way, but for use on 1500 volts. The No. 5 machine operated O. K. but the No. 6 gave some little trouble after being placed in service and will be referred to later.

A compound-wound machine was now designed along the lines given and will be referred to as No. 7. The No. 7 machine was intended to replace the No. 3 machine which was not entirely satisfactory as regards flashing characteristics. The result obtained was highly satisfactory, and it was evident that a compound-wound motor could be designed to start at full voltage at any point and without having abnormal proportions. The No. 7 machine had exactly the same design as the No. 3, except for change in field and shape of air-gap. The beneficial results were practically all obtained from the changed field as the No. 3 machine was equipped with a new field and had as good flashing characteristics as the No. 7 machine. Flash tests were made on the No. 7 machine, using the connections as shown in Fig. 8. From previous discussions the object of the resistance in the shunt field will be understood. In a given machine, the introduction of outside resistance in the shunt field may or may not be beneficial as regards flashing. This will be referred to under the discussion of a later machine. The highest voltage which the machine would stand at all points was 750 on low-tension commutator. Flash tests were made on the low-tension winding because, as before stated, the inductance of this winding is much higher than the high-tension. Regular flash tests were made with both windings in series, but with no resistance in series with armature or in shunt field and 1200 volts was applied at all speeds and under all conditions, that is, with compressor on or off, or lighting load on or off, with very good results. Flash tests were also made with resistance in series with armature but no resistance in shunt field. Under these conditions 1500 volts were applied without flashing the machine.

In order to make reasonably sure that the No. 7 machine would operate satisfactorily in service, a full car equipment was mounted on a fly-wheel test, and the control, main motors, and dynamotor compressor run for some time on 1350-volt cycle test. In connection with this cycle test, mention should be made of a rather unexpected source of trouble under service conditions. When a car or locomotive crosses a section break or when the trolley for any reason looses and makes contact while the control is on, the following conditions exist with a compound-wound dynamotor. First, the dynamotor, if the compressor is not on, keeps on rotating and acts as a generator supplying current to the main motor, thus tending to drive the car; second, when the trolley comes in contact with the supply wire again the current is quickly reversed. The strain on the machine is very heavy under the first or second conditions and either may cause a flash. Tests were made on the No. 7 machine, mounted with main motors and control, to determine whether it would stand such service. On these tests the machine gave no evidence of flashing even on 1350 volts with a very heavy generating plant. Oscillographs were taken on the No. 7 machine and are shown in Figs. 9, 10 and 11.

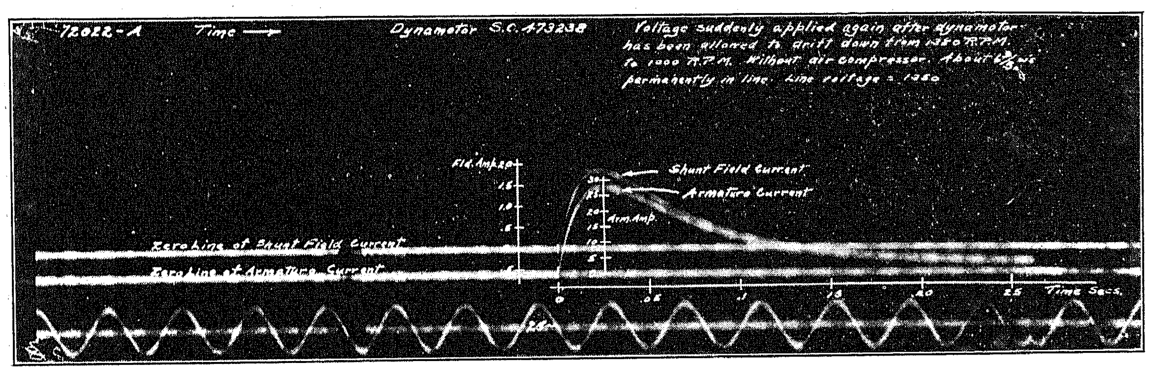

Fig. 9

The oscillograph shown in Fig. 9 was taken at the time 1350 volts were applied after the machine had drifted down to approximately 75 per cent of maximum speed, running light. Taking values from this oscillograph, the resultant ampere-turns are calculated and

plotted against time, as Curve 1 in Fig. 12. The ratio of resultant field ampere-turns per pole to armature ampere-turns per pole are also plotted against time, giving Curve 1 in Fig. 13.

The oscillograph shown in Fig. 10 was taken at the time 1350 volts were suddenly applied to machine at standstill with compressor cut in, and the oscillograph shown in Fig. 11 was taken under the same conditions, except that the compressor was not cut in.

It will be noticed that the main and shunt-field current reaches approximately the same maximum value with compressor either on or off. The maximum value of current, however, with compressor off is reached in a little shorter time than with compressor on.

From the oscillograph as shown in Fig. 11, the same values were calculated as for the oscillograph of Fig. 9 and plotted as curves 2 in Fig. 12 and 13 respectively, in order to obtain a comparison between a standing start and a start at 75 per cent of maximum speed. The resultant ampere-turns are in both cases comparatively low at 1/100 sec., after which they rise rapidly until they reach a fairly constant value, which, of course, gradually falls back to normal. The resultant turns in the case of a standing start are very much higher than is the case with the running start, but the ratio of the resultant field ampere-turns to armature ampere-turns are not greatly different in the two cases.

Considering the values shown in Fig. 12 alone would indicate that the flashing characteristics at standing start would be better than at running start, however, the current commutated at standing start is much higher than at running start, which would offset the advantages to a certain extent. The values of current are therefore plotted against time in Fig. 13 in order to show the magnitude of starting current in each case, when plotted to the same scale. Curve 4, Fig. 13 shows current for running start on machine No. 7 and Curve

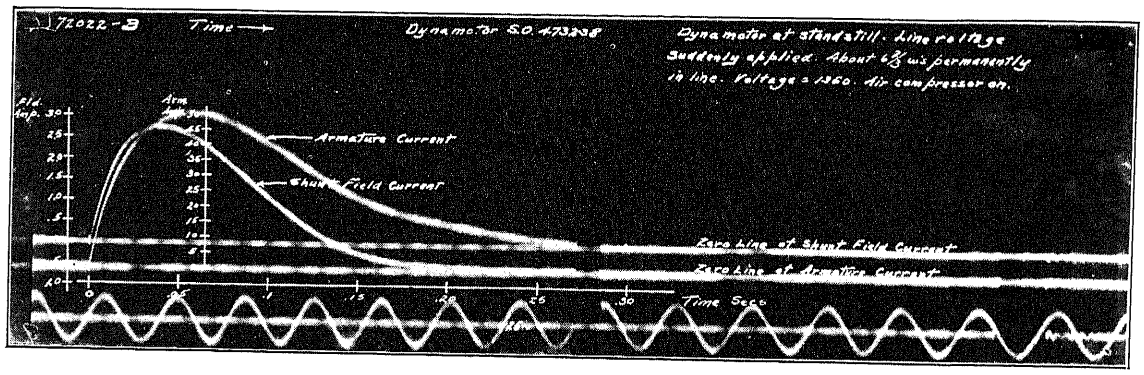

Fig. 10

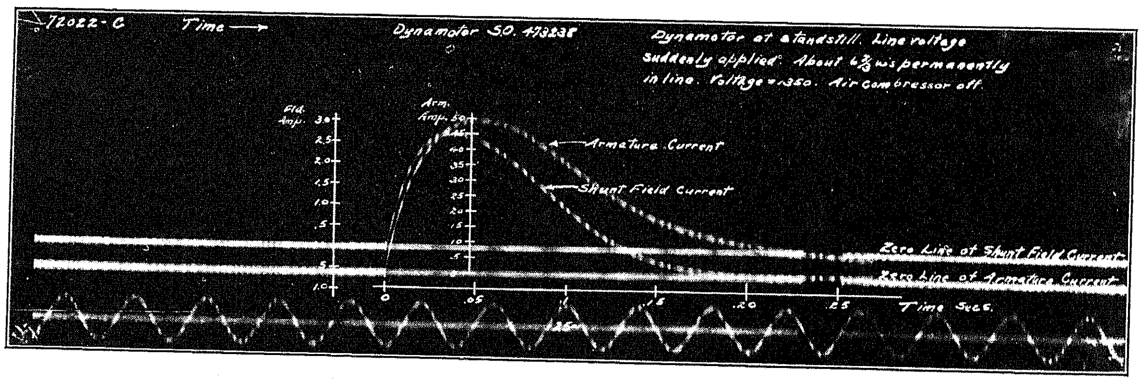

Fig. 11

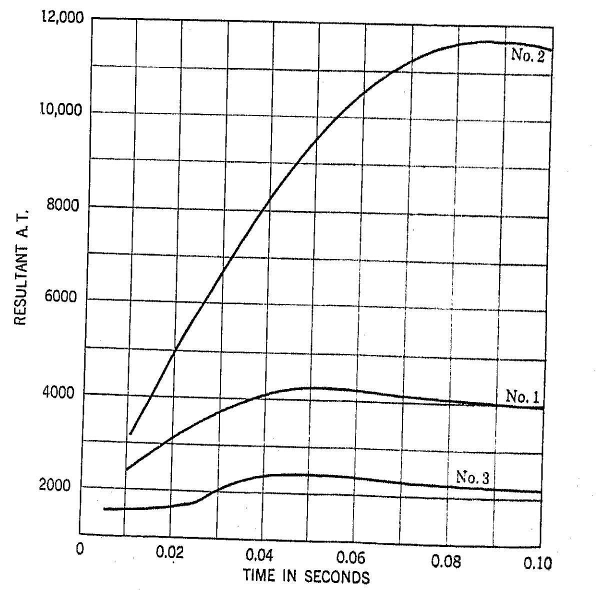

Fig. 12—Resultant Ampere Turns

5 for standing start. Much higher resultant ampere-turns in the case of standing start, even with the same ratio of field to armature ampere-turns as at running start, gives a better field form and consequent lower maximum volts per bar, thus reducing the tendency for bridging arcs before referred to in this paper.

In connection with the No. 7 machine, mention will be made of a specially designed dynamotor and tests on same. As brought out in the previous discussion, the shunt and series field on the same magnetic circuit

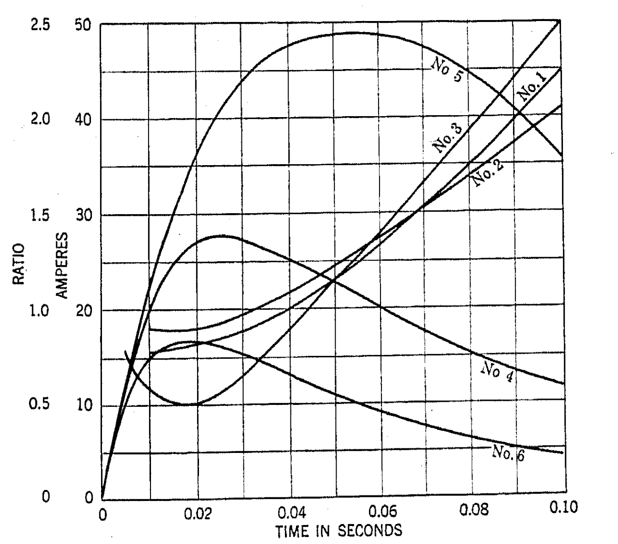

FIG. 13—RATIO OF RESULTANT FIELD AMPERE TURNS TO ARMATURE AMPERE-TURNS AND CURRENT IN ARMATURE

form in fact a series transformer, the shunt bucking the series at start. An obvious theoretical solution of this difficulty is to place the shunt and series field on a separate magnetic circuit, but practically this solution is rather hard to apply. One method of splitting up the magnetic circuit is shown in Fig. 14. The trouble with a design such as shown in Fig. 14 is that the machine would be quite bulky. A second method would be, considering a four-pole machine, to place the shunt coils on two-poles, a north and a south, and the series coils on the other two poles. A third method is to place series coils on all four poles and shunt coils on only two poles. The series coils which are in combination with the shunt coils are to be of a fewer number of turns than those on the other pair of poles. This last method has the advantage of permitting the fields to be so designed that they are magnetically balanced under the most prevalent load conditions.

In order to test the advantages as regards flashing of this third method, the shunt coils were cut out on two poles of a No. 7 machine. With this arrangement of field, the machine stood 1300 volts under all conditions which was materially better than with the regular field. This better-flash voltage, however, might have been due to the fewer total number of shunt turns. The effect of fewer shunt turns and higher drop per turn has been discussed previously. The results obtained on this preliminary test were considered sufficiently good to warrant designing special field coils for further tests. The special coils were wound with a comparatively large number of series turns on the straight series coils and the remaining necessary series turns placed on the compound coil. Sufficient shunt ampere-turns were used to keep the maximum speed down to approximately what it was on the regular machine.

On flash tests this machine which will be called No. 7-*A* commutated very well at all running starts, but at standing start flashed to ground at a little over 1200 volts, or in other words, the regular No. 7 machine was better at standing start than the No. 7-*A*. The No. 7-*A* machine was different from all the other compound-wound machines, in that it had better flashing characteristics at running start than at standing start. The reason for this was not understood just at this time, but tests of later machines gave an explanation and solution and will be referred to later.

At about this time a dynamotor which will be called No. 8 was developed for use on 1500-600 volts, that is, with 900 volts on one commutator and 600 on the other. The winding lying in top of slot was made the high-voltage winding, as the commutation volts for a given number of turns are lower on the top winding than on the bottom winding. The compound-wound field was designed in the best possible proportions, using an external resistance in series with the shunt to give a more quickly established and stronger resultant field, as will be understood from the previous discussion. Flash tests were made on the No. 8 machine but the

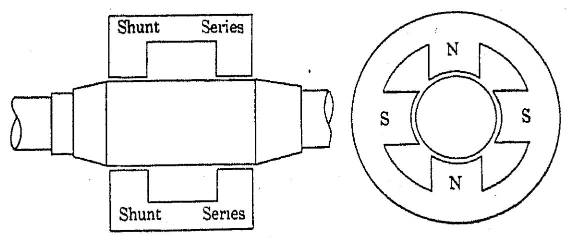

FIG. 14

results were not as good as expected, due probably to the reduced total number of commutator bars. However, with an additional series resistance over that estimated, the machine was considered safe.

A question had been raised as to the effect the so-called "lighting load" has on the flashing characteristics of a given machine, so to settle this question oscillographs shown in Figs. 15 and 16 were taken. The connections of dynamotor and oscillograph resistance are shown in Fig. 15.

The oscillograph of Fig. 15 shows the current A of high-tension winding, current B of lighting load, current C of low-tension winding. As shown by this oscillograph, the lighting load current rises at once to approximately full value and is not affected by the heavy rush of current in the dynamotor. At any given time the sum of the current in B and C should equal the current in A.

explained as follows: On all previous machines the flashovers had all occurred on the low-voltage commutator, but on the No. 8, due to the 900 volts on high-voltage commutator, the flashover seemed as likely to occur on the high-voltage as on the low-voltage commutator. On ordinary tests, but with lighting load, the high-voltage commutator commutates more current by the amount of the lighting load, and in the same

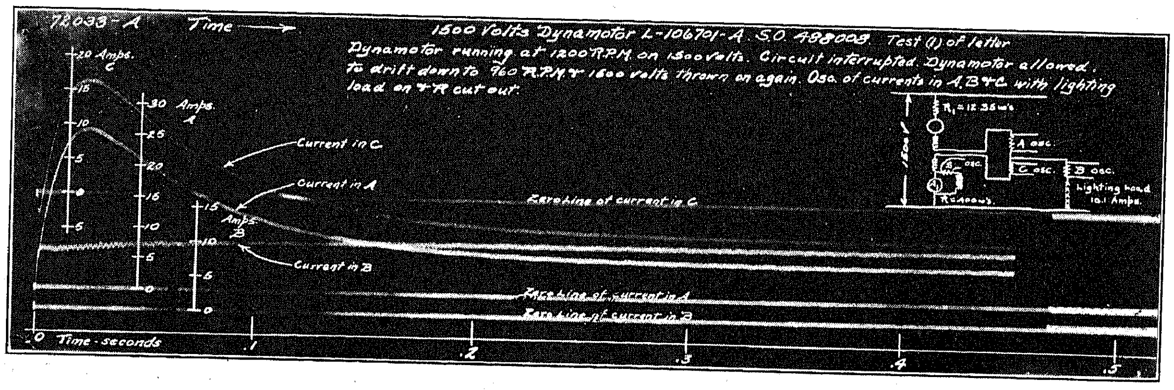

Fig. 15

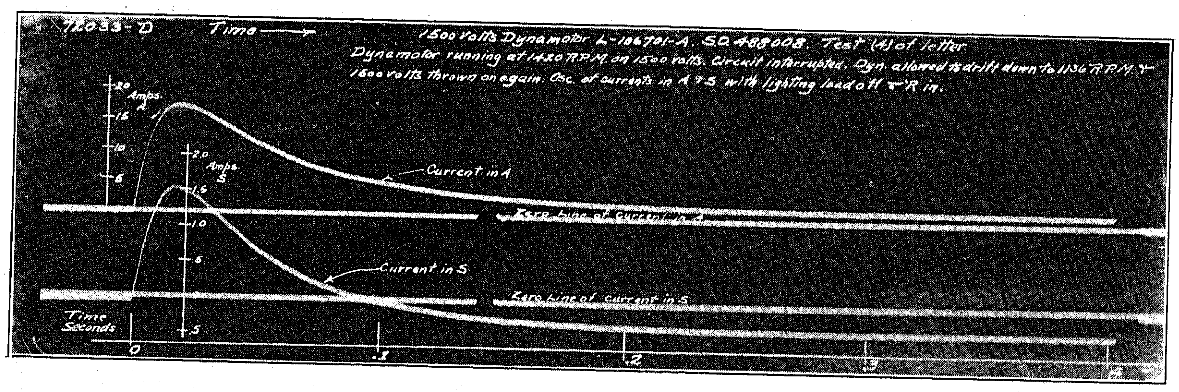

Fig. 16

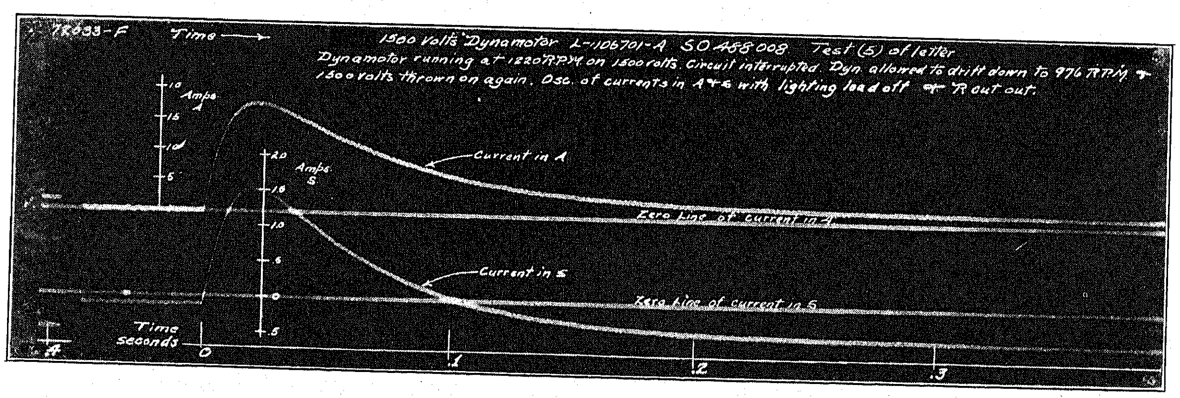

Fig. 17

Flash tests were made on the No. 8 machine at 1500 volts without lighting load and without resistance in shunt with satisfactory results. However, under the same conditions but with lighting load on, the machine flashed over on high-voltage side. The same tests as above were made with resistance in shunt with the same result. The greater susceptibility of the No. 8 machine for flashing with lighting load on may probably be

proportion lowers the flash voltage on the machine over that without lighting load.

The oscillographs shown in Figs. 16 and 17 were taken to show the effect of the external shunt resistance R. These two oscillographs show very little, if any, difference in either the maximum value of the current or shape of current wave. As a matter of fact, the use of external resistance in the shunt does not in itself better

the flashing characteristics of a given machine, but does permit the design of the shunt field with comparatively few turns without overheating. It was actually found on test that in most cases the insertion of resistance in shunt field of dynamotor, while running light, made the flashing characteristics worse. When the machine was driving a blower, however, the insertion of resistance in shunt field made the flashing gradually better, until after reaching a high point with the resistance the flashing was eliminated. These two results on the face of the matter may seem contradictory, but the following is a possible explanation. With no resistance in shunt and while running light the dynamotor speed is say, 1300. As resistance is placed in the shunt the speed runs up. Now it is found on test that the worst flashing on any particular machine is at a speed which is some certain per cent of maximum speed, say, *i. e.*, 80 per cent.

The shunt field is active as long as the armature is rotating so the counter e. m. f. dies out gradually. The highest current rush may be at standing start but the flashing is a function of the current commutated and the speed. Therefore, if at a speed of 1300, the counter e. m. f., per armature is 600, then at 80 per cent of 1300 or 1040 rev. per min. the counter e. m. f. is 480, and the current rush would reach a certain value say, 40 amperes. Now, when resistance is placed in shunt field the speed runs up to say, 1600 rev. per min., at 80 per cent of 1600 or 1280 rev. per min. the counter e. m. f. is again 480 and the current rush would again be 40 amperes or more. It is readily seen, therefore, that the machine is commutating 40 amperes at 1040 rev. per min. in one case and 40 amperes at 1280 rev. per min. in the other and would naturally expect worse flashing. If, however, the speed is held down by the series field when machine is loaded by the fan, the speed will not run up very much when resistance is placed in the shunt. As explained in another place, the resistance in shunt will help, providing it is not more than offset by high speed which would be the case where the machine was running light.

From oscillograph of Fig. 16 the resultant field ampere-turns and ratio of resultant field ampere-turns to armature ampere-turns were calculated and the results plotted against time, giving Curve 3 of Fig. 12 and Curve 3 of Fig. 13. The value of current is also plotted against time as Curve 6 in Fig. 13. In comparison to the same curves from the No. 7 machine, it will be noticed while the ratio of field to armature ampere-turns is much lower on No. 8 machine for running start, the current commutated is also much lower. Results similar to the above are not shown for any machine except the No. 7 and No. 8, as the oscillographs of preceding machines were not taken in just the same way, so comparison would show nothing.

All the No. 2 machines had been placed in service with compound field even though some were driving a fan and could therefore be operated with a series field. After these machines had been out for some time it was decided to equip one with a series field. This will be called the No. 9 machine. The series field was designed with a very large number of turns and the dynamotor was thus expected to have fine flashing characteristics, but when placed on test was found to flash at standing start at normal voltage, as had been the case with the No. 7-*A* machine. At all running starts the machine did not flash. The nature of the flashover did not seem to be the same as with the compound-wound machine, not being nearly so vicious. Apparently this flashover was due to the quickly established field, this field giving rise to high voltage between bars, due to transformer effect, which in combination with heavy starting current caused the flash. Evidently therefore, a certain amount of damping effect was desirable on this machine and in order to determine as nearly as possible the proper amount, a compound-wound field was used and resistance placed in shunt field in increasing amount until a point was found where the dynamotor did not flash, at either running or standing start. A copper damper of equivalent damping effect to the shunt field was made up and placed on the series-wound No. 9 dynamotor. The results on flash tests with this arrangement were very fine indeed, the dynamotor starting without any resistance in series with armature, at all speeds and under all conditions without signs of flashing.

The above results would seem to indicate that the flashover voltage at standing start of a series machine such as railway motors might be raised by the use of a damper. However, on railway motors high-flash voltage at running start is most essential and any damping effect apparently lowers the flashover voltage.

The No. 7-*A* machine will be referred to again in connection with the tests made on copper dampers in the above. After the results obtained on the No. 9 dynamotor by the use of dampers, the two series coils of the No. 7-*A* machine were assembled with similar dampers. On flash tests the No. 7-*A* machine equipped with dampers gave very much better results than it did without dampers, but at 1300 volts flashed from high voltage brush holder on low voltage commutator to ground. At all running starts the dynamotor gave no signs of flashing. From this it was evident that a heavier damper would give better results. A heavier damper was not tried but the brush holder which flashed to ground was insulated by taping with treated cloth, and when this was done the machine stood 1425 volts at all speeds and under all conditions without a flash.

It should be noted that unless otherwise stated all flash tests are made without external resistance in series with the armature.

It has previously been stated that further reference would be made to the No. 6 dynamotor. After being in service it was reported that this machine would flashover under some conditions at standing start. Copper dampers similar to those used on the No. 9 dynamotor

were made up and placed on the No. 6 machine. After these were installed the flashing was entirely eliminated on this machine and demonstrated thoroughly the decided benefit obtained from the damper.

The No. 4 and No. 5 machines were both series-wound but the fields were not of sufficient strength to require dampers, which shows that dampers might not in all cases prove beneficial.

After the No. 8 machine had been in service a short time, it was found that at certain points on the line and under certain conditions the dynamotor would flash on the high-voltage side. The flashing was most prevalent at the point where the 1500-volt line crossed a 1200-volt line, which involved as a matter of protection two grounded sections. A short description of the tests which located the point of trouble may be of interest. A car was equipped with a No. 8 dynamotor and variable resistance connected in series. Flash tests were made by running over dead sections and making and breaking contact with the trolley at short intervals. These tests were made with a high resistance in series with dynamotor and continued with resistance down to a fairly low value, but at no time did dynamotor flash over. The car was then run over the above-mentioned crossover which involves the following sequence: First from 1500-volt trolley to dead section, then to grounded section, then to second dead section, then to 1200-volt trolley for a distance of approximately 18 in., then back over the dead and grounded section to the 1500-volt trolley. Each of the grounded and dead sections was approximately two ft. long.

The car was first run over the crossover at a speed of 15 to 25 mi. per hr. with the series resistance at a low value, under all conditions of operation, but at no time did a flashover occur. The car speed was then reduced to approximately six mi. per hr. with the same results. It was found, however, that when running at an approximate speed of 10 mi. per hr. even with a high resistance in series that the dynamotor would flash nearly every time the car passed the crossover. The flashover appeared to occur at the time the trolley made contact with the second grounded section after passing over the 1200-volt trolley.

The above details of tests are given to show the severe service sometimes met and also the difficulties of locating the exact point of trouble. The effect on the dynamotor of the sequence of dead and grounded sections will be understood by the oscillograph on the No. 7 machine. Of course, with the ground switch to grounded section open and the control off no flash occurred at the crossover. It was decided to apply a remedy which has been mentioned in connection with tests on the compound-wound No. 4 machine, that is; to connect the shunt field in two parallel circuits and place resistance in series to keep it from overheating. When this was done the flashing on the No. 8 machine was entirely eliminated. The effect of the parallel shunt field will be understood from the discussion on the effect of number of turns in shunt and also from Figs. 1 and 3. In Fig. 1 where the shunt is connected all in series, the total transformer volts induced by rush of current in series field will be twice as great as in Fig. 3. The resistance of each parallel circuit in Fig. 3 is one half the total of Fig. 1, but in addition, the external resistance is added which cuts down the opposing current of shunt on start but permits the running strength to remain the same.

The last dynamotors designed were the No. 10 and No. 10-*A* for use on 1500-750 volts, and were intended to replace the No. 2 machine in the standard line. All refinements of design were incorporated in the No. 10 machine, and in addition, a larger number of commutator bars were used then on the No. 2 machine. The results as expected were very good, flash tests being made at 1800 volts with only a comparatively small resistance in series.

In conclusion, therefore, it can be said that a compound or series-wound machine can be designed which will give little trouble from flashing though subjected to the most severe operating conditions, if the following points are observed:

(1) Certain reasonable physical limits which have not been touched on in this article must be maintained, such as number of commutator bars, distance between brushholders and total thickness of mica between brushholders.

(2) Strong field in comparison to armature.

(3) High ratio of series-field turns to shunt-field turns. This may be accomplished in two ways with a given difference between maximum and full-load speed.

(a) By working motor well up on the saturation curve.

(b) By working shunt at a high volt drop per turn, accomplished by either using a high value of amperes per sq. in. in shunt field if heating permits, or with external resistance in series.

(4) For series-wound machines it may be found in some cases that a damper is required to prevent flashing at standing start.

(5) For some types of machines a divided magnetic circuit for shunt and series winding may be used with good results.

A 35,000-Kw. Induction Frequency Converter

Description, Operating Characteristics and Test Data

BY O. E. SHIRLEY
Associate, A. I. E. E.
General Electric Co., Schenectady, N. Y.

Review of the Subject.—The application of the induction frequency converter is not new, but its use for connecting together very large systems had not been undertaken until the machines described in this paper were put in operation.

This paper describes the rating and mechanical construction of the two units, with special attention to the induction machine.

The testing of the machines was done after installation, and the results of these tests are given.

The theory of the operation of the induction unit is developed, being simplified by neglecting losses and resistance, thus avoiding complicated equations, but securing results agreeing quite closely with the more accurate calculations.

The behavior of the set under short circuits is discussed.

THE rapid extension of the idea of interconnection of power systems has resulted in a greatly increased use of frequency converters as a tie between lines of different frequencies, and has led to a corresponding increase in size of the individual units until to-day there are installations capable of transferring 35,000 kw. from one system to another.

The type of frequency converter most frequently used up to the present time consists of two direct-connected synchronous machines, and acts simply as a power tie between the systems. The power transfer is directly dependent on the governing characteristics of the prime movers of the generating units, up to the load at which one of the converter units pulls out of synchronism. The voltage regulation of one system is entirely unaffected by that of the other system as long as the power transfer is not changed. A voltage disturbance on either system, which is not severe enough to drop one of the converter units out of step, has practically no effect on the other unit or its system. In case one unit loses synchronism, the load transfer will decrease to a low value and its current will fluctuate widely. The other unit will operate at the reduced load as a synchronous machine. The voltage on the undisturbed system will remain at almost exactly its normal value.

This characteristic of the synchronous frequency converter is desirable in many installations, but there may be operating conditions where it would be desirable to have the voltage of both systems affected similarly by a disturbance on either. In case of sectionalized systems of the same frequency, a tie through reactors, transformers, tie-lines, or combinations of these methods tends to equalize the voltage on the various sections.

With systems of different frequency the voltage equalization may be obtained by the use of an induction frequency converter set, consisting of an induction machine direct-connected to a synchronous machine. This type of set has been used in a few cases, and a number of high-frequency generators direct-connected to induction motors instead of synchronous machines, has been built in small sizes. The theory of these sets is not new, and has been given in several books and other publications. However, the construction of machines of sufficient size to operate successfully between very large metropolitan systems is a new application and this paper is being written to give the general theory, application and test data of such a set.

An induction frequency converter was selected for the New York systems from the following considerations.

1. It is reversible and may be used to supply power either from 25 to 60 cycles or from 60 to 25 cycles. It is therefore practically the equivalent of a spare unit for both systems.

2. When operating between the systems, it will tend to supply reactive kilovolt amperes to either of them whenever the voltage of that system drops below normal. It will therefore tend to hold up the voltage of the disturbed system, although at the expense of transmitting some disturbance through to the other. Its use however, is analogous to the interconnecting of stations of the same frequency, which in general is considered good practise.

3. In the operation of synchronous converters, it is desirable to parallel at the source of a-c. supply, if the d-c. ends are to be connected to a common bus. Where one generating station supplies all the power, the feed for the converters is taken from a common bus or from several sections of bus connected together through suitable reactors. When more than one station of common frequency supplies power, the several stations are connected through suitable tie-lines. Where stations of different frequencies supply power, all stations of a common frequency are paralleled through suitable tie-lines, and the two systems of different frequency are tied through the induction synchronous frequency changer set. Improved parallel operation of converters has been obtained by this scheme of operation as applied to individual systems, and it follows that similar results can be obtained through a frequency converter which forms a voltage as well as a power connection.

The induction machine of the New York set is of considerable interest on account of the mechanical and

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

electrical problems encountered in its design and construction, and a complete account of these features is given. The synchronous unit is one of the larger salient pole units of its class, but it does not have any very unusual features and, therefore, its design and characteristics are given only as they affect the operation of the set. A few illustrations are included to show the general construction details.

Rating

The frequency converter is designed for normal output of 35,000-kw. three-phase at unity power factor at either 25 or 60 cycles, and at 1.0 power-factor input from

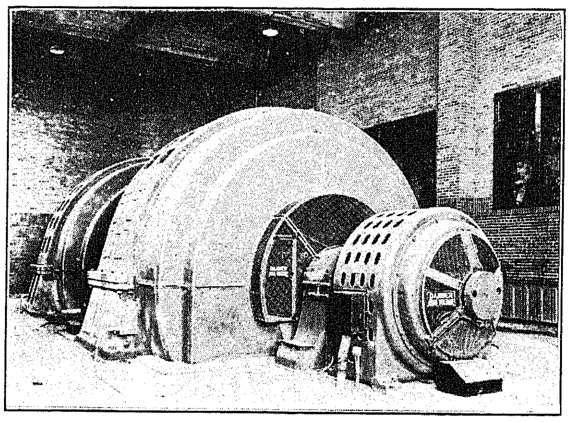

Fig. 1—Completed Installation of the 35,000-kw. Frequency Converter

the system of the other frequency. This input is slightly under 37,000-kv-a. and the 60-cycle induction unit has a nameplate rating of this kv-a. input as a motor. The normal rating of the set is for power transfer from 60 to 25 cycle, that is, normally the induction machine is a motor and the synchronous machine a generator. The 60-cycle voltage rating is 13,800 volts, and the 25-cycle 11,400 volts.

The induction machine has 14 poles. When operating at 300 rev. per min. the rotor revolves at a frequency corresponding to 35 cycles. If the rotor is then excited from the 25-cycle system with the phase rotation corresponding to the rotation of the rotor, the resultant frequency generated in the stator is 60 cycles.

The voltage generated in the rotor corresponding to the rated voltage of the stator is 2730 volts, but due to the fact that the excitation must be supplied through the rotor, it is necessary to raise the voltage applied to the rotor to overcome the reactance drop, due to the magnetizing current. The actual impressed voltage on the rotor to produce rated open-circuit voltage on the stator is approximately 2800 volts.

The rotor is connected to the 25-cycle bus and to the stator of the synchronous unit through a 17,100-kv-a. 3-phase 25-cycle air-blast transformer with taps in the primary to give either 2950 volts or 2850 volts on the secondary side. These taps permit variation of voltage ratio to control the power-factor of the induction unit for different operating conditions.

The mechanical output of the induction rotor through the shaft to the synchronous unit is approximately 35/60 of 36,000 kw. or 21,000 kw., and the electrical output to the transformer is approximately 25/60 of 36,000 kw. or 15,000 kw. The difference between the 37,000 kw. input and the 36,000 kw. output of the induction unit represented approximately the losses in this machine. The output of the transformer is approximately 14,600 kw., there being about 400 kw. required for transformer loss and input to the blower motor. The output of the synchronous machine is approximately 20,400 kw., with between 500 and 600 kw. loss in this unit. The magnetizing current of the induction unit must be supplied through the rotor to maintain unity power-factor on the stator, and the synchronous machine is rated 25,000 kv-a. 0.85 power-factor to furnish reactive kv-a. for this magnetizing current.

Starting of the set is accomplished by the use of a 1600 h. p. 3-phase 25-cycle 11,400-volts induction-starting motor with wound secondary for speed control by external resistance. The synchronous speed of this motor is 375 rev. per min., so that exact synchronous speed of the set can be obtained. The motor is of sufficient capacity to start the set and bring it into synchronism with both units excited for norm alvoltage.

A 115-kw. 250-volt exciter is direct-connected to the 25-cycle end of the set to furnish excitation for this unit.

Two 225-h. p. 3-phase 25-cycle induction motors are provided for direct connection to a blower which supplies ventilating air to the induction unit and air blast trans-

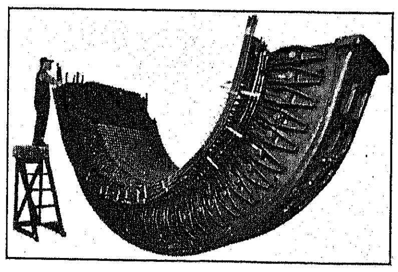

Fig. 2—Upper Half of Stator of 25,000-Kv-a. 25-Cycle, 3-Phase, 11,400-Volt A-C. Generator

former. The motors may be tied solidly into the low-tension side of the transformers, and the fan is therefore sure to start up as soon as the voltage is brought up on the induction unit and transformer. Only one motor is connected to the power supply at a time, the other being a spare unit.

Mechanical Design of Synchronous Unit

The stator of this machine is of standard construction for this class of apparatus and an extended description is not necessary. Fig. 2 is an illustration of the upper half of this stator and shows the double-layer type

winding, binding of the ends of the coils as well as other general details of its construction.

The rotor (Fig. 3) has laminated poles secured to the spider by a number of dovetails. The spider is made up of steel plates riveted together to give a very substantial structure of a material that is practically free from defects. The amortisseur winding consists of brass bars silver soldered to copper end segments, and the segments in turn are bolted securely to solid steel end rings. These rings were cut from solid plates and therefore have no joints. Shrouded fans attached to the rotor spider at each end just below the bottom of the pole add materially to the fan effect of the rotor for supplying air to ventilate the machine.

Mechanical Design of the Induction Unit

Stator. The stator is very similar in mechanical design to the synchronous machine stator, and to many other machines of its class.

It was built in two sections to facilitate shipment.

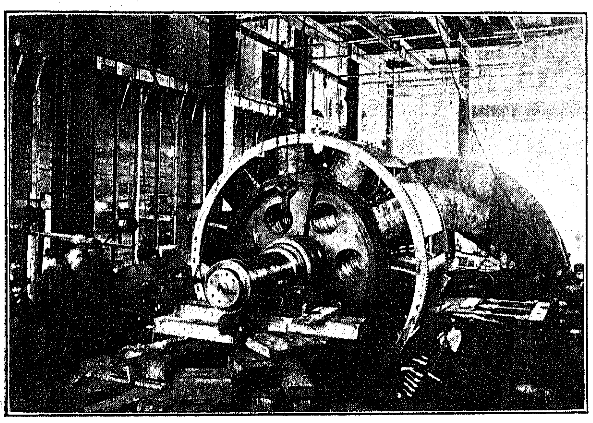

Fig. 3—Rotor of 25,000-Kv-a. 25-Cycle, 3-Phase 11,400, Volt A-C. Generator

The core is made up of laminations of high grade silicon steel. They are held in the frame by dovetail keys and cast steel end clamping flanges. These flanges are secured by bolts extending entirely through the stator frame. The stator slots are open, the formed and insulated coils being held in place by wooden wedges. The assembled coils are securely laced to three binding bands at each end of the stator. The stator coils, clamping flanges and lacing of the coils are very similar to these features of the synchronous unit as shown in Fig. 2.

The use of high grade steel in the core and liberal design with respect to copper results in low operating temperature and good efficiency.

Rotor. The rotor of this unit is the largest of its kind that has been built and it presented a number of very difficult problems in design.

It had to be designed to stand in emergency a run away speed of 514 rev. per min. as it is an induction machine and in case of short circuit on the 25-cycle system it would immediately start to accelerate toward this speed. However, on account of the size of these units, it was deemed desirable as an additional precaution to provide speed-limiting devices, which will trip the 60-cycle line switches at about 15 per cent over speed.

The rotor spider (Fig. 4) consists of two wheels

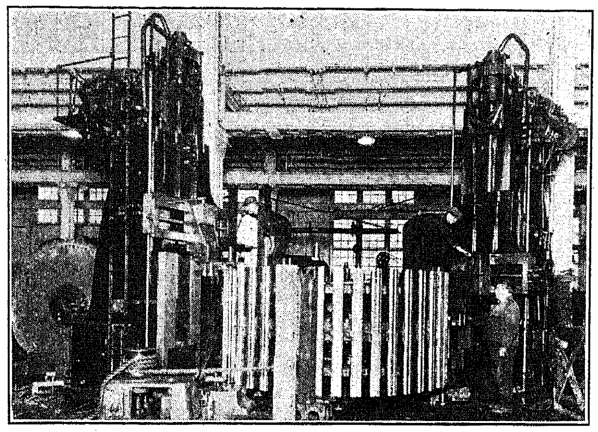

Fig. 4—Machining Rotor Spider of 37,000-Kv-a. 60/25-Cycle 3-Phase, 13,800/2700-Volt Induction Frequency Converter

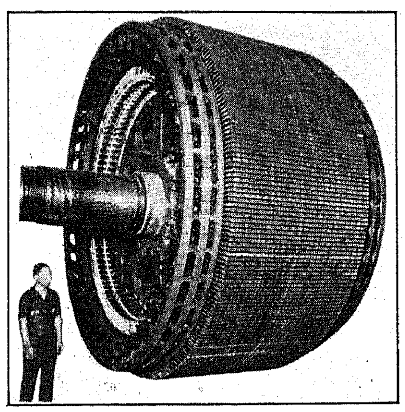

Fig. 5—Rotor of 37,000-Kv-a. Induction Frequency Converter Ready for Winding

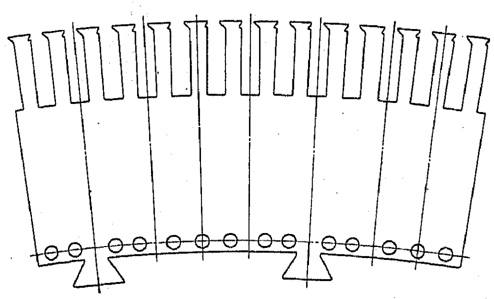

Fig. 6—Lamination for Rotor Core of 37,000-Kv-a. Induction Frequency Converter

bolted in the middle of the rotor. Each wheel has a set of arms at both ends, making a total of four sets of arms for this rotor.

The laminations (Fig. 6) are attached to the spider by dove tails and are also held together by steel pins driven through the completed assembly of the laminations. These pins are located as near as possible to the bottom

of the punchings, to avoid losses and heating. The laminations were made by a blanking die and the slots indexed later. They are indexed to give four different kinds of punchings, and in stacking they are arranged to overlap at the joints, giving three laminations crossing the joint for each break between laminations. The whole rotor is then tied together by the steel pins, so that the strength with the holding effect of the dovetails, pins and friction of the tightly clamped punchings approaches that of a complete circle of laminations. The core is clamped together by steel ring-type end flanges drawn up against the ends of the rotor spider by bolts extending entirely through the spider. The end flanges are of cast steel and each is formed of three rings tied together by cross webs. The two outer rings of each flange are sectionalized to prevent losses and local heating due to magnetic flux leakage. The core has radial air ducts opposite the stator ducts for ventilation. Fig. 5 is an illustration of the rotor ready for winding and shows the general details of its assembly. The sectionalizing of the rotor flanges is very well illustrated by this figure.

The stator slots are open, and it was considered advisable to use partially closed slots for the rotor, to avoid excessive tooth losses. Fig. 7 is a cross section

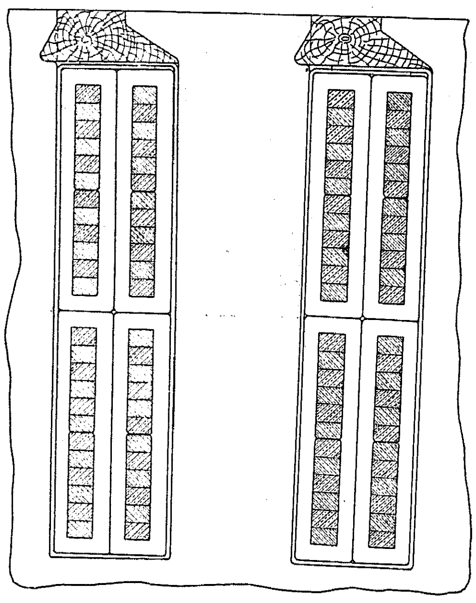

Fig. 7—Cross Section of Rotor Slot of Induction Frequency Converter

of the rotor slot, showing the overhanging tooth and the general arrangement of the coils. These coils are of the double-layer type similar to those in the stators of both units, but had to be made in pairs, each coil about equal in width to one half of the slot width. One coil of a pair was put into the slot and pushed over under the overhanging tip, after which its mate was assembled as it would be with an open slot.

The method of winding and also the fact that collector rings and brushes must be used to connect the winding to the system made it impractical to use full bus potential on the rotor. A stepdown transformer was consequently used, and incidentally gave a convenient and practical way of adjusting voltage for various conditions.

The rotor conductors are made up of several cotton-insulated strands, the individual turns being taped with mica tape. The external insulation consists of several tapings of mica tape with a protective cotton taping filled with insulating varnish. This insulation was

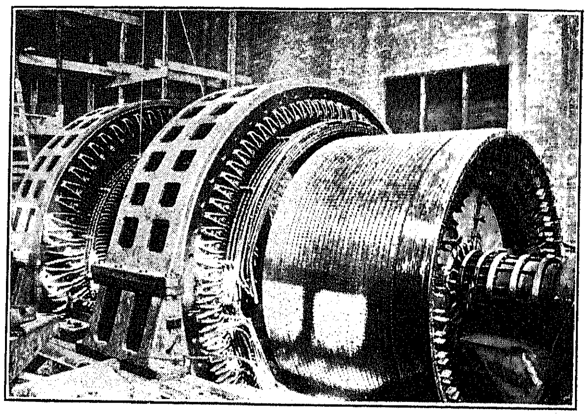

Fig. 8—Assembly of 35,000-Kw. Frequency Converter Set with Stator of Induction Unit Moved over to Clear Rotor

selected on account of its mechanical strength under compression, which is necessary to resist the centrifugal forces to which the coils are subjected.

The ends of the coils required very strong binding bands to prevent distortion due to the rotational forces. The total weight of binding wire is about 2400 pounds. Due to the proximity of conductors with heavy currents, special precautions were taken to keep down the losses and heating in these bands. The layers are insulated from each other by mica separators, and the various layers are sectionalized into small insulated sections decreasing in width from the ends farthest from the core to the inside ends next to the core. The crossovers between sections were spaced with references to polar spacing to neutralize the effects of the leakage flux. Fig. 8, which is a view of the set during installation, shows the details of the completed rotor.

Ventilation

The synchronous unit is an enclosed self-ventilated unit taking air in from under the base, and discharging this air through holes in the stator frame above the base. The air enters through air chutes at each end of the machine, and passes into the rotor fans through circular openings around the shaft. Most of the air is then caught by the poles and forced out through the radial air ducts of the stator core into the space in the stator frame back of the core. The remainder of the air passes through the end windings of the stator and then through the holes in the heads of the stator frame

under the air shields. The total ventilating air is then discharged into the room through the holes in the stator frame.

The arrangement of the induction unit is similar to that of the synchronous machine with regard to entrance of the air, except the air is supplied under pressure from the external blower. A double-shrouded-type fan on the rotor forces the air into the space back of the rotor core. The spaces between the rotor arms at both ends are covered by vertical plates to form an enclosed chamber inside the rotor spider. The plates on the collector end can be seen on Fig. 8, and the rotor fans are also visible in this figure just outside these plates. From the inside of the rotor the air passes through the radial rotor ducts to the air gap, and then through the stator ducts to the space in the stator frame back of the core. The part of the air that cools the end windings of the rotor and stator follows a path similar to that of the synchronous unit. The holes in the stator frame are closed to a plane somewhat above the horizontal center line, and a ventilating hood attached to the top of the stator frame. This hood has baffles to reduce the windage noise of the machine.

There is considerable resistance to air flow in the stator and rotor ducts, and it was not considered that the machine itself would furnish a sufficient supply of cooling air, hence an external blower was provided to secure additional air pressure. This blower was designed to deliver 122,000 cu. ft. of air per minute in the pit below the machine at a pressure of 7 in. of water. The actual quantity of air delivered per minute is somewhat over 100,000 cu. ft. for the induction unit and about 22,000 cu. ft. for the transformer.

Assembly

The set has four bearings each piped for water cooling. The two end bearings are supported by the base, and the two middle bearings are carried on bridges extending across between the two sides of the base, and supported by cast iron pillars extending down to foundation plates grouted into the foundation. The base, bridges, and the foundations are very strongly constructed and the set operates practically without vibration.

The bearings are also equipped with a high pressure oil system which lifts the shafts and greatly reduces the starting torque. The pressure required to lift the shaft initially is from 1000 to 1200 lb. per sq. in. and decreases to about 500 lb. per sq. in. after the shaft lifts and allows the oil to escape around it. As the rotor speeds up, the pressure gradually decreases to a little over 300 lb. per sq. in. at normal speed.

Movement of either stator frame for inspecting, cleaning or repairing the stator or rotor can be accomplished without removing the rotors. The bearing pedestal, bridge, and supporting pillars adjacent to either unit and the air shields of that unit are removed, and the stator lifted by special bolts in the feet. Rollers are then inserted in grooves in the feet, the frame dropped down on the rollers, and rolled along the base until the rotor and stator winding are clear from each other. The stator can then be lifted, rolls removed and the stator lowered to rest on the base. Fig. 8 shows the induction machine stator moved over clear of the rotor. Access to the stator is obtained from the bridge remaining between the two units.

Shipment

The transportation of the various parts to their destination is of interest as some of them were very close to the limit of the facilities available. All parts except the two rotors were shipped by rail, as they were sectionalized enough to permit transportation by this means. The diameter and length of rotors made it impossible to ship them completely assembled by rail, and an investigation of the method of assembly of these parts indicated that considerable time and expense could be saved by building them complete at the factory. They could be handled easily on the New York State Barge Canal and Hudson River, but the problem of loading them on the barge was more difficult and was only solved by securing the services of two railroad wrecking cranes.

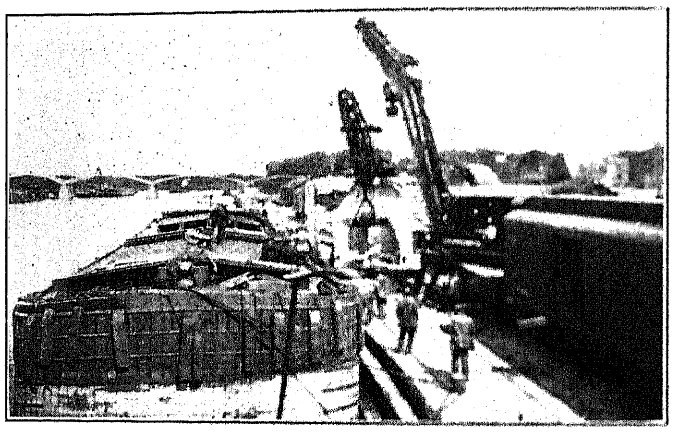

Fig. 9—Railroad Wrecking Cranes Loading Rotor of 25,000-Kv-a. Generator on Canal Barge

Fig. 9 is a view of the synchronous machine rotor being lifted out over the barge, which carried it to the Hell Gate Station.

The rotors were unloaded at destination by one of the derrick lighters available at New York City.

Parallel Operation and Phase Displacement Under Load

The relative phase relations on the 25 and 60-cycle ends of this set are definitely fixed for any particular load condition, the same as a standard synchronous frequency converter, and it is therefore necessary to synchronize on the proper pole of the 25-cycle unit to operate in parallel with other frequency converters. The poles are shifted by reversing the field of the

synchronous machine until the proper phase position is secured.

Assume a second set operating unloaded between the two systems, holding the same relative phase position between them, and the synchronous unit of the induction frequency converter operating from the 25-cycle end. A synchroscope between the 60-cycle end of the set and the 60-cycle system will then show the phase displacement of the 60-cycle voltage of the induction set. If the synchroscope indicates "in phase" position, reversing the field of the 25-cycle unit will cause the unit to drop back one pole or 180 deg. and the synchroscope will move back 1.4 × 180 deg. = 252 deg. or the equivalent of a forward displacement of 108 deg., because one pole of the 10-pole unit covers 1.4 times the mechanical angle that is covered by one hole of the 14-hole unit.

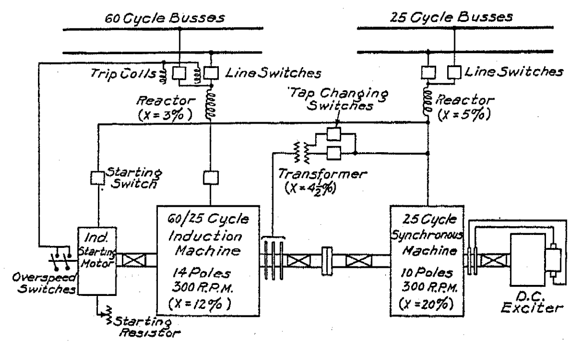

FIG. 10—DIAGRAM OF CONNECTIONS OF SET, TRANSFORMER AND REACTORS

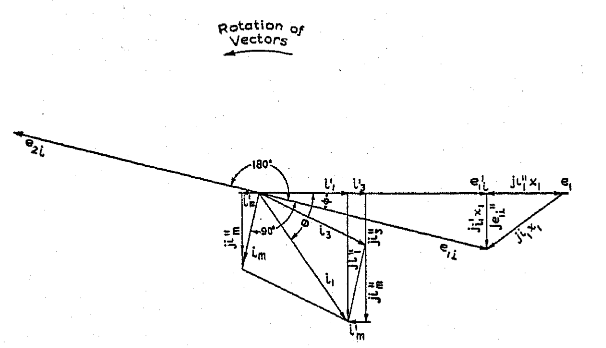

FIG. 11—VECTOR DIAGRAM OF INDUCTION FREQUENCY CONVERTER. PART 1

A tabulation of phase position for the various poles of the 10-pole unit is as follows.

Pole	Phase Angle
1	0 deg.
2	108 deg.
3	216 deg.
4	324 deg.
5	72 deg.
6	180 deg.
7	288 deg.
8	36 deg.
9	144 deg.
10	252 deg.

It is evident from this tabulation that there is just one pole on which the set can be synchronized for parallel operation with other sets, and it is necessary to either synchronize on this pole, or shift poles by reversing the field until it can be reached. The use of two synchroscopes for synchronizing will enable the operator to secure the proper phase relations without much difficulty.

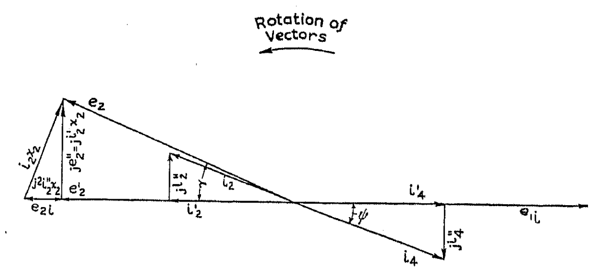

FIG. 12—VECTOR DIAGRAM OF INDUCTION FREQUENCY CONVERTER. PART 2

TESTING

The machines were not completely assembled at the factory and the tests had to be made after the final installation. The testing was done in cooperation with the operating department of the Hell Gate Station of the United Electric Light and Power Company. The excellent facilities available for testing, especially for loading the set, and the large capacity of the power supply made it possible to obtain practically all the

data desired for the set. The starting motor operated from the large 25-cycle system and was not subjected to variations in frequency. Also the secondary resistance could be varied for speed control on the no-load tests. The converter could be tied to the system at one end and to a special bus supplied by one or more large turbine generators on the other end for heat runs and regulation tests. This method of operation made it

possible to hold any desired load from no load to the full capacity of the set with very little fluctuation.

Friction and Windage

The set ran from the starting motor without excitation on either unit, and a number of readings was taken

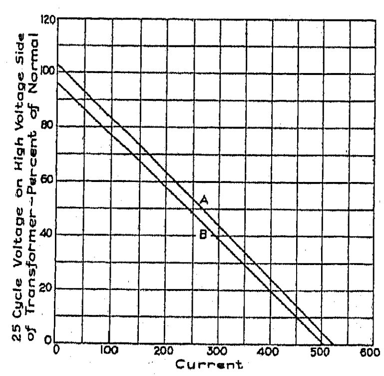

Fig. 14—Curves of Stator and Rotor Current of Induction Frequency Converter. 13,800 Volts Held on 60-Cycle Bus. No-Load Transfer through Set. Voltage on High Side of 25-Cycle Transformer in Rotor Circuit Varied from Normal to Zero

of input to this motor for various speeds as determined by secondary resistance. Fig. 15 is the test curve of friction and windage obtained from these readings.

Saturation and Synchronous Impedance of Synchronous Machine

The saturation data were taken at speeds varying somewhat from normal, but the curve in Fig. 16 is plotted with the voltage values corrected to 300 rev. per min.

The synchronous impedance as given on the same figure was taken under slightly varying speed conditions, but no correction is necessary in this case.

Impedance of the Induction Machine

A special testing generator in the Hell Gate Station was connected through a 2 to 1 step down transformer to the primary of the 17,100-kv-a. transformer. The secondary of this transformer is permanently connected to the rotor of the induction unit and no special test connections were necessary, beyond the connection to the primary of the transformer. The stator of the

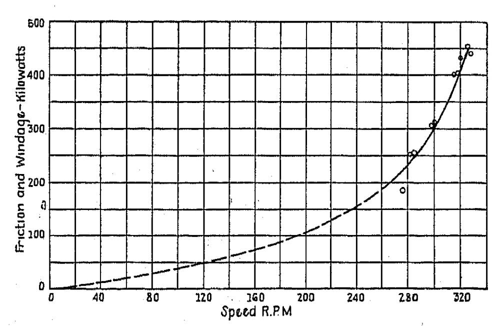

Fig. 15—Test Friction and Windage of Set

main induction machine was short-circuited, and the voltages applied to the rotor for various values of rotor, and stator currents were read. Since this gave the total impedance drop it was necessary to estimate the division between stator and rotor reactance from the calculated values. The total reactance, of course, is a test value and the error in the individual values would be quite small.

Open Circuit Core Losses

The core loss of the synchronous unit was obtained by running at practically normal speed with the field excited for approximately normal voltage. The kilowatt input to the induction starting motor was measured and the output to the set calculated by taking out the losses in this motor. The output then represented friction and windage of the set, exciter input, and core loss of the synchronous unit. The exciter output was measured, and its input calculated from its efficiency data, so that the core loss could be determined by subtracting the test value of friction and windage and the exciter input from the output of the induction motor.

In taking the core loss of the induction unit, it was necessary to excite it from the synchronous unit. One of the tap-changing switches in the high-tension circuit of the transformer (see Fig. 10) was closed, and input to the starting motor measured with the induction

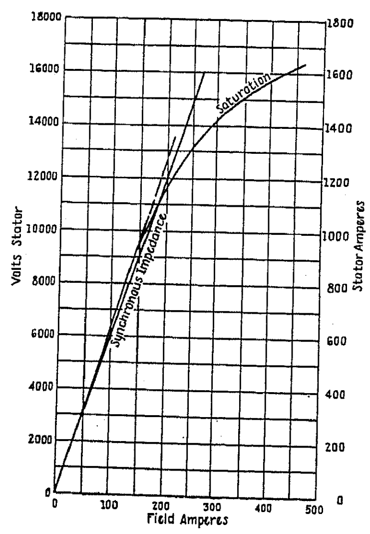

Fig. 16—Saturation and Synchronous Impedance Curves of 25,000-Kv-a. Synchronous Machine.

machine stator voltage brought up to normal. The starting motor output then represented friction and windage of set; exciter input; $I^2 r$ losses in synchronous machine stator, transformer and induction machine rotor for its magnetizing current; blower motor input; core loss of the synchronous unit, and core loss of the induction machine. Since all these losses except blower motor input and induction machine core loss had been previously determined, it was possible to obtain the induction machine core loss and blower motor input by subtracting the known losses from the total. The blower motor input could be closely estimated and thus the core loss quite accurately obtained.

It should be noted here that this test gives the entire running light loss of the set when operating with normal voltage on both units, and the total loss under load will therefore require only the addition of the $I^2 r$ losses, due to increase in the various currents, the additional load losses, and increase in exciter input. Errors in estimating individual losses from this test will therefore tend to compensate each other, and the final results of efficiencies will be very close to the actual values. Figs. 17 and 18 are the open circuit core losses of the two units. These curves are based on the test values at normal voltage and assume the loss varies as the 2.2 power of the voltage. This exponent is based on experience with other alternating current machines,

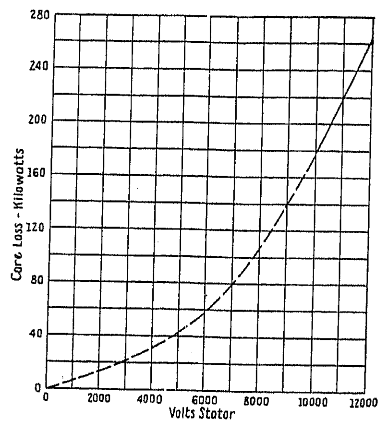

Fig. 17—Open Circuit Core Loss Curve of 25,000 Kv-a. Synchronous Machine. Curve from Test Values at Normal Voltage and Assumes Core Loss = K (Voltage)$^{2.2}$

and the curve will give quite accurate values for voltages in the vicinity of normal.

Magnetizing Current of Induction Machine

The machine was excited through the rotor, and the magnetizing current read for various values of stator voltage around the normal value. The results are plotted in Fig. 19.

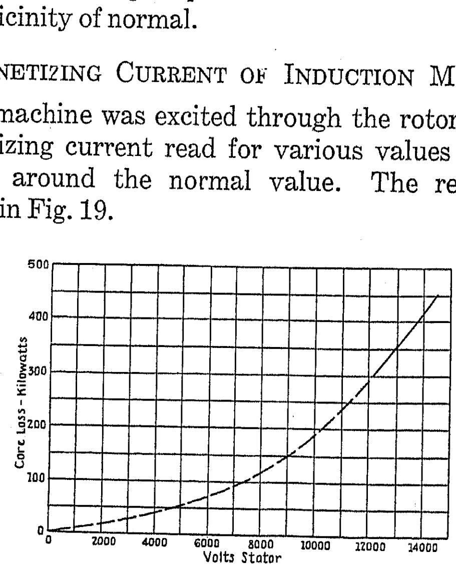

Fig. 18—Open Circuit Core Loss Curve of 37,000 Kv-a. Induction Unit. Curve from Test Values at Normal Voltage and Assume Core Loss = K (Voltage)$^{2.2}$

Short Circuit Core Losses

The stator of the induction machine was short-circuited, and the rotor tied in through the transformer to the stator of the synchronous machine. The blower motor was disconnected from the transformer. The input to the induction motor was read for various values of stator currents on the short-circuited machine. The output of the starting motor is given in Fig. 20 as "Total Losses." Friction and windage, $I^2 r$ losses

·ion losses were obtained from the tests pre- de on the set and from excitation readings, se tests. The total short-circuit core loss achines is the difference between the two es in Fig. 20 and is given in the lowest curve re. Test values of speed, synchronous ma- T I) stator current, and induction machine :or current are also plotted in Fig. 20. ELECTRICAL CHARACTERISTICS

trical operating characteristics of this type cy converter are developed quite fully in Steinmetz', "Theory and Calculations of Electrical Apparatus." Edition of 1917, Chapter XII.

The following theory is derived from the same general principles, but is simplified by neglecting resistances, and by making the calculations for the normal rotor frequency only.

The vector diagrams of the induction frequency converter, Figs. 11 and 12, are drawn for the machine operating as a motor, taking lagging current from the line, but the equations derived from them may be extended to the leading current condition simply by reversing the sign of reactive component.

NOTATION OF VECTOR DIAGRAMS

(See Fig. 11)

e_1 = line voltage on 60-cycle system.

$\dot{i}_1$ = line current on 60-cycle primary of induction frequency converter, that is in the stator circuit.

x_1 = sum of reactances of stator and series reactor between the stator and 60-cycle bus.

i_1' = energy component of $\dot{i}_1$.

i_1'' = reactive component of i_1, 90 deg. behind e_1. This current is negative for lagging-current input, and positive for leading-current input.

x_m = magnetizing reactance.

i_m = magnetizing current.

i_m' = component of magnetizing current in phase with e_1.

i_m'' = component of magnetizing current 90 deg. behind e_1.

$\dot{i}_3 = \dot{i}_1 - \dot{i}_m$.

i_3' = component of i_3 in phase with e_1.

i_3'' = component of i_3, 90 deg. behind e_1.

e_{1i} = component of e_1 which overcomes the internal induced voltage in the stator, and is equal to e_1 minus the reactance drop through x_1.

e_{2i} = internal induced voltage in rotor circuit.

It will be noted that the values of voltage are not laid out in proportion to the actual voltage, but on the basis of a percentage of the actual values, so that the vectors e_{1i} and e_{2i} are equal in length.

(See Fig. 12)

This diagram is a continuation of Fig. 11, but e_{1i} is now taken as the reference vector and i_3 is called i_4 to avoid confusion between the components of the current in the two diagrams.

e_{1i} and e_{2i} are same as in Fig. 11.

$\dot{i}_4$ = $\dot{i}_3$ from Fig. 11 and equal to it in scalar value.

i_4'' = component of i_4 in phase with e_{1i}.

i_4'' = component of i_4 90 deg. behind e_{1i}.

ψ = angle between i_4 and e_{1i}.

$\dot{i}_2$ = rotor current corresponding to $\dot{i}_4$ and 180 deg. in phase from $\dot{i}_4$.

i_2' = component of i_2 in phase with e_{2i}.

i_2'' = component of i_2 90 deg. behind e_{2i}.

x_2 = reactance of rotor and transformer in rotor circuit.

$i_2 x_2$ = reactance drop in x_2.
e_2 = voltage on high-voltage side of transformer, divided by transformer ratio to keep it in the same terms as e_{2i}.

Expressed as an equation in actual volts.

$$\frac{e_{2i}}{e_{1i}} = \frac{f_2}{f_1} \times \frac{n_2}{n_1}$$

where
f_1 = stator frequency.
f_2 = rotor frequency.
n_1 = stator turns in series per phase and circuit.
n_2 = rotor turns in series per phase and circuit.

The division of power output from the set may be derived from the usual equations of the induction motor. The power output from the collector rings, or secondary loss, if the power output of the collector rings is dissipated in an external resistance, is equal to the power input multiplied by the slip, and the mechanical output is equal to the power input multiplied by (1 − slip): That is

$$\text{Electrical output} = \frac{f_2}{f_1} \times \text{total output.}$$

$$\text{Mechanical output} = \frac{f_1 - f_2}{f_1} \times \text{total output.}$$

The electrical output of the converter is from the collector rings through the transformer, and the mechanical output through the shaft to the synchronous unit.

Let $e_1 = 1.0$ when its actual value is the rated voltage of the stator, 13,800 volts.

$e_2 = 1.0$ when its actual value is equal to

$$e_1 \times \frac{n_2}{n_1}\ \frac{f_2}{f_1} \text{ or 2730 volts.}$$

$i_1 = 1.0$ when it is the rated stator current.
i_3 and i_4 are expressed in same units as i_1.
$i_2 = 1.0$ when it is the rated stator current multiplied

$$\text{by the ratio } \frac{n_1}{n_2}$$

The calculations of the machine may be derived by assuming the magnetizing current to be supplied from either stator or rotor, and subtracting this current vectorially from the total current on that member. The ampere-turns, due to the resultant current in that member, will then be equal and opposite to the ampere-turns in the other member.

That is, when the currents are expressed on the basis of the above values as unity,

$$i_3 \text{ (which is also } i_4) = i_2$$

With the above equations as a basis, the equations from Fig. 11 are derived as follows:

$$\begin{aligned}
e_{1i} &= e_1 - j\, i_1\, x_1 \\
&= e_1 - j^2 i_1''\, x_1 - j\, i_1'\, x_1 \\
&= e_1 + i_1''\, x_1 - j\, i_1'\, x_1 \\
&= e_{1i}' + j\, e_{1i}''
\end{aligned}$$

$$\begin{aligned}
i_m &= \frac{e_{1i}}{j\ x_m} \\
&= \frac{e'_{1i}}{j\ x_m} + j\, \frac{e_{1i}''}{x_m} \\
&= -\frac{j\, e_{1i}'}{x_m} + \frac{e_{1i}''}{x_m} \\
&= i_m' + j\, i_m'' \text{ where } i_m' = \frac{e_{1i}''}{x_m} \text{ and } i_m'' = -\frac{e_{1i}'}{x_m}
\end{aligned}$$

$$\begin{aligned}
i_3 &= i_1 - i_m \\
&= i_1' + j\, i_1'' - i_m' - j\, i_m'' \\
&= i_1' - i_m' + j\,(i'' - i_m'') \\
&= i_3' + j\, i_3''
\end{aligned}$$

When the scalar value of e_{1i} and i_3 are determined, the values are transferred to Fig. 12, and the calculations carried out using e_{1i} as a new reference vector. The current i_4 in Fig. 12 is the same as i_3 in Fig. 11, but to avoid confusion between the components of this current in the two diagrams, it is changed to i_4 in the calculations made from Fig. 12.

$e_1\, i_1'$ = power input to the stator
$e_{1i}\, i_4'$ = power output of stator.

Since it assumed that there are no losses, these values must be equal.

$$\text{Then } i_4' = \frac{e_1\, i_1'}{e_{1i}}$$

Then from Fig. 12

$$\cos.\ \psi = \text{power factor of stator output} = \frac{i_4'}{i_4}$$

$$i_4'' = i_4 \sin \psi$$

The same flux cuts both rotor and stator conductors, and therefore the induced voltage is the same direction in both members, and when expressed in the units given above for e_1 and e_2 the induced voltages in both are equal in value.

But since e_{1i} is the voltage to overcome the induced voltage in the stator, it is 180 deg. out of phase with this induced voltage, and e_{2i} is therefore 180 deg. out of phase with e_{1i} and equal to it in value.

The following relations can now be derived from the preceding discussion.

$$\begin{aligned}
e_{2i} &= -\, e_{1i} \\
i_2 &= i_4 \\
i_2' &= -\, i_4' \\
i_2'' &= -\, i_4''
\end{aligned}$$

The rotor terminal voltage e_2 is determined by subtracting the reactance drop in the rotor from the induced voltage e_{2i}.

$$\begin{aligned} e_2 &= e_{2i} - j i_2 x_2 \\ &= e_{2i} - j^2 i_2'' x_2 - j i_2' x_2 \\ &= e_{2i} + i_2'' x_2 - j i_2' x_2 \\ &= e_2' + j e_2'' \end{aligned}$$

Table I is a set of calculations for e_{1i} and i_3 for full-load input to the converter with varying values of power factor, and is derived from the vector diagram Fig. 11.

Table II covers the calculation of i_2 and e_2, the secondary current and voltage on the high side of the transformer. The magnetizing current of the transformer is neglected in the calculations.

The constants used in these calculations were determined from tests and calculated data, and are as follows:

External reactance in 60-cycle lines—3 per cent based on 37,000 kv-a. at 13,800 volts.

Stator reactance 6.6 per cent.

Rotor reactance 5.4 per cent based on 15,400 kv-a. at 2730 volts.

Transformer reactance 4.5 per cent.

Equivalent reactance for magnetizing current—273 per cent.

Ratio stator to rotor current, based on effective turns = 0.475

Stator normal voltage = 13,800 volts
Stator normal current = 1545 amperes
Rotor normal voltage = 2730 volts
Rotor normal current = 3250 amperes.

In the calculations the values of x_1, x_2, etc. are expressed as the percentage values divided by 100.

Then total primary reactance

$$x_1 = 0.03 + 0.066 = 0.096$$

Total rotor reactance

$$x_2 = 0.054 + 0.045 = 0.099$$

$$x_m = 2.73$$

60-cycle bus voltage $e_1 = 1.0$ at 13,800 volts.

25-cycle voltage on high side of transformer e_2 1.055 for 11,400 volts, or 1.0 for 10,800 volts.

Ratio transformer = 10,800 to 2730
= 3.96 to 1.0

The curves in Fig. 13 are plotted on the basis of 13,800 volts held on the 60-cycle bus, and the transformer ratio held at the value to give 11,400 volts on the high side of the transformer at 1.0 power-factor input to induction unit with full load on the set.

Characteristics Under Short Circuit Conditions[1]

Fig. 14 shows a curve giving the relation of the stator current, and the current in the 25-cycle rotor and transformer circuit, to the voltage on the high side of the transformer for a variation in this voltage from normal to zero with transformer ratio to give 11,400 volts on high side and 2730 on low side. This curve was calculated by the same method as Fig. 13. The equivalent reactance is 19 per cent for calculations of kilovolt-ampere taken from the 60-cycle system, and 19.8 per cent for calculations of kilovolt-ampere delivered to the 25-cycle system. These percentages are based on the ratings of the respective circuits, 37,000 kv-a. for the stator and 15,400 kv-a. for the rotor.

In case of short-circuit on the 25-cycle system, the additional reactance between the transformer and the bus, which is 5 per cent based on 35,000 kv-a. or 2.2 per cent based on 15,400 kv-a., must be added. The synchronous reactance of this unit at rated load field current is 36 per cent based in this 15,400 kv-a. capacity of rotor circuit.

The reactance circuit for the 25-cycle side is thus a 35 per cent reactance and a 19.8 per cent reactance in parallel, and this combination in series with a 2.2 per cent reactance.

The combined reactance is 14.8 per cent, and the kilovolt-amperes delivered to the 25-cycle system is

$$\frac{15{,}400 \times 100}{14.8} = 104{,}000 \text{ kv-a.}$$

This value of kv-a. corresponds to the sustained short-circuit current, and is considerably less than the initial value, as the output of the synchronous unit would be limited only by the transient reactance which is 20 per cent based in 25,000 kv-a. or 12.3 per cent based on 15,400 kv-a.

The combined reactance is then 9.8 per cent and the input to the 25-cycle system on the initial current rush after short circuit would be equivalent to $\frac{15{,}400 \times 100}{9.8}$ = 157,000 kv-a.

The 104,000 kv-a. supplied to the 25-cycle system is divided inversely as the reactances in the synchronous machine and the rotor circuit of the induction unit.

Thus the kv-a. supplied by the induction unit is

$$\frac{35}{35 + 19.8} \times 104{,}000 = 66{,}300 \text{ kv-a.}$$

This kilovolt-ampere is equivalent to 430 per cent of normal current and the stator current for this rotor current is 450 per cent, and the voltage in the high side of the transformer and thus at the synchronous motor terminals is approximately 14 per cent.

The kv-a. from the 60-cycle line is $\frac{37{,}000 \times 450}{100}$ = 166,000 kv-a.

The author wishes to express his appreciation of the co-operation of Mr. H. Y. Hall, Superintendent of the Hell Gate Station of the United Electric Light and Power Company, and of Mr. H. W. Oetinger in the testing of the set, and to acknowledge the assistance of

1. See "Frequency Converter Ties Between Large Power Systems" by J. W. Dodge, *G. E. Review*, June, 1923.

Messrs. R. E. Doherty, R. F. Franklin, and D. S. Snell, in the preparation of the theoretical part of the paper.

Discussion

F. C. Hanker: There is some question as to the application of the machine described that I want to discuss, particularly on the basis of considerations that Mr. Shirley has outlined. He has given in his paper three considerations. If you will analyze them, you will find the first is applicable to either the synchronous unit or the type described. In the second, in the amount of inductive kv-a. returned to the system there appears to be a question as to whether the type described is as effective as the straight synchronous, because the induction machine must of necessity receive its magnetization from either the 25-cycle or the 60-cycle system, depending on the voltage condition. That means that you have to compensate for that excitation or magnetization from the line either through other apparatus connected to, say, the 25-cycle system, or an additional machine that would be supplied with the set. If you take existing conditions, it would not be very serious or very harmful to supply the magnetization from the 25-cycle systems but in other cases where the power factor of the 25-cycle load is much lower, then it is a handicap to the machine.

If you take the third consideration he has given, I fully agree with him as to the desirability of maintaining voltage in connecting the two systems, but it is questionable in my mind whether the reactance of the magnitude, that you obtain with the special machine, is going to be particularly effective and whether it is going to be of sufficient advantage to overcome the disadvantage of cost both in reduction in efficiency and in the complication of the machine.

If you take a similar machine which fortunately is available for comparison, the efficiency as given by Mr. Shirley shows losses of some 2000 kw. at full load. On the Brooklyn system they have a straight synchronous machine of practically the same rating, with about 500 kw. lower losses. In other words, the efficiency of the two sets inherently penalizes the special induction outfit. As the 500 kw. are largely constant losses, they are present all the time the machine is in operation. At 7000 hours a year they represent three and a half million kilowatt hours, which represents a considerable investment if capitalized, and would indicate the disadvantage to which this special outfit would be subjected.

From the other standpoint of the voltage, it is undoubtedly true that low reactance between stations of the same capacity is of considerable advantage, but it is also true that the tie must be of sufficient magnitude and low enough reactance in order to be effective in maintaining the voltage on the two systems. In the present instance that reactance is given as about twenty per cent, which represents a very appreciable drop, particularly when you consider the relative sizes of the two systems.

Here is a machine of some 35,000 kw. between systems of, 200,000 kw., or that order, of one frequency and at least 100,000 kw. of a different frequency, which means that the tie between those two systems is of comparatively high reactance. If you take the synchronous converters, only a small difference in voltage between the two supply circuits will cause reversal on one, which is the particular point that Mr. Shirley is endeavoring to overcome.

It would be interesting to ask if there has been any operating result that substantiates the advantages claimed for the induction type, and whether there has been any improvement observed in operation under abnormal conditions. It is only under those conditions that any difficulty may be expected from the reversal of synchronous commutating machines. The slight advantage if any is secured at a considerable expense, and the question of application should be very carefully considered before any of the special outfits are utilized.

It does involve complications and does cause both losses and increase in the magnetizing which every power company is endeavoring to keep down just as much as possible.

E. B. Shand (by letter): Mr. Shirley has described a type of frequency converter which has had a very limited application, therefore, it is quite justifiable to discuss it from a comparative standpoint with respect to the type of machine ordinarily used in similar applications, that is, the frequency converter set composed of two synchronous machines. This discussion intends to follow this above idea, using the data presented by Mr. Shirley to represent the induction or cascade type of machine.

Attention may be called to the three considerations enumerated by Mr. Shirley as determining the selection of the cascade type of machine for tying together the particular systems mentioned. The first of these, that of reversibility of operation, allowing the set to be considered a spare unit for either system, applies equally well to synchronous sets, and is rather a consideration for the installation of a frequency converter, regardless of type. The two remaining considerations deal with the ability of the cascade machine to transfer reactive kv-a. as well as power between the two interconnected systems. This is the main differentiation between the abilities of the two types of apparatus considered. In the synchronous set, the interconnection between the two electrical systems being through the common shaft is purely mechanical, so that power alone may be interchanged. In the cascade set, the interconnection is partly through the common shaft, and partly through the air-gap flux of the induction machine, this magnetic link allowing the interchange of the reactive kv-a. If my memory serves me rightly, this characteristic has given to the induction-type frequency converter the name "general transformer" for it serves approximately to connect systems of different voltage and frequency as the transformer does systems of the same frequency.

It may be noted that with the induction-type converter the synchronous machine plays no direct part in the interchange of magnetization, so that for the purpose of a simple analysis it may be assumed non-existent or disconnected. The frequency converter then becomes a wound-rotor induction motor with the stator windings connected to the 60-cycle system, and the rotor windings, through a suitable transformer, to the 25-cycle system. This combination is capable of interchanging magnetization, but is completely incapable of interchanging power. By analogy, therefore, this apparatus might be designated "the general synchronous condenser." The rotor will rotate at 25/60 of the synchronous speed at 60 cycles, and the air-gap flux interlinking both windings will generate voltages in the stator and rotor windings in the ratio of 60:25, on the basis of an equal number of turns in each winding. If the voltage ratio of the two systems varies from that determined from the design of the converter, the reactive kv-a. will flow until the reactive drop in the machine has equalled the voltage difference. The magnetizing current is supplied from the system with the relatively higher voltage. This is all similar to the flow of reactive kv-a. in a transformer, except that the frequency and the voltage per turn is not the same in the two windings. It thus happens that for every 60 kv-a. drawn from the 60-cycle system only 25 kv-a. is supplied to the 25-cycle system; and, conversely, 25 kv-a. drawn from the 25-cycle system becomes 60 kv-a. when taken from the stator terminals.

In the above mentioned arrangement of the "general synchronous condenser" there is no definite frequency ratio between the two circuits; this depends entirely on the frequencies as determined by the governors of the two systems thus interconnected. When the synchronous machine is connected to the same shaft, and electrically connected to the rotor of the induction machine, the frequency ratio becomes as definitely fixed as in the case of

the two synchronous machines mechanically connected together. The induction set, therefore, locks in synchronism the two systems which it interconnects. The relative phase displacement of the two systems will determine the load on the set, and if the phase displacement becomes too great, the set will drop out of step. The overload at which this will occur depends upon the design of the two machines, making up the set. The extreme overload capacity of such a set is of the same order as in the case of the synchronous type of set. With this in mind, it is believed that some of the statements in the second paragraph of Mr. Shirley's paper will be seen to give a deceptive idea of the relative limitations of the two types of sets with respect to pulling out.

Returning to the subject of the interchange of reactive kv-a. it will be seen that the ordinary transformer diagram may be used to determine the relative values of this interchange. Utilizing Mr. Shirley's data, the following impedances may be set down.

Stator reactance	6.6%
Rotor reactance	5.4%
Transformer reactance	4.5%
Magnetizing current	36.5%
External reactance (60-cyc. system)	.3%

It is assumed, in addition, that the synchronous generator is excited to furnish the magnetizing current, that is, that the set will operate at unity power factor at no-load. The results of these conditions will be as follows:—If the 25-cycle voltage drops so that the stator input is 37,000 kv-a. at 60 cycles, the output from the secondary alone will be 10,000 kv-a.; assuming, however, that the magnetizing kv-a. from the generator is added to this, the total 25-cycle output will be 15,000 kv-a., while the voltage drop in the set will be 17 per cent. Assuming now that the 60-cycle voltage drops until the stator output is 37,000 kv-a. the rotor input will be 21,000 kv-a., of which 5500 kv-a. will be supplied from the generator so that the net set input will be 15,500 kv-a. The corresponding voltage drop in the set will be 23 per cent. The above calculations check roughly with Fig. 13 of Mr. Shirley's paper.

It is considered that the logical conclusion from these figures is that the average interchange of reactive kv-a. should be

$\frac{37000 + 15400}{2}$ or 26,300 kv-a. with an average drop of

20 per cent. The set reactance based on its rating of 37,000 kv-a. would then be about 28 per cent from the standpoint of voltage regulation of the two systems. If the installed capacity of frequency changers of this type were considered to be from 20 per cent to 25 per cent of the capacity of smaller system, a figure which is not generally exceeded, it will be seen that the reactance of the tie between the two systems will be of a magnitude of between 110 per cent and 140 per cent, as compared with the smaller of the systems. With a tie of this value of reactance, it is evident that the effect of the induction frequency converter in equalizing the voltages of the two systems must be very limited, in fact, in considering a transformer tie of this nature, the regulating effect on voltage would ordinarily be disregarded.

The third consideration enumerated in the paper is closely connected with the above discussion; it regards the possibility of paralleling synchronous converters fed from the systems of both frequencies because of the tie formed by the induction frequency converter. The load distribution between two converters paralleled on the direct-current side depends upon the relation between their supply voltages. Under full-load conditions, one machine will reverse its power flow and the other carry double load when the supply voltage on one machine drops more than 10 per cent with respect to the other. The fact that the induction frequency changer set will allow double this voltage variation to carry full load reactive kv-a. signifies that the adoption of this type of machine will not be a deciding factor in determining whether or not converters may be paralleled under the conditions referred to above.

From the analysis as developed above, the writer's conclusion is that as a voltage tie between systems the capabilities of the induction type of frequency converter are negligible so far as any practical results are concerned, and that this characteristic of the induction converter should have no particular influence on the choice of sets.

O. E. Shirley: The discussions of this paper by Mr. Hanker and Mr. Shand both point out that the first point given for the selection of the induction frequency converter for the New York systems is applicable to the synchronous set as well. This, of course, is quite evident, and it was not intended to convey the idea that this characteristic was the exclusive property of the induction set, but simply to present, as completely as possible, the considerations that led to the choice of the induction frequency converter.

With regard to the question of magnetization of the induction machine it should be noted that under normal load conditions the magnetizing current for the induction machine is supplied by the synchronous unit and, therefore, the power factor on both sides, as it affects the systems, is unity. It is, therefore, evident that the additional machine suggested by Mr. Hanker is not necessary.

The comparison of the efficiency, presented by Mr. Hanker, shows a difference of about 1.4 per cent at full load. Part of this difference is accounted for by the assumption of a round number of 2000 kw. for the losses of the induction set. This value is somewhat high and, when used as a basis for calculating the difference of efficiency, it introduces an error of considerable magnitude. A comparison of efficiency of sets designed for the same characteristics as to insulation, break-out torque, and temperature rise shows that the difference is more nearly ¾ per cent than the value given above.

The break-out torque, which is mentioned in Mr. Shand's discussion, in the case of the induction frequency converter is largely dependent on the torque of the synchronous unit, since the torque of the induction machine with voltage maintained on the two systems is considerably above that of the usual synchronous machines. The maximum torque of this frequency converter with voltage maintained on both systems is over 200 per cent of normal, being very appreciably in excess of the 150 per cent torque of the usual design of unity-power-factor synchronous machines with a short-circuit ratio only slightly over unity. (Note that by short-circuit ratio is meant ratio of field amperes for no-load normal voltage to the field amperes for rated current on short circuit.)

The behavior of synchronous converters, operating in parallel on the d-c. buses with a-c. supply from systems of different frequency, is affected by a number of factors which have not been taken in account in either of the discussions, nor the original paper, but which must be considered in judging the operating characteristics of the converters in this way. These synchronous converters are usually located in substations, and the drop in the line and transformers will have a very decided practical effect in limiting the current taken by them during disturbances. The induction frequency converter being located at the central station and close to the bus will transmit a very considerable amount of reactive kv-a. balancing the voltages to a marked degree, and then the additional drop between the main buses and the synchronous converters should limit the current sufficiently to prevent injury to the converters under many conditions which would cause serious trouble if the induction frequency converter were not used.

The calculations by Mr. Shand from which he concludes that the effect of the induction set is negligible in causing a drop in voltage on one system, when a disturbance takes place on the other system, can best be answered by data taken from recording charts showing the results of a severe disturbance on

the 25-cycle system under actual operating conditions. The connected capacity on the 60-cycle system was 35,000 kw. at Hell-Gate, 14,000 kw. at Waterside, and 108,000 kw. at Sherman Creek. The voltage on the 25-cycle system dropped to 62 per cent of normal and on the 60-cycle to the following values:

Hell-Gate	71 per cent
Sherman Creek	81 per cent
Waterside	76 per cent
East 188 Street Sub-Station	76 per cent

These values of voltage drop do not bear out Mr. Shand's statement that "the regulating effect on voltage would ordinarily be disregarded."

A similar problem in parallel operation of synchronous converters from different stations of the same frequency had been encountered on the New York systems and this was worked out by tie lines between the stations. The size and characteristic of the induction frequency converter was based on experience with these tie lines, and since the tested values of reactances agreed very closely with the calculated values, there is no reason to believe that the operation with the frequency converter tie should not be as successful as with the ordinary tie lines.

The induction frequency converter has not been used to secure parallel operation of synchronous converters as outlined above, since the operating conditions of the two systems have not yet been such as to make this method of operation desirable. A second converter, however, is being built for parallel operation with the first and there is every reason to believe that the equalization of the voltages of the two systems will be successful whenever this method of operation is required, as the use of the two sets will take care of increased capacities which will be available and may be used later.

The Inertaire Transformer

BY W. M. DANN

Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*Oxidation is the cause of almost all of the troubles that develop in service in connection with transformer oil and it is thought by the authors of this paper that the obvious remedy for such troubles is to isolate the oil completely from contact with the oxygen of the air. A new method of providing this complete protection in the Inertaire transformer is described.*

In this transformer, a body of insert gas—nitrogen—is automatically created and maintained inside the case above the surface of the oil. This nitrogen is obtained from the outside atmosphere by a breathing process in which the breathed air passes into the transformer through chemicals which absorb the 21 parts of oxygen, leaving only the 79 parts of nitrogen to pass into the case.

A second purpose of the nitrogen gas is to eliminate the danger of fire or explosion above the oil surface for no fire or explosion can start or continue without oxygen.

A distinction is made in the paper between a "primary explosion," which term is used to designate a sudden abnormal pressure produced by gas expansion due to arcing in the oil, and a "secondary explosion" by which is meant an abnormal pressure produced by the combustion of an explosive mixture of gases. The hazard of the secondary explosion is eliminated by the absence of oxygen and effective protection against the primary explosion is given by the cushioning effect of the nitrogen body and a new form of diaphragm relief device.

A description of the Inertaire transformer equipment is given, also an account of a number of explosion tests which were made to demonstrate the effectiveness of the gas cushion in reducing the abnormal pressures due to arcing under the oil and of the new diaphragm device in relieving the pressures.

* * * * *

THE Inertaire transformer is an oil-immersed unit having a space above the oil surface filled with an inert gas composed almost entirely of nitrogen. The distinctively new feature of this type of transformer is that the body of nitrogen is automatically created and maintained above the oil surface through the controlled natural breathing of the transformer. The purpose of the new feature is to secure the decided benefits that are derived from contact with the oil of an inert and protective gas having no oxygen content. The very desirable results obtained are:

a. the prevention of oxidation of the oil,
b. the exclusion of moisture from the oil,
c. the elimination of risk of fire or explosion of inflammable gas above the oil surface,
d. the useful cushion of compressible gas above the oil surface, remarkably effective in case of a sudden increase of pressure due to an internal breakdown of the transformer.

A rise in temperature of the oil, due to load conditions in an oil-immersed transformer of the ordinary type, causes the oil to expand and exerts a pressure on the air above the oil level. If the transformer has an open vent, a portion of the air is expelled from the case. Conversely, a fall in the temperature of the oil causes it to contract and lessens the pressure above the oil level, thus drawing air into the case. This "breathing" action, which is unavoidable and which has heretofore been objectionable, is utilized through a combination of simple and automatic devices to create and maintain the inert gas body of the new Inertaire transformer. When conditions produce in-breathing, the air drawn in passes first through a quantity of deoxygenating and dehydrating chemicals. In the passage through these chemicals the oxygen content and whatever moisture is present are absorbed, and dry nitrogen is drawn into the gas space. A "breathing regulator" contributes to the economy and successful working of the equipment by its automatic control of the breathed air.

The new features of the inertaire transformer, which mark it physically as being distinctively different from the ordinary transformer having an air space above the oil level, are:

a. A cabinet mounted upon the side of the case, which contains a quantity of deoxygenating and dehydrating chemicals and a breathing regulator.
b. An improved form of relief device for abnormal pressures, placed in the cover of the transformer.

A detailed description of these parts and their functions will be found on page 4.

The Need of Inert Gas in a Transformer

Although the high-grade transformer oils of the present day are far superior to those of several years ago they have some undesirable characteristics which seem to be inherent in all oils of this class and these undesirable features apparently cannot be entirely eliminated even by the most careful refining. The principal undesirable characteristic is perhaps the tendency of oil to oxidize, with possible consequent sludge formation, when raised to moderately elevated temperatures in the presence of air. The darkened color of transformer oil after it has been in use for a time at ordinary temperatures is a manifestation of oxidation in a mild form. In a more pronounced form, a sludge gradually deposits upon the hottest parts of the core and windings of the transformer. This type of sludge seems to have little effect on lowering the dielectric strength of the oil but if it becomes pronounced it interferes with oil circulation and the dissipation of heat from the surfaces upon which it forms. Analysis of sludge of this type shows the presence of oxygen in abundance.[1]

Another form of sludge, called the "soap type,"

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

is produced by oxidation when acids, liberated by slow decomposition of the oil, interact with metals inside the case[1]. This type of sludge has a great affinity for water and its presence has considerable effect upon lowering the dielectric strength of the oil.

Since oxidation is the great cause of sludging, the obvious remedy is to eliminate the possibility of oxidation. A rather common way of minimizing sludge formations is to fill the transformer case completely, providing an expansion tank to take care of the increase in volume when the oil heats up in service. This method is successful in a great measure. However, the volume of oil in the expansion tank, which diffuses through the whole structure, is exposed to the oxidizing effects of the atmosphere even though it is at a comparatively low temperature. The oil in the tank of an ordinary transformer may contain as much as 15 or

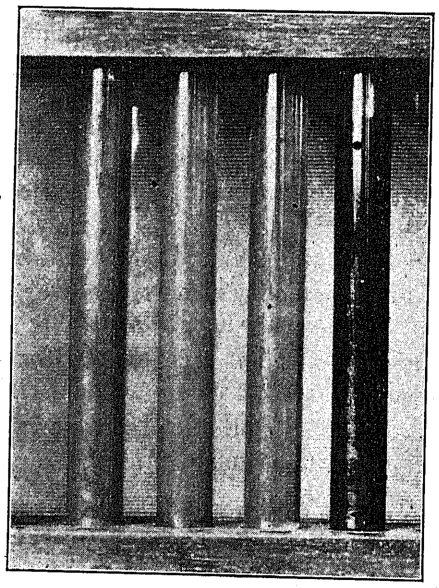

FIG. 1—COMPARISON OF FRESH GRADE "A" TRANSFORMER OIL WITH SAMPLES GIVEN ACCELERATED SLUDGE TESTS WITH AND WITHOUT THE PROTECTION OF INERT GASES

20 per cent of its volume of air carried in solution at ordinary operating temperatures. The oxygen in this dissolved air, being in such intimate contact with the oil, is very effective in producing oxidation.

A blanket of inert gas above the oil level is a complete remedy for oxidation troubles, for it effectively protects the oil against contact with oxygen. Furthermore, the air carried in solution in the oil gradually diffuses into the gas body and the inert gas takes its place. A striking illustration of the protective effects of inert gas in contact with oil is shown in Fig. 1. The test tube at the extreme left contains clean filtered grade "A" transformer oil sealed in the tube. The second tube contains oil of the same description having nitrogen sealed in with it. The third tube contains another sample of the same oil sealed in with carbon dioxide. The tube on the extreme right contains oil of the same grade but the tube was left open to the atmosphere. No heat tests were made on the first tube which was left in its original state for purposes of comparison, but the second, third and fourth tubes were subjected to an accelerated sludge test at a temperature of 200 deg. cent. for several days. The tubes in which the oil was protected by inert gas plainly show the entire absence of oxidation, while in contrast, the darkened color of the oil in the fourth tube clearly shows the effects of oxidation.

If an electric arc occurs under the oil level of a transformer, due to some internal fault, another undesirable characteristic of transformer oil develops. The effect of an arc is to cause breakdown of the oil and the sudden evolution of hydrogen, methane, carbon dioxide and gases belonging to the unsaturated series, with hydrogen forming by far the largest part of the liberated gases.[2] The evolution of these gases and the sudden increase of pressure due to their rapid expansion are for the purpose of this paper called a "primary explosion." The abnormal pressures due to a primary explosion are transmitted with almost no diminution by the practically incompressible oil to all parts of the case, if it is completely filled with oil, resulting often in strains in these parts which are excessive enough to disrupt the case. A gas or air cushion above the oil level helps greatly to reduce the internal pressures due to a primary explosion.

The vapors arising from transformer oil in normal operation, mixing with air above the oil level, are often thought of as explosive and therefore a menace to the transformer. However, it has been demonstrated that the danger of explosion with such mixtures is very remote.[3] Conditions are entirely different when the gases evolved from oil breakdown due to arcing rise above the oil level. When air is present above the oil level in sufficient amount, the mixture of air and hydrogen, which is the principal product of disrupted oil, is explosive within a wide range of proportions and a violent explosion follows if the gases reach the air space in an incandescent state or if their is arcing or corona to ignite the mixture. Such an occurrence for the purposes of this paper is called a "secondary explosion."

Another undesirable characteristic of transformer oil is its inflammability. Fortunately, troubles due to this characteristic are rare, but occasionally fires have been

Characteristics of Transformer Oils: O. H. Eschholz, *Electrical Journal*, February, 1919.

identified with primary and secondary explosions which have been excessive enough to disrupt the transformer case. When inert gas is used above the oil level of a transformer, secondary explosions and fires are impossible because there is no oxygen present to support them.

The advantages to be obtained from the use of inert gas in a transformer have been appreciated for some time and the idea of using it is not new. It has been tried in some form or other with little success, but it is thought that the principles presented in the Inertaire transformer are new and that the arrangement is the first commercially successful application.

Inert Gases

Of the various gases which might serve as protective means for transformers, there are two which are commercially available and which have been shown by laboratory tests to be entirely suitable for the purpose. They are nitrogen and carbon dioxide.

Nitrogen has commonly been called an inert gas because, except at high temperatures and under high pressures, it will not combine with other elements. It is harmless and entirely without action upon oil or any of the materials used in transformer construction. There are two general methods of producing it commercially, both using the cheapest and most abundant material—air. One method removes the oxygen by liquifying the air and then distilling off the nitrogen. This is by far the most common method of producing it commercially. The other general method is to remove the oxygen by allowing it to combine chemically with some material from which the residual gas is easily separated. This residual gas is chiefly nitrogen, but the gases found in the atmosphere which are truly inert—helium, argon, krypton and xenon—are present in relatively small amounts and are equally beneficial. No effort is made, with either of these processes, to separate these gases from the nitrogen of commerce unless there is a demand for them separately. The gas space of the Inertaire transformer contains these gases also, since they are not absorbed in passing through the deoxygenating chemicals.

The carbon dioxide dispensed in the liquid form in steel cylinders is made either from the gases given off in burning lime or by passing an excess of air through incandescent coke. The carbon dioxide resulting from either of these processes is then cooled and liquified by pressure.

The Inertaire Compound

A large amount of research work has been done in the Westinghouse Laboratories in connection with oxidizing agents ranging all the way from the extremely active but poisonous and inflammable yellow phosphorus to the simple, safe and effective mixture now used in the Inertaire transformer. Many of them failed to meet the exacting requirements of the problem involved in the Inertaire scheme on account of such objectionable features as: (a) instability at high temperatures, (b) too slow action at low temperatures, (c) the liberation of water or of hydrogen, or, (d) danger in handling or the fire hazard of supposedly spent material. Data referring to this work will appear later in technical papers.

The chemical compound adopted for the Inertaire transformer is made from an intimate mixture of finely divided copper and ammonium chloride mixed with enough kieselguhr to render the mass porous, and a small amount of concentrated calcium chloride solution. Before it is used, the mixture has a color about like that of cocoa powder, but as it absorbs oxygen it turns a beautiful robin's egg blue. The compound is used in a

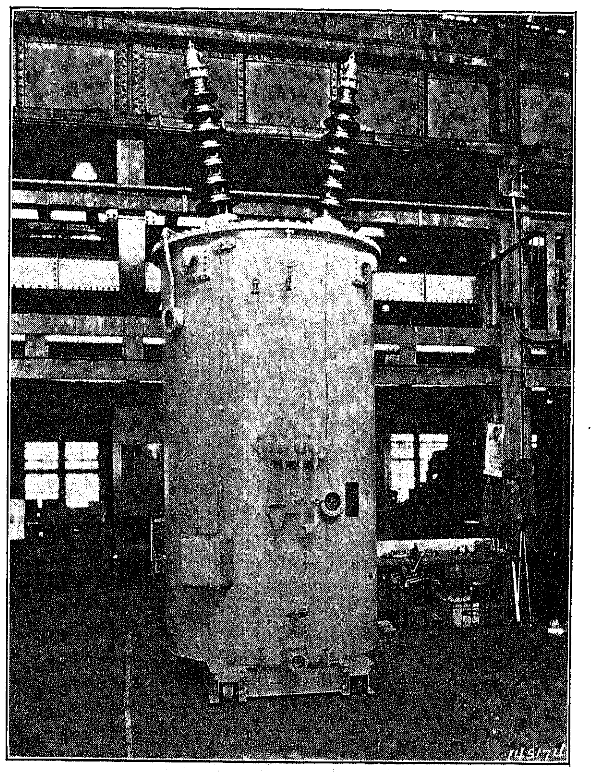

Fig. 2—The Inertaire Transformer

glass container and as the difference of color between the unused and spent portions is very pronounced, it is always easy to see how much unused material there is and hence to form a good estimate of the time when renewal will be necessary.

The reaction by which the compound removes oxygen from the air liberates a very small quantity of ammonia and, like nearly all reactions at moderate temperatures, requires a certain, although extremely small, amount of water. In order to prevent any water from this source or from humid atmosphere being carried over into the transformer, as well as to catch any traces of ammonia vapor which might be present, the nitrogen coming from the mixture is forced to pass through a generous charge of calcium chloride,

which is not only a very satisfactory dehydrator, but an extremely active and effective ammonia absorber as well.

An important and valuable feature of this deoxidizing mixture is its ability to function satisfactorily at all temperatures to which a transformer will ever be subjected. At −37 deg. cent. it continues to remove the oxygen completely, the only noticeable difference between this and at ordinary temperatures being a broadening of the line separating the unused and spent portions. It has also been operated successfully at 85 deg. cent. at which temperature it behaves just as it does at room temperatures.

The Inertaire Transformer in Detail

The equipment referred to in the opening paragraphs of this paper, as it appears on the Inertaire transformer, is shown in Fig. 2. The several features are described in detail in the paragraphs that follow.

The Chemical Container

The deoxygenating and dehydrating chemicals are contained in a glass jar which fits in the cabinet shown in the illustration. This jar contains about 50 lb. of the deoxygenating compound and a relatively small amount of dehydrating material. The cover is sealed in place like the cover of a battery jar with a compound which makes it gas tight. The chemicals, which of course, would begin to function immediately if exposed to the air, are in this way sealed at the manufacturer's works and they need not be handled from that time until they have become exhausted and the jar is discarded. Charging the Inertaire equipment with chemicals

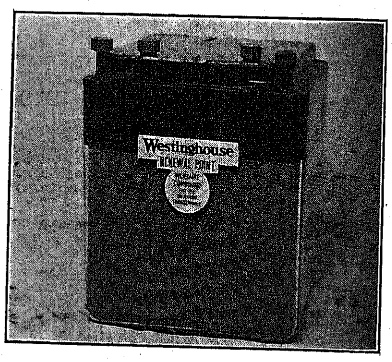

Fig. 3—Inertaire Compound in its Glass Container

requires simply placing the glass jar in the cabinet and making the four pipe connections which are necessary to complete the breathing circuit.

Air is drawn into this container at *a*, Fig. 4, by the suction which in-breathing action on the pipe *d* creates. It is drawn into the bottom of the glass jar and from there it passes upward through the deoxygenating compound. In this passage the oxygen is absorbed by the chemicals and nitrogen passes out at *d* and into the dehydrating chemical at *b*. Whatever moisture and traces of ammonia it contains are absorbed in its progress through this chemical. The dry nitrogen leaves the container at *c* on its way through the breathing regulator and into the gas space of the transformer.

There is a direct relation between the life of this charge of deoxygenating compound and the load cycle of the transformer, for changes of load by their temperature effects produce changes in oil volume and the expansion and contraction of the oil produce breathing. If the load is fairly steady, the breathing is moderate

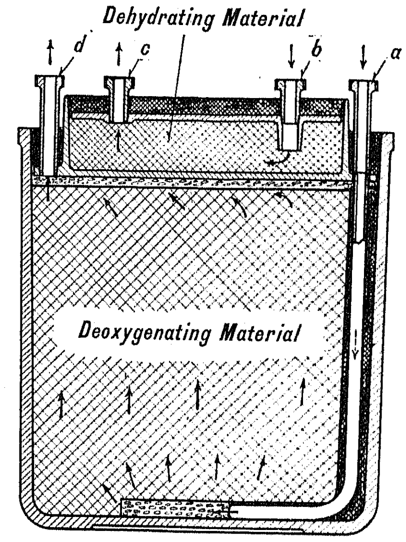

Fig. 4—Showing the Path of the Air through the Chemicals

and a charge of Inertaire compound should last as long as a year. If the load is widely fluctuating the charge may have to be replaced at the end of six months.

The decided change in the color of the deoxygenating compound as it functions is a useful characteristic. The line of demarcation between the used and the unused chemicals slowly advances from the bottom to the top of the jar as the deoxidizing action progresses. It can be seen clearly through the glass walls of the container and it forms an index of the condition of the chemicals and a guide for replacement.

A stock of Inertaire compound can be kept conveniently available for renewal purposes, since the sealed construction of the chemical containers makes it suitable for storing for indefinite periods.

The Breathing Regulator

The breathing regulator is the mechanism that controls and limits the natural breathing action of the transformer. It permits sufficient breathing to create and to maintain the inert gas body. In addition, it helps to conserve the gas body when it is once established. Lastly, by limiting the breathing, it reduces the burden upon the chemical compounds.

The breathing regulator functions as a two-way valve having characteristics which differ with the

direction of the pressure. It permits in-breathing of nitrogen into the transformer case with very little hindrance but when the conditions favor out-breathing, it interposes a barrier which prevents and delays actual out-breathing of nitrogen until the pressure within the transformer case reaches a certain predetermined point. At this point the regulator opens and allows the escape of sufficient nitrogen into the atmosphere to maintain the internal pressure below the predetermined point. In-breathing occurs only when the pressure within the transformer case becomes less than atmospheric. After a rise of oil temperature and an accumulation of pressure, due to the functioning of the breathing regulator, the oil temperature may decrease considerably before this accumulated pressure is reduced to the

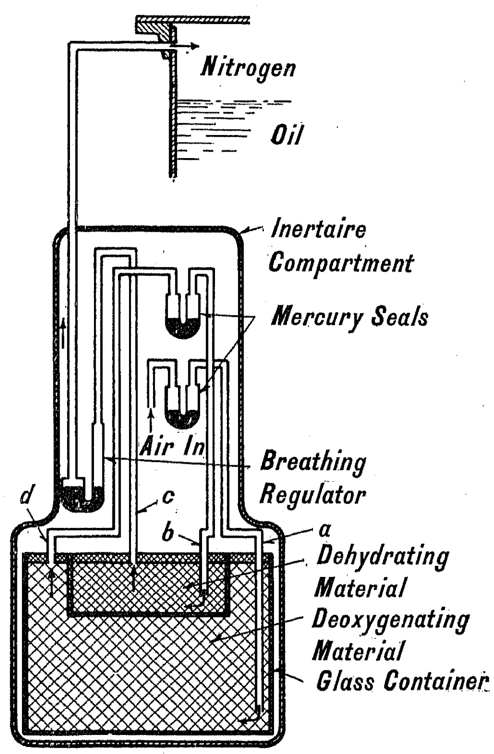

FIG. 5—DIAGRAMMATIC SKETCH SHOWING THE ARRANGEMENT OF THE PARTS OF THE INERTAIRE EQUIPMENT AND THE PATH OF THE BREATHED GAS

atmospheric point. During this period of cooling, which without the regulator would be an in-breathing period, no actual breathing action takes place. The regulator, therefore, not only conserves the gas body when oil temperatures are rising, but also delays and reduces in-breathing when temperatures are falling. Both actions reduce the demands made upon the chemicals and result in economy in the production of the nitrogen.

It is possible, though very unusual, that the load carried by a bank of ordinary transformers might be so steady and so free from fluctuations that the oil level would remain practically stationary and the breathing be nil. The condition of practically no breathing can be maintained with the inertaire equipment, even when there are fluctuations of load so long as they are within the range of the breathing regulator. There are, no doubt, many installations where Inertaire transformers can carry their ordinary cycles of load within the range of the breathing regulator and with no actual breathing and no burden upon the chemicals.

The breathing regulator is simply a mercury manometer, or U-tube, having refinements of structure

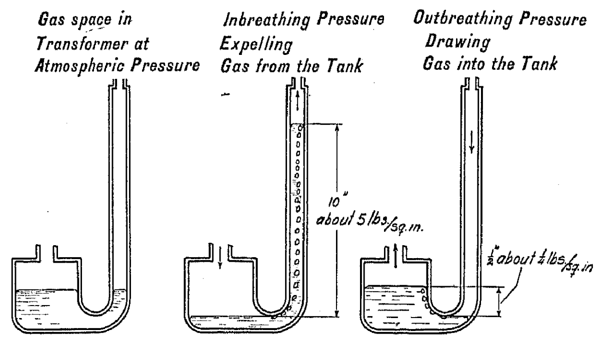

FIG. 6—SKETCHES SHOWING THE U-TUBE ACTION OF THE BREATHING REGULATOR

which cause it to carry out its functions without the possibility of blowing the mercury out of its proper channels when it operates. It is normally a closed valve which cuts off communication between the transformer case and the atmosphere. It becomes an open valve when the pressure in either leg is sufficient to lower the level of the mercury below the bend of the U-tube. When this point is reached communication is established between the two legs of the tube, and gas

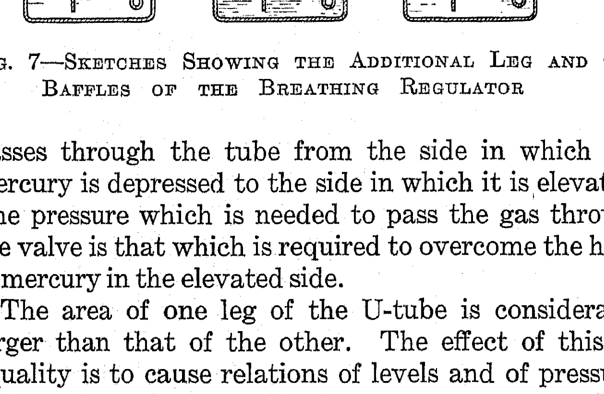

FIG. 7—SKETCHES SHOWING THE ADDITIONAL LEG AND THE BAFFLES OF THE BREATHING REGULATOR

passes through the tube from the side in which the mercury is depressed to the side in which it is elevated. The pressure which is needed to pass the gas through the valve is that which is required to overcome the head of mercury in the elevated side.

The area of one leg of the U-tube is considerably larger than that of the other. The effect of this inequality is to cause relations of levels and of pressures which differ with the direction of the pressure. It is

evident from Fig. 6 that greater pressure is needed to pass gas from the leg of large area to the leg of small area than in the reverse direction.

The large leg is connected to the gas space above the oil level of the transformer. The small leg is connected to the jar containing the chemicals. To breathe outwardly, the pressure in the transformer case must be enough to raise the mercury level in the small leg to a height of about 10 in., *i. e.*, 5 lb. per sq. in. In-breathing, on the other hand, can take place against a head of ½ in. of mercury, or about ¼ lb. per sq. in.

Fig. 7 shows schematically how the actual construction of the regulator combines the principle of the simple U-tube with a duplicate small leg and a set of baffles. When the excess is in the large leg of the regulator, the mercury is depressed in that leg and elevated in both of the small legs *a* and *b*. When the pressure reaches 5 lb. per sq. in. in the transformer

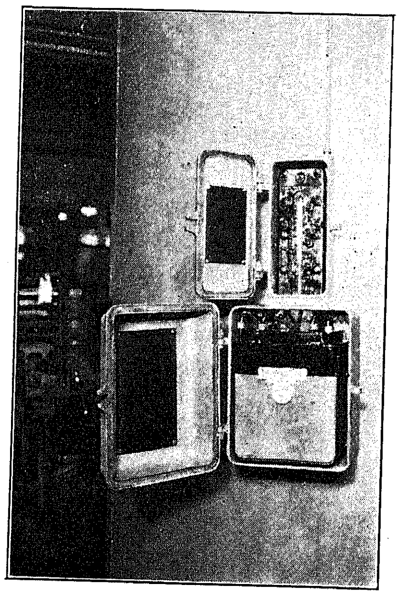

Fig. 8—The Cabinet Containing the Inertaire Compound and the Breathing Regulator

case and in the large leg, a passageway is opened into the leg *a*, but the mercury still seals off the connection into leg *b*. The nitrogen consequently finds its way up through the mercury in leg *a* and out to the atmosphere through the chemical container.

The purpose of the extra leg and the baffles is to prevent beyond question the carrying over of mercury with the gas when movement of the gas in either direction takes place. When the gas passes upward through the leg *a*, whatever mercury might be thrown over the top of the tube by a particularly high breathing rate is deflected back into the tube *b* by the baffle shown at *c*. When the action is in the reverse direction, the movement of nitrogen is down the leg *a* and the baffle at *d* serves to return to the well of the large leg any mercury that might tend to pass over with the nitrogen when the in-breathing rate is particularly high. This type of breathing regulator has been tested with breathing rates in both directions, ranging from small values to rates which are twenty times as high as the maximum that normally occur in power transformer service. No mercury has been carried over with the gas in these tests and the construction has been demonstrated to be an effective guard against such an occurrence.

In the actual construction of the breathing regulator, shown in Fig. 8, the mercury in leg *a* is visible through a window at the front of the regulator. A scale marked in pounds per square inch is provided in the cover adjacent to this window. The level of the mercury in connection with this scale indicates directly the condition of pressure within the transformer case. The small mercury seals, which are shown diagrammatically in Fig. 5, are placed in the middle portion of the breathing regulator. At times when there is no breathing, one of these seals isolates the deoxygenating chemicals from the atmosphere and one serves as a barrier between these chemicals and the dehydrating chemical. The levels of the mercury in these seals are visible through the small windows shown in Fig. 8.

The curves in Figs. 9 to 16 show the breathing action of an 8333-kv-a. transformer under various conditions. They illustrate the performance of the breathing regulator in limiting the breathing action, thus conserving the nitrogen body and the deoxygenating and dehydrating chemicals.

Initial Displacement of Air from the Gas Space

Since it is desirable to start a transformer in service with inert gas in the gas space rather than to wait for the natural breathing gradually to dilute and displace the air originally present, some means should be provided for either removing the oxygen quickly from the air already in the transformer, or replacing it at once with an inert gas. While the former method is entirely feasible, the method of displacing the air immediately with inert gas from a cylinder is so simple and so convenient that it is recognized as the preferred practise.

The Inertaire equipment includes a fitting at which a gas cylinder may be connected. It is provided with a special device which restricts the flow of gas, with the high pressure of the cylinder behind it, to a reduced

rate which effectively and safely displaces the air from the gas space in a short time. When the cylinder is exhausted, it may be returned to the nearest of the numerous points of manufacture of nitrogen and a fresh supply may easily be obtained, if at any time it becomes necessary to open the transformer case for inspection.

the abnormal pressure following an arc is often great enough to disrupt the tank at its weakest point if no effective relief means are provided.

The accepted means of protecting a transformer case against abnormal internal pressure is to provide a thin diaphragm of some suitable material which is ruptured by the pressure should it become dangerous.

The Relief Device for Abnormal Pressure

The inert gas body above the oil level of an Inertaire transformer makes explosions in that space impossible. It is always possible, however, that some fault under the oil level may result in a primary explosion. While the wave-front of pressure created in this way is not so steep as that of a secondary explosion of hydrogen and air above the oil level and the results are not so violent,

The relief device of the Inertaire transformer forms part of the manhole opening in the cover. It consists of a circular diaphragm of thin sheet micarta which is clamped to a support placed directly beneath the manhole cover. The manhole cover itself rests upon the gasketed surface of the diaphragm support and it is free to move upwardly except for its weight and the retarding action of a number of heavy springs. The diaphragm is clamped in position with a ring and a

gasket, forming under normal conditions a seal which is gas and oil tight. The completely assembled mechanism is bolted down against a gasket on a machined flange which forms part of the transformer cover. This construction has the advantage of effectively exposing a large diaphragm area directly to the seat of internal disturbances and it requires no room in addition to that taken up by the usual manhole opening.

If an abnormal pressure develops inside the transformer case, the diaphragm is ruptured. The impact of the pressure against the manhole cover raises it almost instantly and forms an annular opening around

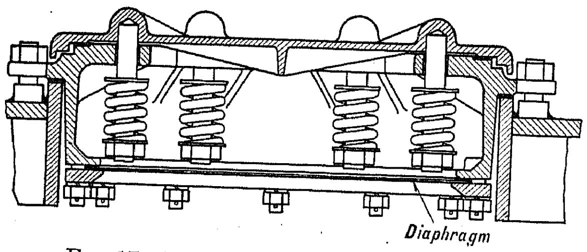

Fig. 17—The Inertaire Relief Device

its periphery through which the pressure is relieved. The springs absorb the energy imparted to the rising cover and quickly bring it back to its original position, in which it closes the annular opening. This prevents the discharge of oil or the entrance of water or diffusion of air into the case.

When the manhole opening is to be used for entrance into the transformer case, the outer row of bolts is removed and the complete assembly is withdrawn, leaving a full-size opening in the cover. It is unnecessary at such a time to disturb the diaphragm

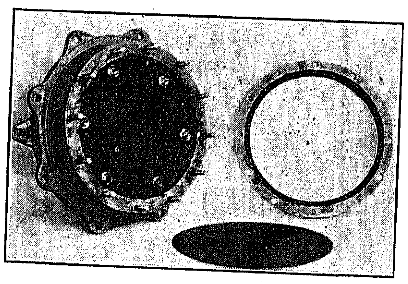

Fig. 18—Parts of the Inertaire Relief Device

itself. Fig. 17 shows a line drawing of a section of the complete mechanism and Fig. 18 shows the parts.

The selection of a suitable material for the diaphragm is a matter of some importance. In order to be reliable it must have a uniform rupturing characteristic under the conditions presented in relieving abnormal pressures. It must, at the same time, be a material of sufficiently substantial nature to be handled easily without the danger of accidental breakage. Of the three principal materials available for the purpose—sheet micarta, glass and thin metals—sheet micarta has been proven to be the most satisfactory. It is a laminated fibrous material which is bon[d] bakelite under heat and pressure. It is una[ff] oil, gas or water. It has strength, tough[n] flexibility and yet when subjected to shock in of a thin sheet securely clamped around its edge an almost brittle characteristic not unlike glass causes it to be shattered with a very fair [d] uniformity in its performance. The mica[r] phragms used in the Inertaire relief device are in thickness and 13 in. in diameter. These dia[p] rupture at approximately 10 lb. per sq. in.

An alarm mechanism is provided as part Inertaire relief device which gives a visual sem indication at the transformer and a distant alarm when the diaphragm is ruptured. When the m cover rises, a rod which is hooked in a lug on th is released. A spring causes it to project a sem over the edge of the cover and to close a set o contacts. The semaphore enables an attend

locate the particular transformer in which troubl occurred. The alarm device may be seen on the of the transformer shown in Fig. 19.

Tests of an Inertaire Transformer with Abnormal Internal Pressures Suddenly Applied

A number of tests was made in a preliminary way on a small scale to illustrate what happens in a when arcing occurs under the oil level. A round b iron tank, 16 in. in diameter and 28 in. high, desi for a circuit breaker, was used for these tests and were created between electrodes placed under th level and fed by a 50-kv-a. transformer.

Fig. 20 shows a time-pressure curve obtained wh gas space above the oil level, with a depth of 4½ was filled with nitrogen. The rise in the pres curve is very gradual and the maximum pressur limited to a very small value. It will be observed f

the curve that there is no secondary explosion because the nitrogen above the oil level makes such an explosion impossible.

Fig. 21 shows what happened with all the conditions the same except that the space above the oil level was filled with air. At first, the rise of pressure was gradual, as before, but when the mixture of disruptured oil

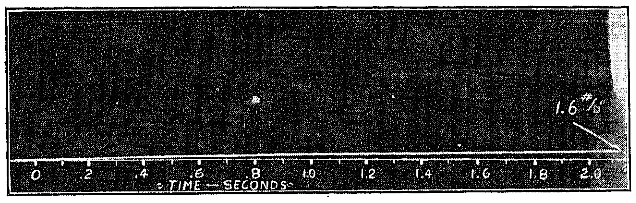

FIG. 20—"PRESSUREGRAM" OF A SMALL-SCALE PRIMARY EXPLOSION, WITH A CUSHION OF NITROGEN

gases and air in the air space came within the explosive limits, a secondary explosion occurred and it will be noticed that the pressure jumped very suddenly to a comparatively high value.

Fig. 22 shows the pressure resulting under the same conditions, except that the tank was filled completely,

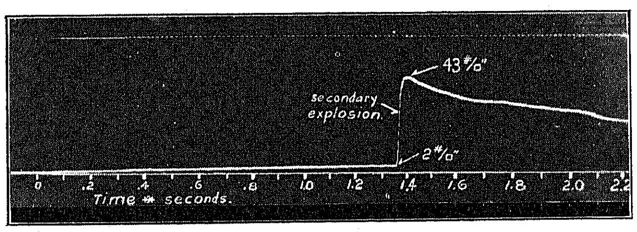

FIG. 21—"PRESSUREGRAM" OF SMALL-SCALE PRIMARY AND SECONDARY EXPLOSIONS, WITH A CUSHION OF AIR

with no gas or air space. There is, of course, no secondary explosion but the pressures due to the primary explosion are seen to be very much greater than those due to primary explosions of Figs. 20 and 21. These curves illustrate the protective effects of a compressible cushion of gas or air in reducing the

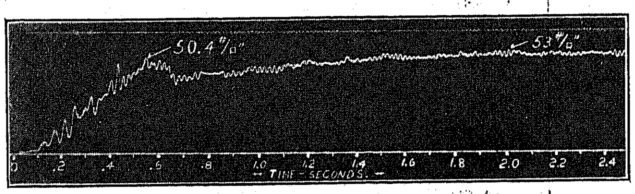

FIG. 22—"PRESSUREGRAM" OF A SMALL-SCALE PRIMARY EXPLOSION, WITH TANK COMPLETELY FILLED WITH OIL

internal pressures due to arcing, and the value of the inert gas as the cushion.

Following these small-scale tests, a complete set of explosion tests was planned and carried out on a full-size transformer tank to demonstrate first, whether the standard case construction for a power transformer would successfully withstand internal pressures equivalent to those created by arcs under the oil level; second, to determine how the Inertaire diaphragm relief device would function when called upon to relieve internal pressures of an explosive nature; and third, to get actual data regarding the effects on internal pressures of gas cushions of different volumes.

As a convenient method of obtaining definitely correlated results in large scale tests, a plan of using gunpowder bombs for producing explosive effects was worked out and adopted. These bombs were designed and made up in standard units, 1 ¼ in. in diameter and about 3 in. long, containing 40 g. of Dupont FFFG black powder. Considerable care was taken in weighing the powder and in loading the tin containers in order to get uniformity. An electric squib was embedded in the powder for firing purposes. Having a standardized unit of this kind made it possible, by using a number of them in multiple, to get a range of explosions of definitely related intensities.

Considerable thought was given to suitable means for measuring the instantaneous pressures during the tests. Through the courtesy of the engineers of the Bureau of Mines in Pittsburgh, the engineers of the

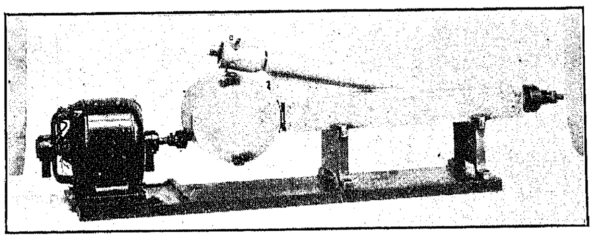

FIG. 23—PRESSURE INDICATOR, BUREAU OF MINES TYPE

Westinghouse Company were fortunate enough to obtain instruments which had been developed and used successfully for the purpose of recording the instantaneous pressures occurring in mine explosions.

This pressure indicator, shown in Fig. 23, has a specially hardened circular steel disk clamped around its periphery in a frame and having one face exposed to the pressure to be measured. Deflections of this disk are transmitted by a small pin to a pivoted mirror, which reflects a beam of light from a fixed point source onto a strip of sensitized film on a revolving drum. Instantaneous pressures exerted on the steel disk are faithfully reproduced by the line traced on the film. A time scale is also recorded on the film. With this time scale and a calibration of pressures, the resulting pressuregrams may be thoroughly analyzed and studied.

The transformer case used for the explosion tests was a round boiler iron tank, 72 in. in diameter and 134 in. high, belonging to a 6667-kv-a. 66000-volt transformer. A flat boiler-iron cover of standard design was bolted down on a ring flange with a cork gasket between. The usual bushings were removed, since they played no part in the tests to be made and their openings were covered with blind flanges. The Inertaire diaphragm

relief device was mounted in the cover and used in all tests except those in which the tank was completely filled. A transformer was placed inside the tank in order to produce the same interference or reflections of pressure waves from the surfaces of the transformer that might be present in ordinary service. One of the pressure indicators was used to measure pressures in the gas space, while three others of the same type were placed to record the pressures at different heights under the oil level. The gas given off by the exploding bombs consisted almost entirely of carbon dioxide

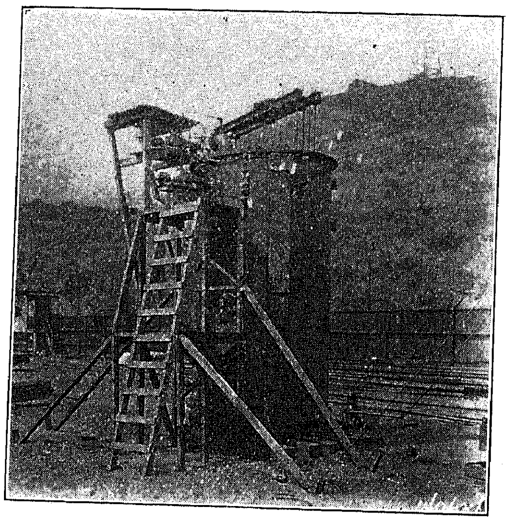

Fig. 24—Set-Up of Transformer for Explosion Tests

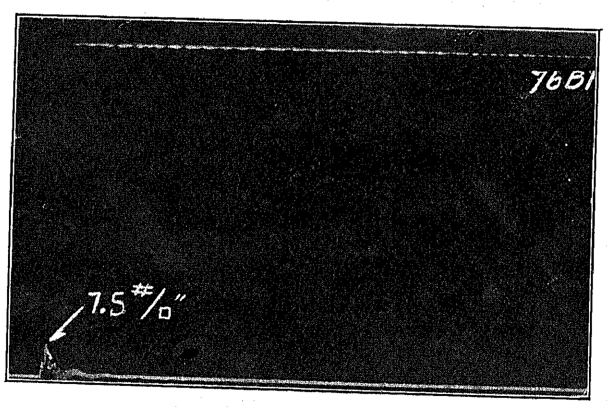

Fig. 25—"Pressuregram" of a Large-Scale Explosion with 120 Grams of Powder. Depth of Gas Space, 12 in.

and nitrogen, and since in this case there was no danger of a secondary explosion above the oil level, no effort was made during the tests to maintain an inert gas in the gas space.

The pressure indicators and the firing of the bombs were controlled electrically from a distance with all of the operations effected automatically in their proper sequence. The throwing of a single switch first started the d-c. motors operating the film drums and after allowing them sufficient time to attain constant speed, lighted the timing lamps and exploded the bombs. Fig. 24 shows the arrangement of the transformer case, the pressure indicators and the wires leading to the control point.

Approximately 90 explosion tests were made with the

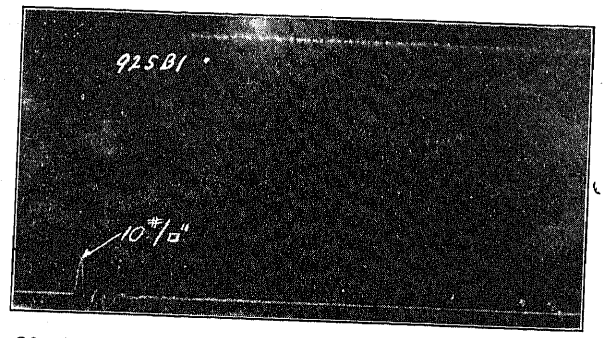

Fig. 26—"Pressuregram" of a Large-Scale Explosion with 120 Grams of Powder. Depth of Gas Space, 10 In.

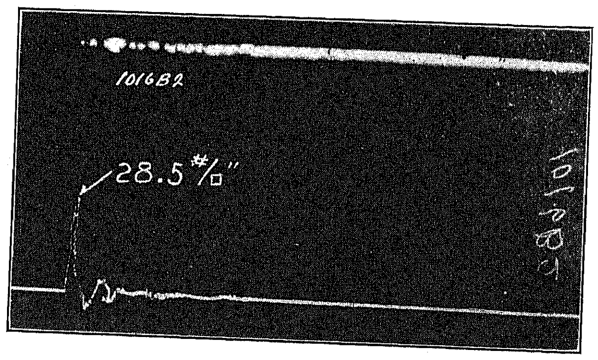

Fig. 27—"Pressuregram" of a Large-Scale Explosion with 120 Grams of Powder. Depth of Gas Space, 4 In.

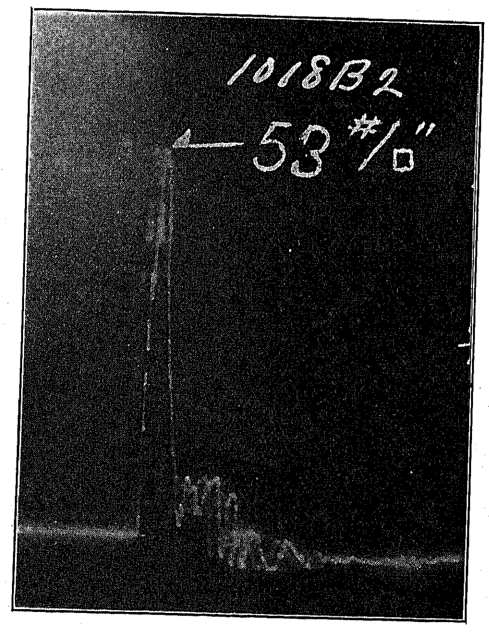

Fig. 28—"Pressuregram" of a Large-Scale Explosion with 120 Grams of Powder, with Tank Completely Filled with Oil

gunpowder bombs. During these tests gas spaces were used ranging from a depth of 12 in. below the cover to zero, where the tank was completely filled with oil. In the tests with the tank completely filled with

oil, an expansion tank was used for the overflow, and the usual relief diaphragm was placed in a pipe elbow above the oil level in the expansion tank. In all tests the bombs were placed uniformly 24 in. below the cover, near the center of the tank.

A detailed report of the results of these explosion tests must be reserved for other papers on the subject, since it would be too lengthy to include in the present paper, but typical results are shown in the pressuregrams in Figs. 25 to 28.

Fig. 29 shows a curve of maximum peak pressures measured in the gas space for different depths of gas space measured in inches. The curve shows in a striking way the important effect of the gas cushion in reducing internal pressures. It is interesting to note that the curve is beginning to flatten out when gas spaces corresponding roughly to the present air space practise are reached.

A rough idea of the equivalent arc-energy of these gunpowder explosions may be obtained from cal-

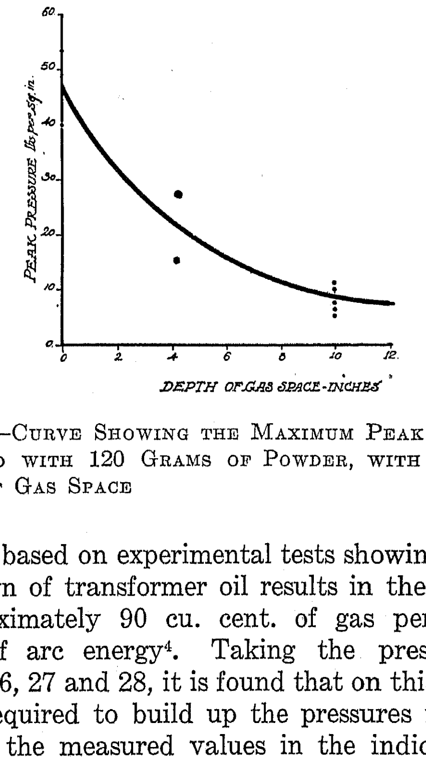

Fig. 29—Curve Showing the Maximum Peak Pressures Developed with 120 Grams of Powder, with Different Depths of Gas Space

culations based on experimental tests showing that the breakdown of transformer oil results in the evolution of approximately 90 cu. cent. of gas per kilowatt second of arc energy[4]. Taking the pressuregrams in Figs. 26, 27 and 28, it is found that on this basis the energy required to build up the pressures in the gas space to the measured values in the indicated time interval appear as given in Table II.

TABLE II
CALCULATED EQUIVALENT ARC-ENERGIES FOR THE EXPLOSIONS OF FIGS 25 TO 27.

Figure	Depth of Gas Space	Peak Pressure Lb./Sq. Inch	Time Interval to Peak-Seconds	Kilowatts Seconds	Kilowatts
26	12 in.	7.5	0.016	4550	285,000
27	10 in.	10.	0.018	5050	280,000

4. Arc Action on Some Liquid Insulating Compounds, by C. J. Rodman, *American Electrochemical Society*, Sept. 25, 1922.

These particular explosions were each made with three 40-g. bombs representing the same explosion energy and the values for arc energy check each other within reasonable limits of accuracy. They indicate that it is reasonable to think that the explosions made with 120 g. of gunpowder are not of a different order from those which can be expected from a fault in a transformer under modern conditions.

Explosion tests were made with as many as twelve 40-g. bombs and from the foregoing tabulation it is evident that they represent arc energy in extremely large amounts. In one of the early tests made with 200 g. of powder, one of the vertical welded seams of the tank was opened up for a distance of several inches; it was found that in making the tank these vertical seams had been welded only on the outside, instead of both inside and outside. After the seams were welded also on the inside the case successfully withstood all of the later explosions of greater intensity. In all of the explosions made with gas cushions, the Inertaire relief device functioned perfectly and relieved the internal pressures without damage to the case, with the exception of the incident just noted. With the exception of those explosions made with gas spaces of such small volume that the oil was on a level with, or above, the diaphragm, which is not a condition to be met with in practise, the quick operation of the relief device in returning to its closed position prevented the throwing of oil, which is remarkable, considering the severity of the explosions.

The principal conclusions to be drawn from these tests are:

1. Secondary explosions with their steep wavefronts are eliminated by the gas space of the Inertaire transformer.
2. The gas cushion is very effective in reducing the internal pressures due to a primary explosion under the oil level.
3. Round boiler iron tanks of standard construction, when protected by a gas cushion and an effective relief device, are sufficiently strong to withstand the shock of extremely abnormal internal pressures of short duration.
4. The Inertaire relief device is remarkably effective in protecting the transformer case against the shocks of extremely abnormal internal pressures and are quick enough in operation to prevent the throwing of oil at such times.

Resume of the Advantages of the Inertaire Transformer

The blanket of inert gas gives the maximum of protection to the oil against deterioration from oxidation or moisture. Sludging troubles are minimized and no filtering or cleaning of the oil is necessary. It is expected that the oil will even improve with service, due to the gradual elimination of the dissolved air.

The possibilities of fires and explosions above the oil level are eliminated. It should represent a better fire risk than other types of transformers.

The destructive effects of internal pressure due to arcing under the oil level are minimized by the gas cushion and the relief device.

It is simple and automatic in operation and the cost of maintenance is thought to be not greater, and perhaps less, than the usual cost of filtering and cleaning the oil.

The authors wish to acknowledge the work done in connection with the Inertaire Transformer by L. H. Hill, A. J. Maslin and L. E. Rossel, of the Westinghouse Company's Engineering Department, and to C. J. Rodman, A. H. Maude, W. C. Wilharm, C. A. Styer and J. G. Ford of the Westinghouse Research Laboratory.

The chemical part of the research work on deoxidizing materials has been under the immediate direction of C. J. Rodman. It is very largely due to his vision, persistence and faith, that the problem has been solved and the authors wish to express here their appreciation of his work.

Discussion

A. H. Maude: Transformer oil, in common with most liquids dissolves the gases of the atmosphere to some slight extent. Though the quantity of oxygen which can be held in solution by transformer oil is very slight when expressed in weight units and insufficient to produce any appreciable quantity of oxidation products, it would nevertheless, be sufficient to destroy the effectiveness of the inert atmosphere of the Inertaire transformer should any large part of it diffuse from the oil into this atmosphere. It is well known that any gas thus held in solution will readily diffuse out into an atmosphere of some other gas until a certain equilibrium depending on the partial pressures and solubilities of the gases present is reached.

The above facts being indisputable it became necessary in the course of the development of the Inertaire transformer to go pretty thoroughly into this matter and determine some solubility constants not heretofore published and work out methods to analyze oil for these gases which will be published in a future paper. However, the solubility of the gases of the atmosphere in "Wemco A" oil can now be stated as follows:

	Gas temp. Deg. Cent.	Coeff. of absorption cc. of gas per cc. of solvent.	Solubility g. of gas per g. of solvent
Nitrogen.......	25	.0925	.000127
Oxygen........	25	.1705	.000266

From these figures by the application of the law of partial pressures it follows that this oil when in equilibrium with air will contain per cc. the following in solution:

Nitrogen...............	.0734 cc.
Oxygen................	.0353 cc.
Total..................	.1087 cc.

Now, if this oil has stood in contact with air so long as to reach an equilibrium with it and is then used in an Inertaire transformer it will, as soon as the air above the oil has been swept out by the inert gas, commence to liberate the oxygen it holds in solution.

Another factor of importance in this discussion is the chemical combination which is known to go on between oxygen and transformer oil and possibly goes on with structural materials of the transformer as well.

To find out what influence these factors, *i. e.*, physical solution and chemical combination, will have on the Inertaire transformer atmosphere it seems desirable to answer, at any rate approximately, the following questions.

1. How much oxygen will, in this way, be introduced into the inert atmosphere?
2. Will this oxygen be chemically reabsorbed and, if so, how quickly?
3. How quickly will oil exposed to air dissolve oxygen?
4. How much oxygen does transformer oil customarily carry in solution?

From the experimental data available it may be said that, if air-saturated oil be charged into an Inertaire transformer in which a gas space of the usual proportions is used, between 7 and 8 per cent of oxygen may be expected in the atmosphere one or two days after all air has been swept out, this quantity of oxygen having diffused out of the oil in which it had been held in physical solution. The oxygen will after this be slowly reabsorbed by chemical combination with the oil, but would take many weeks to be eliminated.

These difficulties can be overcome by using oil free from dissolved oxygen. The oil could be freed from this either by treatment under vacuum, by bubbling nitrogen through it or else the atmosphere can be cleared of oxygen on 2 or 3 successive days as has been heretofore done in the installation of the inertaire transformer. Otherwise, the nitrogen used initially to displace the air in the transformer can be bubbled through the oil thus displacing oxygen in solution as well as the oxygen in the atmosphere.

With regard to the rate at which oil will take up a gas by solution, this seems to be considerable and leaves no doubt that oil left exposed to the atmosphere or handled with pumps drawing in air around glands or pistons will contain some considerable quantity of oxygen in solution.

It was experimentally determined that 10 sq. cm. of tranquil oil surface with a large depth of gas-free oil beneath it will absorb 1 cc. of gas in 7 minutes.

The following results were obtained by analyzing various samples of "Wemco A" oil for dissolved gases:

	Per cent by Volume of Gas. N_2	O_2	CO_2	Total
Oil from sealed can..........	6.1	.2	.0	6.3
Oil from pump from storage tank (No. 1)............	6.0	2.5	.2	8.7
Oil from pump from storage tank (No. 2)............	9.1	3.3	.2	12.6
Oil from transformer with air atmosphere............	7.0	2.2	.2	9.4

These figures point to the conclusion that oil except when it comes from a sealed can must be expected to contain oxygen in solution and precautions must be taken in some one of the above ways of preventing this oxygen from contaminating and reducing the effectiveness of the inertaire gas cushion as a preventative of explosion and as a preserver of the oil.

L. H. Hill: It was my privilege to supervise the installation of the first Inertaire transformers, seven 8333 kv-a., 66000 volt units at the Grand Tower Station of the Middle West Power Company.

One of the interesting things noted in connection with this installation was that the oxygen content in the gas space before any nitrogen was blown or drawn in was only about 17 per cent, instead of 20.7 per cent, which is the oxygen content of the atmosphere. These transformers had been set up and the gas space closed some two or three months before these analyses were made and no breathing is believed to have taken place in that time. The reduction in oxygen content is largely due to slow oxidation of the oil. Oxygen is also somewhat more soluble in oil than nitrogen, which would also make for a reduction in oxygen content in the gas space.

This question of absorbed gases in the oil appears in another connection. The oxygen was initially removed from the gas space of the Middle West Transformers by blowing in nitrogen from a cylinder. The oxygen was reduced to less than 1 per cent by this method. After the transformer had stood over night it was found that the oxygen had come up to 3 or 4 per cent. After blowing down again to less than 1 per cent, the oxygen came up to about 2 per cent the next day and remained around this figure.

Tests previously made have shown that practically perfect mixing of the gases is obtained during the blowing-in process, so it is logical to assume that the increase is due to the oxygen coming out of the oil.

During the first week that the transformers were in operation the load curve showed about one-third to one-half full load for eight hours during the day, with no load during the remainder of the time. The breathing regulators prevented breathing entirely during this period, which shows the value of using a breathing regulator with the Inertaire transformer.

D. R. Dalzell: I think we will all agree that there are two distinct types of explosions that have occurred in transformers, namely, the rapid generation of gas due to decomposition of the oil by internal arcing, or, as it is termed by Messrs. Dann and Kellogg, a primary explosion; and also an explosion of secondary nature, due to the ignition of a gaseous mixture above the oil level in the tank. In the first case, the rate of increase of pressure is a function of the energy liberated at the fault, and occasionally may be so great as to produce effects much the same as those following a secondary explosion.

In the case of the ordinary "open" type of transformers not having their tanks completely filled with oil, a few secondary explosions have been experienced. These usually resulted in the cracking or breaking of the cover and sometimes the tank, and in a few cases burning oil was thrown about, with serious damage to the station. The usual cause of these explosions was arcing or static discharge on the exposed portion of the leads above the oil level, igniting a mixture of air and gases due to internal arcing in the oil.

The primary explosions, having a less sudden increase in pressure, usually blew off the manhole cover, and were not generally attended by burning oil above the surface. These were caused an internal failure in the windings.

It was realized that although explosions had occurred on only a very small percentage of transformers, yet their seriousness warranted all possible study to determine means of preventing them and minimizing their consequences.

Of the study made on this subject, beginning as early as 1913, it will be of interest to relate briefly those tests illustrating that a relief diaphragm would not protect the tank from secondary explosions.

Tests were made to determine whether an explosive mixture of gas and air could be produced above the oil level by arcing under oil, and also whether a diaphragm covering the manhole opening would break and prevent damage to the tank in case of a secondary explosion. A large transformer tank was nearly filled with oil, and arcs passed between electrodes under the oil, thereby generating gas which mixed with the air. Horn fiber diaphragms of thickness ranging from 5 to 10 mils. were placed over the manhole opening. A spark-gap was located above the oil to explode the gas.

Preliminary tests were made to determine the most explosive mixtures of gas and air, and when this value, about 40 per cent gas, was obtained, the gas exploded, resulting in the breaking of cover bolts, breaking and lifting of the cover, and scattering of burning oil. The diaphragm was destroyed, but failed to protect the cover.

Similar tests were made using an oil seal between the cover and tank. In this case, the tank was nearly filled with water, then oil added up to the normal oil level. Gas was introduced to the air space and the mixture ignited. Again the cover was blown into the air, proving that the seal was of no value.

One of the earliest steps (about 1910) taken to prevent the ignition of gas above the oil, was to place a metal shield around the lead, extending from the cover to a point below oil level, and grounded to the cover. This ground shield of course prevented arcing between leads or any static discharges, and has since been generally adopted as a standard construction in terminal bushings.

The next scheme tried was that of filling the space in the tank above the oil with a gas chemically inert, using a gasometer with which to maintain slight constant outward pressure and a tube of gas from which the gasometer was replenished when necessary. Patent No. 1,326,049 covering this combination, was issued to Mr. F. C. Green, a General Electric Field Engineer, (now deceased). The first test, using carbon dioxide gas, was on some 750-kv-a. transformers at the Remington Arms Plant at Ilion, N. Y., in March, 1916. In May of the same year, a 5000-kv-a. transformer of this type was installed at the Narragansett Electric Co., Providence, R. I. Considerable difficulty was experienced in reducing the outward leakage of gas to a reasonable amount, since the sealed cover construction, as we now know it, had not yet been completely developed. While this scheme no doubt would have been effective, yet it was at best an inconvenience to the operator to maintain.

In the meantime, the conservator was being developed by the General Electric Co., the first installation being made at Laurinsburg, N. C., later in 1916. This construction, with its completely oil-filled main tank, absolutely prevented any further secondary explosions. A pressure relief, consisting of a thin metal diaphragm mounted above the oil level in the end of a large pipe on the cover, was provided to take care of any increase in pressure due to generation of gas from internal failures.

In addition to this function, the conservator also prevented moisture from entering the main transformer tank and prevented air from coming in contact with hot oil, together with the re-

sulting possibility of sludging. Therefore, since we believed that the conservator provided all the advantages of inert gas, without requiring any attention from the operator, and that the possibility of damage to the tank from primary explosions was so remote, no further experiments of this nature were made.

Our subsequent experience with this type of transformer has been that to date, with about 1600 units in service having a total rating of over 8,000,000 kv-a., so far as we know there have occurred explosions in only 15 units, all of these being of the primary type of explosion previously mentioned. In only 5 has any damage resulted to the tank or cover, the diaphragm in all other cases relieving the pressure. Where tank damage resulted, it was in the earlier types using a metal diaphragm, which was found bulged, but did not break quickly enough to prevent the manhole cover from being blown off or the cover from cracking. Of course, as the diaphragm bulged, it automatically increased its strength against bursting.

These cases emphasized the necessity of using a diaphragm having a definite breaking point, independent of the suddenness of the applied pressure. With this in view, thin glass was adopted several years ago, and in no case has this failed to function properly.

The service record of the conservator units just outlined indicates that the standard construction of conservator with pressure relief will dissipate any except extraordinary pressures without damage to a reasonably strong tank.

In the application of an inert gas as a further precaution a against harmful pressures, we have favored the maintainence of the gas pressure by an auxiliary supply tank rather than by an automatic breather, primarily because of the uncertainty of the latter type and secondarily because of its demand on operating attention. It should not be overlooked that if a slight leak develops in any of the joints above the oil level when an automatic breather is used, there is no very convenient means of detecting the presence of oxygen and moisture which may be drawn in through such leaks, whereas with a slight pressure maintained at all times by an auxiliary tank, we have an easy and positive method of discovering leaks in the same manner as oil leaks are discovered in a conservator transformer.

Any inert gas may be applied to the conservator transformer by extending the pipe from the auxiliary oil tank down into the main tank far enough to form a pocket for the gas which may be introduced from commercial containers. Any outward leakage of gas would be indicated by a gradual dropping of the oil in the oil gage on the conservator. Expansion and contraction of the oil takes place in the usual way in the conservator, and the gas-cushion remains undisturbed. Such a pocket may also be formed by inverted chambers located at any convenient place in the tank directly under the cover, and when so located, there is retained the advantage, inherent in the conservator construction, of having any leak made visible by oil. This construction also obviates the necessity for periodic changing of the deoxidizing chemicals in the breather of the "Inertaire" construction.

C. F. Scott: The authors of the paper have set out the desirable results to be obtained in the handling of transformer oil and then have shown how, by a very simple means, these results are accomplished. The simplicity of the results is sometimes an indication of the difficult path and the many problems which have occurred in the solution of the problem. The result in this case seems to be a very happy one as the effective prevention of oxidation is secured by means which can be added in a simple way to present transformers provided their cases are tight.

The operation of electrical apparatus meets various limitations. Temperature is one of the most serious and in general the reason why temperature is serious is because it causes deterioration of materials. I remember the story of a discussion between Mr. Westinghouse and a theoretical engineer who was quibbling about rise of temperature and insisting upon some very low figures. Mr. Westinghouse suddenly asked him why not operate the machine red hot if it did not damage the insulation? The present paper does show that when oxygen is not present the oil maintains its integrity at a very much higher temperature, hence the temperature limitations usually applied to transformers can be very considerably raised in so far as the oil itself is concerned. If other materials are found which can be used as solid insulating material in transformers which are durable at higher temperatures than at present, then the way is open for operating them at present temperatures with higher factors of safety. Under emergency conditions of extreme overload, Inertaire transformers should be found serviceable and safe.

This transformer, therefore, appears to me to meet satisfactorily some of the present difficulties and limitations in transformer operation by preserving the oil, and it also indicates a way of making safe the operation of the transformer at higher loads and higher temperatures.

W. M. Dann: The discussion on this paper seems to bring out the fact that it is agreed that an inert gas is a very desirable thing to use in a transformer. A point that ought not to be overlooked is that while the freedom from the dangers of both primary and secondary explosions which the Inertaire transformer gives is a decided advantage from the insurance point of view, it is by no means the prime consideration in advocating its use. The elimination of the injurious effects of oxygen on the oil is a feature which, apart from the insurance against explosions, makes the use of the Inertaire transformer economically well worth while.

I think that Mr. Dalzell's feeling that the automatic breathes of the Inertaire transformer involves uncertainty is wrong and is probably due to his not having actual experience with its operation in service. It is very simple and is very much freer from uncertainly than the auxiliary supply tank with its reducing valve which must be depended upon to protect automatically the transformer from the high pressure of the auxiliary tank.

A New Type of Single-phase Motor

BY S. R. BERGMAN

Associate, A. I. E. E.

Consulting Engineer, General Electric Company,

Review of the Subject.—This paper deals with the development of a constant speed a-c. motor for application to single-phase current. A description is given of the derivation of this new type of motor from the plain repulsion motor. The novel feature lies in the armature which consists of a combination of three elements, namely: a commutated winding, a squirrel cage of high reactance, and a commutating device consisting of shielding metal strips.

It is shown that this motor in starting and acceleration possesses the characteristics of a series motor and when up to speed has the characteristics of a shunt motor. The changing over from the series to the shunt type is accomplished without the use of any automatic device, this change taking place due to the inherent qualities of the motor.

An explanation is given of the high power-factor possessed by this motor and also an elementary theory of commutation, which has proved to be as good as that in a d-c. motor with commutating poles.

WHEN looking back on the development of the electric motor, it appears that the traction motor with its severe service has had a great influence on both the mechanical and electrical design of the stationary motor for general purposes. Both for d-c. and a-c. applications, the traction motor has served as a model and particularly has its influence been strongly felt in the evolution of the a-c. motor. Great contributions to the art of the a-c. motor are found in the records of the A. I. E. E., which records describe not only discoveries of new means of improving results, but also establishing the theories governing the operation. Chief among these contributions are the papers by Lamme on the Series Motor; Steinmetz, on the Repulsion Motor; Alexanderson, on the Series Repulsion Motor; and Milch on the Repulsion Induction Motor. All of the motors mentioned, except the Milch motor, have the characteristics of the series type, the Milch motor approaching shunt-motor characteristics.

The new motor which will be described in this paper has the characteristics of a shunt motor over the running range, and the series type characteristics during starting and acceleration. The change over from the characteristics of the series motor to that of the shunt motor is accomplished in this new motor without the use of any external automatic device. Since the motor is a combination of a repulsion motor and a squirrel cage induction motor, for want of a better name, it will be referred to as the squirrel cage repulsion motor.

Through the work of Steinmetz and Alexanderson above referred to, the characteristics of the plain repulsion motor are well understood. In Fig. 1 is shown diagrammatically, Professor Elihu Thomson's well-known repulsion motor. This motor has in many respects the same characteristics as that of a series type d-c. motor. It differs, however, from the operation of such a motor in some respects and in examination of such differences, one in particular is rather striking; namely, the difference in the speed and torque curve. The series type d-c. motor will attain very high speeds if the load is removed; whereas, the repulsion motor will not run away, but will stop at a certain limited speed. The reason for this limitation in speed is due to the influence of the currents in the coils short-circuited by the brushes, and it may be stated that the larger these currents are, that is, the poorer the commutation, the lower will be the running free speed.

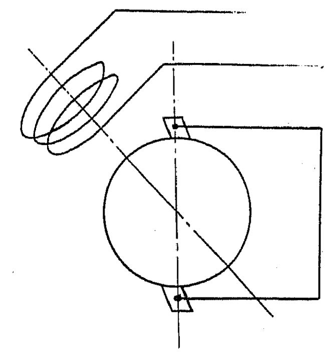

FIG. 1

With this observation in mind, the writer conceived the idea that if it were psosible by artificial means to exaggerate the influence of these short-circuited currents then it should be possible to so limit the running free speed that the result would lead to a nearly constant speed motor. In order to carry out this thought, a motor was made a number of years ago in accordance with Fig. 2. The field carries a single winding corresponding to the field winding in Fig. 1. The armature carries a commutated winding with its short-circuited

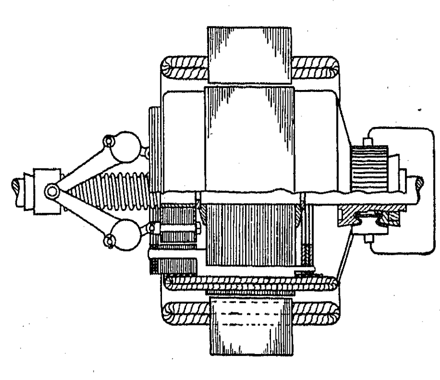

FIG. 2

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

brushes in accordance with Fig. 1, but in addition, there are placed in the same slot as the commutated winding, the bars of a squirrel cage. These bars are extended, as shown in Fig. 2, at one end projecting through a laminated ring rigidly attached to the shaft. Inside this laminated ring moves a circular core which is acted upon by a centrifugal mechanism in such a fashion that when the motor is at standstill, the moving core is entirely inside of the laminated ring, and when the motor speeds up, the inside core is moved out, until, near synchronism, the core is entirely moved outside the laminated ring. This mechanism, therefore, provides the squirrel cage with an automatically adjustable reactance which is a maximum at standstill and a minimum when running near synchronism.

When the motor is at standstill, the squirrel cage carries a comparatively small current due to the high value of the adjustable reactance, and the current is, therefore, flowing mainly in the commutated winding. Therefore, at standstill, this motor possesses about the same torque and starting current as in the case of the plain repulsion motor, Fig. 1. It is well understood that at synchronism the plain repulsion motor sets up a circular revolving field similar to that existing in the polyphase motor. Hence, at synchronism, the squirrel cage revolves at the same speed as this revolving field and is, therefore, at this speed, not producing any torque. Above synchronism, currents are generated in the squirrel cage, the condition being very similar to that of an induction generator. The torque in the squirrel cage is then a generator torque, thus opposing the motor torque in the commutated winding. Tests show that this motor will only exceed synchronism by 1 to 2 per cent. As soon as the speed drops below synchronism, the squirrel cage becomes active, producing a motor torque, and at these speeds, both the squirrel cage and the commutated winding pull together. Tests show that the maximum output, which occurred at about 10 per cent slip, was 250 per cent of the normal output; that is, very similar to a well designed polyphase induction motor. The power-factor was very excellent; *i. e.* close to unity, which is far better than that of either a plain repulsion motor or a squirrel cage induction motor, for reasons which will be explained in the following. The commutation of this motor was excellent, as good as that of a well designed d-c. motor with commutating poles. A brief theory of the commutation will be discussed later.

Although this motor performed in accordance with expectations, it was felt that it was capable of further development toward the ends of eliminating the moving parts. The thought naturally presented itself as to whether or not it would be possible to make the adjustable reactance an integral part of the motor proper.

The next step in the development was an armature structure shown in Fig. 3. The squirrel cage S is placed underneath the commutated winding R and the slots carrying these two windings are interconnected through the narrow slot L.

No external cores are used, the result being that the squirrel cage is given a permanent high reactance. Since this is the type of motor which was ultimately adopted for production, no further account will be taken of the motor, shown in Fig. 2, which has merely been mentioned as being one link in this development.

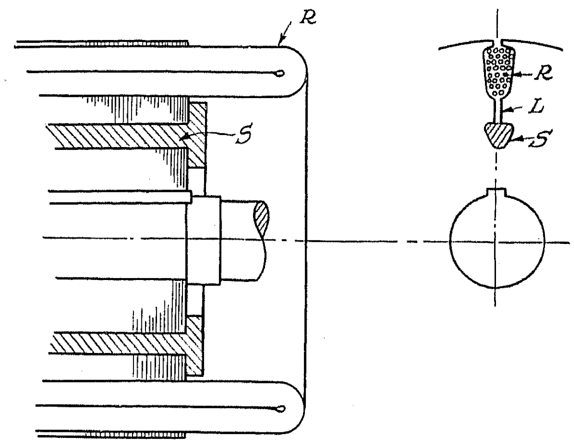

FIG. 3

In order to explain the working of the squirrel cage repulsion motor, shown in Fig. 3, the conditions existing in the plain repulsion motor will first be briefly considered. Following Steinmetz' paper of 1904, the field winding is resolved in two parts at right angle in space shown in Fig. 4. That portion of the field winding which magnetizes in direct opposition to the armature is called the compensating or transformer winding T. That portion of the field winding which magnetizes

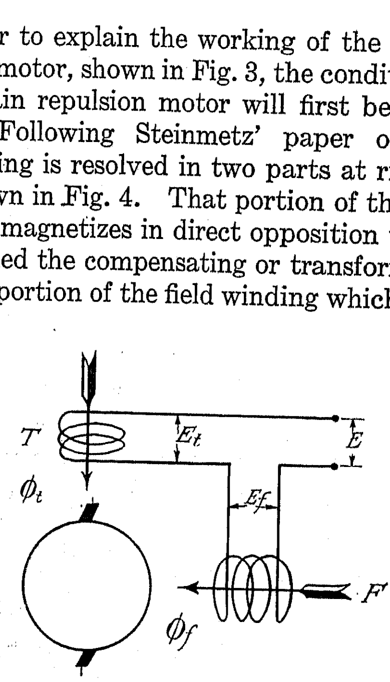

FIG. 4

at right angle to the armature is called the main field winding F. The transformer and the armature windings constitute a transformer, inter-linked by the mutual flux ϕ_t. The field winding F has no corresponding secondary winding on the armature except the coils, which are short circuited through the brushes. Since the influence of these short-circuited currents is small, below synchronism at least, these currents will be

neglected and then the field flux ϕ_f acts as pure self-induction.

When running at speed, there are two e. m. fs. induced in the armature, one E_{at} by alternation of the transformer flux ϕ_t and a second E_{af} set up due to the rotation of the conductors through the field flux ϕ_f. Since in a reactive coil the flux and the current are in phase and since the e. m. f. of rotation must be in phase with the field flux, the vectors I, ϕ_f and E_{af} are in time phase as shown in Fig. 5. Since the armature is short-circuited (neglecting the impedance drop) the e. m. f. of alternation must be equal and opposite to the e. m. f. due to the speed as shown in Fig. 5. Since the mutual transformer flux is 90 deg. ahead in time of the secondary e. m. f., the vector of the flux ϕ_t is placed accordingly in the diagram from which it now may be seen that the fluxes ϕ_f and ϕ_t are in quadrature in time.

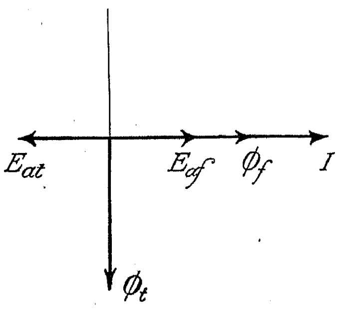

FIG. 5

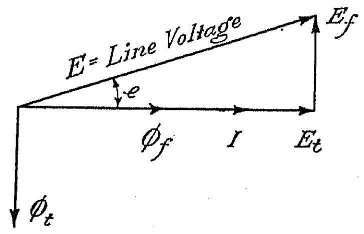

FIG. 6

Numerically, $E_{at} = C \times f \times \phi_t$, $E_{af} = C \times f_0 \times \phi_f$ where C = constant, f = primary frequency, f_0 = frequency of rotation. Hence, $C \times f \times \phi_t = C \times f_0 \times \phi_f$. At synchronism $f = f_0$. Hence, $\phi_t = \phi_f$, thus confirming the statement already made that at synchronism a circular revolving field exists.

A repulsion motor may, therefore, be looked upon as formed of two elements; namely a transformer loaded on non-inductive load in series with a reactive coil. Since, in a transformer loaded on a non-inductive load, the impressed voltage and the primary current are nearly in phase, in Fig. 6, is shown as a first approximation, the line current I in phase with the voltage E_t which is impressed on the transformer winding. If E_f is the voltage impressed on the field winding, this voltage leads the current by 90 deg. Cos φ is then the power-factor and thus Fig. 6 represents in an elementary way, the diagram of the plain repulsion motor.

It is obvious that by making E_f small as compared with E_t the power-factor will be good, which means running a weak field as compared with the armature reaction. In a repulsion motor of the size here considered, the power-factor at full load would range between 80 and 85 per cent. Test on the squirrel cage repulsion motor reveals, however, the fact that the power-factor at full load is close to unity. Thus, by adding a highly reactive squirrel cage, the power-factor has been considerably raised, a fact which at first appears paradoxical. The explanation is as follows:

In Fig. 6, we assumed that the current I in the field was in phase with the field flux ϕ_f. This is, however, not quite true even in the plain repulsion motor, since, due to the losses in the iron, there always exists an angle of hysteretic advance, and in addition, the coils short-circuited by the brushes act like the secondary of a transformer loaded on mixed reactance and resistance. In such a transformer, the primary current leads the mutual flux by a certain angle. In Fig. 7, the current I leads the field flux ϕ_f by a certain angle α. Completing the diagram, it is easily seen that the power-factor has improved since the whole voltage triangle has been turned in the diagram so as to decrease the

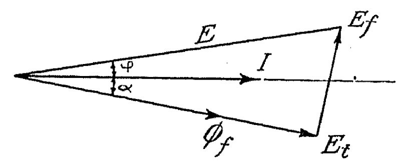

FIG. 7

angle φ. In the plain repulsion motor, the angle α is comparatively small, but nevertheless, there exists in such a motor, below synchronism, a certain amount of power-factor compensation.

It is now obvious that if a separate squirrel cage is used, a similar effect to that due to the currents short-circuited by the brushes is taking place, although, in a much more pronounced way. At full load, the squirrel cage actually delivers about the same amount of energy as the commutated winding. The primary corresponding to the squirrel cage consists of two phases; namely, the transformer winding and the field winding, each contributing about one-half of the output. Thus, at full load, each of these phases delivers about one-quarter of the output and hence, the angle α has become considerable at full load and the improvement of the power-factor is, therefore, appreciable. In Fig. 8 is shown a break test of a motor rated 3 h. p. and it may be seen that the power-factor at full load is close to unity.

It has thus been proven that by adding a highly reactive squirrel cage to the commutated winding in a repulsion motor, the power-factor, below synchronism, is improved,—a result which may at first appear contradictory, and the explanation as shown above

may best be summarized by the following quotations from Steinmetz:

"Exciting the field by a lagging current in the field, a lagging e. m. f. of rotation is produced which is equivalent to a leading current. As it is easy to produce a lagging current by self-induction, the commutator thus affords an easy means of producing the equivalent of a leading current. Therefore, the a-c. commutator is one

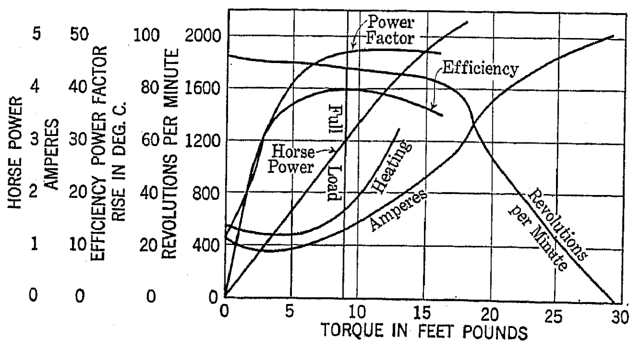

Fig. 8

of the important methods of compensating for lagging currents."

Similar conditions exist in the plain series motor in which power-factor compensation can be obtained by turning the time phase of the field flux by shunting a resistance across the exciting winding, which proposition, I believe, was first suggested by McAllister. In this case the efficiency suffers slightly due to the loss

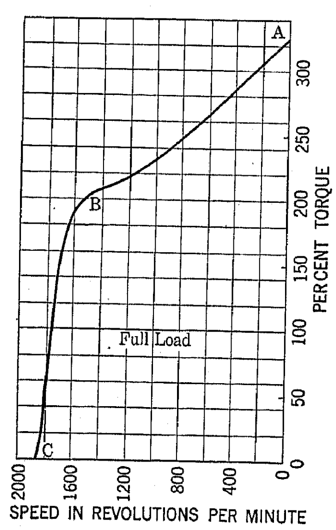

Fig. 9

in the resistance, and in addition, such an arrangement introduces a certain mechanical complication. In the squirrel cage repulsion motor, the addition of the squirrel cage cuts down the losses in the secondary, thus improving the efficiency. Thus, the squirrel cage raises both the efficiency and the power-factor, which conditions may be confirmed from the break test shown in Fig. 8.

Fig. 9 gives the typical relation between the speed and the torque for this type of motor. From this figure it may be seen that the torque curve may be divided into two branches; namely, the branch $A\ B$ corresponding to starting and acceleration and the branch $B\ C$ corresponding to the normal running conditions of the motor. During the period $A\ B$ the motor has, obviously, the characteristics of a series motor. During the period $B\ C$ it possesses in a marked degree the characteristics of a constant-speed shunt motor.

As the speed decreases and the motor performs along the curve $B\ A$, the current increases, due to the fact that the field is excited by the line current. The field flux increases with the decreasing speed. At standstill, corresponding to point A, we have the following conditions:

The squirrel cage has inherently, due to its construction, a high inductance. It is then penetrated by a current having primary frequency. Its reactance, therefore, is quite high. The commutated winding on

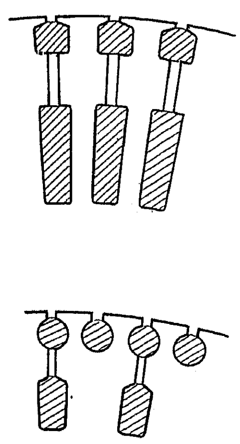

Fig. 10

the other hand has inherently a low reactance and the current, therefore, will flow mainly in this winding. We may also look upon this from a somewhat different viewpoint by stating that the magnetic flux seeks the path located between the squirrel cage and the commutated winding and thus the flux, which acts as self-induction for the squirrel cage winding, is torque-producing with respect to the commutated winding.

From the shape of the curve $A\ B\ C$, it will be seen that the torque during retardation increases without a break from B to A, thus securing a high "pull-up" torque, guaranteeing that the motor will pull up to speed the load that it starts. Over the branch $C\ B$, it possesses, as stated, the characteristics of a shunt motor to a marked degree, the full-load speed regulation being from 3 to 4 per cent. The branch $C\ B$, therefore, corresponds to running conditions generally obtained in a polyphase motor with low secondary resistance.

Since the mechanical construction possesses a certain similarity to the Boucherot double squirrel cage induction motor, it becomes of interest to examine whether

such a similarity exists from an operating standpoint. The double squirrel cage induction motor, may be constructed in a number of various ways as shown in Fig. 10. The main principle consists in providing one squirrel cage of high resistance and low reactance and a second squirrel cage of comparatively high reactance and low resistance. This principle aims at improving the starting conditions of the squirrel cage induction motor. In starting, when the frequency in the secondary corresponds to the primary frequency, a large portion of the current flows through the high-resistance winding, thus securing a high torque efficiency. When running at speed, the frequency in the secondary is the slip frequency; that is, only a small fraction of the primary frequency, and then the secondary current seeks the path of lowest resistance, consequently, taking the path of the low-resistance winding. Thus, near synchronism, this motor has a good speed regulation and a high efficiency. The power-factor of this motor suffers, however, for the following reason. In its reaction upon the primary, the secondary currents are of primary frequency, since they are always located in space in such a manner as to oppose the primary currents and thus the primary and secondary may be considered connected in series. It is, therefore, from the standpoint of power-factor, equally as bad to introduce reactance in the secondary as in the primary. Hence, the power factor, as well as the maximum output, suffers in the Boucherot type of motor. From this point of view, the squirrel cage repulsion motor, as has already been discussed, has opposite characteristics to the Boucherot motor, since both the power-factor and the maximum output improve by the use of the two windings.

Another distinction is the fact that the excitation in the squirrel cage repulsion motor has, in many respects, the character of that of a series motor, *i. e.*, the field flux increases somewhat with the line current. In the Boucherot motor, conditions are exactly opposite since it has the characteristics of a plain induction motor, the exciting flux (the mutual flux) decreasing with the increasing load. The two types of motors are, therefore, from an electrical standpoint, widely different.

One of the great difficulties with a-c. commutator motors has always been the question of commutation. Different means have been adopted for improving the commutation, such as the use of high-resistance commutator leads in the plain series motor in accordance with Lamme, or the use of fractional-pitch winding in the repulsion motor as suggested by Alexanderson, as well as providing for the proper commutating field also suggested by Alexanderson in his series repulsion motor. In the motor we are considering, another means for obtaining good commutation has been adopted.

In the plain repulsion motor, when it is running near synchronism, the field revolves with about the same speed as the armature conductors and, therefore, it is reasonable to assume that at such speeds the commutation is fair. The transformer flux, which is set up by the mutual action of the transformer winding and the armature, may be considered a commutating flux since it has not only the right time phase, but also the right strength to compensate for the electromotive force induced in the short-circuited coil by the field flux. On the other hand, there is another electromotive force induced in the short-circuited coils which causes sparking,—namely, the electromotive force of self-induction. In the squirrel cage induction motor, the squirrel cage is inter-linked with the leakage flux which causes self-induction in the short-circuited coils as shown in Fig. 11. The leakage flux, therefore, serves as a mutual flux of transformation between the short-circuited coil and the squirrel cage, thus transferring the energy, which would otherwise appear as a spark, to the squirrel cage. Part of this leakage flux over the length L is, however, not inter-linked with the squirrel cage and this leakage flux would, therefore, cause a slight amount of sparking. In order to eliminate this condition, a thin sheet of metal M is introduced in this slot. This metal strip is of

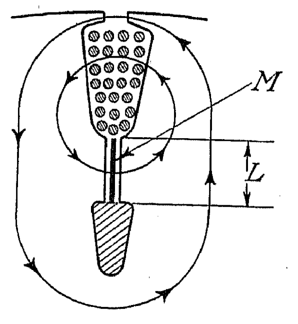

Fig. 11

comparatively high resistance. It should now be observed that the leakage flux over the length L must penetrate this metal strip and the corresponding energy is, therefore, dissipated in heat. In other words, instead of appearing as a spark, this energy appears as heat in the metal strips. Due to the fact that the frequency of commutation is very high, it is obvious that the resistance of the metal strips can be made quite high so as not to interfere with the flux distribution in starting, which conditions have already been discussed.

Thus, the armature of this motor consists in reality of three elements, each of which has an important function. These elements are the commutated winding R, the squirrel cage S and the commutating strips M. The commutated winding secures for this motor a high starting torque and it also contributes to the output when running at speed. Due to the fact that it is connected to a commutator, it secures power-factor compensation. The squirrel cage winding procures the characteristic of a constant speed type of motor over the running range and also secures perfect commutation in combination with the commutating strips.

Discussion

V. Karapetoff: An impression may be gathered from the paper that the power factor of the motor is improved because the squirrel-cage winding is highly inductive. It seems to me that the squirrel-cage winding necessarily has to be highly inductive so as not to interfere with the series characteristics of the motor at the start. If it were not for an additional mechanical complication (Fig. 2), it would be better to make this winding less inductive at and near synchronism. A transformer diagram at constant current will readily show that the common flux is lagging behind the primary current at a non-inductive load more than at an inductive load. Therefore, the less inductive the squirrel-cage winding, the more the flux ϕ_f is lagged behind I (Fig. 4). But the flux in T must be in time quadrature with ϕ_f in order that the total e.m.f. between the brushes be equal to zero. Therefore, lagging ϕ_f also causes ϕ_t and E_t to lag more behind I; in other words, it causes the vector of the current to come nearer that of the total voltage E. Thus, the power factor is improved even though the squirrel-cage winding has a high inductance, and the power factor would be improved more, if it were advisable to reduce the inductance of this winding in normal operation.

E. Bretch: About twenty to twenty-five years ago when the single-phase motor business was developing, considerable trouble was experienced with off-frequency circuits. In those days the single-phase generators were comparatively small and were designed for lighting service. When motors were connected to them, difficulty was experienced in keeping up the voltage and the generator was often speeded up to build up the voltage.

Single-phase motors with a centrifugally operated device to change from repulsion to induction were in difficulty on these off-frequency circuits, as they would short circuit the rotor at a fixed speed which on high frequency would be too low for the motor to come up to speed, causing severe fluctuations on the line as well as annoyance to the motor user. In considering the problem of constructing a motor that would be responsive to slip rather than speed in making the change from repulsion to induction, the writer conceived the idea of using a rotor with both the repulsion winding and the short-circuited winding permanently in circuit, the short-circuited or squirrel-cage being "loosely coupled" so as to be inactive until near synchronous speed.

During 1904 and 1905 several experimental motors were built and tested, and a patent (No. 848719) was issued to the writer April 21, 1907. This patent covered broadly the idea of a commutated winding at the surface of the rotor, a squirrel-cage or short-circuited winding beneath the commutated winding and by-pass or leakage path whereby the magnetic flux would pass between the squirrel-cage and commutated windings at stand still, or low speeds, when the alternations of the flux were high; but at, or near synchronous speed the flux of slip frequency would penetrate the squirrel-cage and give the motor the constant speed characteristic. The squirrel-cage from its inductive relation to the commutated winding also eliminated the sparking at the commutator.

During the next few years several hundred of these motors were placed in service, and were successful electrically and mechanically. However, due to the prejudice, at that time, against single-phase motors with brushes in service continuously and to the fact that some people insisted "wrongly" upon making the no-load losses a criterion for judging the efficiency of the motor, this line of motors was later equipped with a short-circuiting device and the squirrel-cage omitted. A description of these motors with the double-wound rotor was published in the *Electrical World*, July 1907.

Various combinations and proportions are possible between the three elements of the combination, the commutated winding, the squirrel-cage winding and the magnetic by-pass. In the motors as originally constructed, the control of the flux in the by-pass was accomplished by proportioning the cross section of the iron in the magnetic bridge between the two windings, and depending on the saturation of the iron.

Various other methods have been proposed, such as short-circuited loops encircling, or partially encircling the by-pass, making the by-pass of solid magnetic material and utilizing the choking effect of the eddy currents in the solid material, making the squirrel-cage conductors themselves of magnetic material, air gaps in the by-pass, as well as the one outlined by Mr. Bergman. The methods of using solid magnetic bars as a by-pass, and of leaving a thin bridge of iron in the rotor punchings between the two windings, have been in use for many years.

As to commutation, Mr. Bergman's statements are well founded. Only a few weeks ago, one of these motors with the double-wound rotor that had seen service for fifteen years, was returned for repairs. The rotor was perfect, and the commutator not as much worn as would be expected on a direct-current motor of similiar age.

As pointed out in the specifications of the above mentioned patent, the fact was then noted that the power factor was higher than that of the straight induction, but the reason for it was not understood. The problem had been to produce a sparkless motor that would change from repulsion to induction in response to slip rather than speed, with no particular thought of increasing the power factor.

I have a test sheet, dated Jan. 17, 1907 of a ¼ H. P. motor of this type, showing practically the same characteristics as Mr. Bergman's tests:

V. A. Fynn: A thing which strikes one in reading Mr. Bergman's paper is his disregard of that which has been accomplished by others. Others have worked on the very type of motor which Mr. Bergman now claims as new, have built such machines and have long ago published their results.

The motor of Mr. Bergman's Fig. 2 has a squirrel-cage and a commuted winding on the rotor but both of these windings are in the same rotor slots. Series conduction and induction motors so built were proposed many years ago by Lundell, they have no magnetic shunt or bridge between the two rotor windings and differ widely from the machine shown in Mr. Bergman's Fig. 3. The laminations shown at one end of the squirrel-cage are not the equivalent of magnetic shunts.

The motor of this Fig. 3 was patented in this country on September 2, 1907. See U. S. P. 848,719. The patentee, Mr. Edward Bretch, of St. Louis, has built and sold thousands of these machines and the fact that his patent is about to expire does not rob him of his priority. The motor shown by Mr. Bergman in his Fig. 3 does not differ from the Bretch motor in principle. There is nothing new about this machine. It differs from that of Lundell in that it provides a magnetic bridge between the two rotor windings.

In discussing the theory of the so-called repulsion motor, Mr. Bergman omits all consideration of the all important self-compensating feature of such machines. It is useless to go into this matter here since this point is fully explained, for instance, in my "Classification of Alternating Current Motors," PROCEEDINGS A. I. E. E., May 1915, page 972. Nor does Mr. Bergman's theory take into account the fact that in the motor of his Fig. 1 the rotor ampere-turns are in excess of the cophasal stator ampere-turns.

The power factor of the Bretch motor is high at some loads because below synchronism both the squirrel-cage and the commuted windings contribute to the motor field, a condition which results in a retardation of the phase of the resultant motor field as against that of the motor field which the squirrel-cage alone would produce. Just how such a retardation affects the power factor of a single-phase motor was shown by me, for instance, in "A New Single-Phase Commutator Motor," see *Proceedings* I. E. E., March 8, 1906.

It would be interesting to know just how the "field winding" of a motor, see page 3, column 2, line 13 from last of Mr. Bergman's paper, can contribute "about one half of the output." Field windings do not transfer energy. The fact is that the field winding of which Mr. Bergamn speaks, and which is shown in his Fig. 4 at *F*, does not exist. His motor is excited from the rotor and not from the stator as he supposes.

I cannot see how the flux "which acts as self-induction" spoken of on page 4, column 2, line 16 from last, which must be a leakage flux merely linking with the two rotor windings, can possibly produce a torque available on the shaft of the motor.

As to the short circuit *M* in the path of any flux threading the magnetic bridge between the commuted and the squirrel-cage windings, this is by no means novel. I have patented such a shield on June 6, 1911, see U. S. P. 994,381 and similar means on November 28, 1911, see U. S. P. 1,010,135.

I may further point out that I have done considerable developing work in connection with single-phase motors having a commuted and a squirrel-cage winding on the rotor with a magnetic bridge therebetween, producing different forms of series induction motors (Mr. Bergman would call them "repulsion motors") with an added "sunk" squirrel-cage and have fully discussed the theory of these machines. I refer to my several and old patents on this subject and to my paper "Single-Phase Squirrel-Cage Motor" which describes a machine showing considerable advance over the Bretch motor. Among other features my motor shows leading power factor at no load and practically unity power factor at most loads. When operated without auxiliary or external phase-compensating means it exhibits a power factor very near unity over a considerable range of loads as evidenced by Figs. 15, 16, 22, 25 of the paper last named, see PROCEEDINGS A. I. E. E., October, 1915.

Recently in discussing my paper entitled "A New Self-Excited Synchronous Induction Motor," Mr. Bergman found fault with the presence of a commutator and notwithstanding the fact that the machine in question is compensated at all loads and that its commutator carries nothing but exciting current and unidirectional exciting current at that. Now Mr. Bergman advocates a motor which although it has a commutator is not compensated at light loads, is not fully compensated at any load and is of such design that the commutator carries load current of full line frequency. If the criticism he directed against my machine is justified, is it not obvious that the same objection applies to a prohibitive extent to the motor he now describes.

P. M. Lincoln: The motor characteristics given in the paper, both the calculated and the observed, are very satisfactory. They show a very good shape of speed-torque curve, and I would like to ask about the commutation. Are they satisfactory in commutation, both at start and under running conditions, and how is that commutation obtained?

They are so satisfactory in comparison with the standard squirrel-cage polyphase induction motors, that undoubtedly if they can be made at a cost comparative to the cost of the standard squirrel-cage motor, they would receive a large application in commercial practice.

I would like to ask how about that cost. How much above the standard squirrel-cage motor will it be?

Also, how large a motor can be made in this manner?

G. H. Garcelon: Mr. Bergman's description of his conception of this motor is very interesting to me, as it varies somewhat from my own experience a few years ago in carrying out the commercial development of a line of motors similar in principle and operating characteristics.

Designers have long realized the more or less uncertain operation and expensive construction of mechanically operated devices used to combine the desirable characteristics of two or more types of motor, and have striven for a purely electrical means of securing such combination.

For starting and accelerating, the series and repulsion windings were most suitable, with the repulsion type lending itself more readily to commerical use, because of the following characteristics:—

1. Armature voltage is independent of line voltage, permitting reconnection of stator for different voltages without affecting the rotor winding.
2. Armature voltage may be selected for best mechanical and electrical design.
3. Simplicity of brush rigging.

For running, the squirrel-cage induction winding was most desirable because of its close speed regulation and mechanical simplicity.

Considering also the well known generating characteristics of the induction motor above synchronous speed, these two types of winding seemed to be ideal for combination except for the fact that their starting characteristics were normally antagonistic; as the squirrel cage would draw large currents at standstill and set up a field in opposition to the normal repulsion-motor field, greatly reducing, if not entirely annulling, the desirable starting characteristics of the repulsion winding.

The problem then seemed to be that of minimizing the effect of the squirrel cage at starting, and using it as much as possible after the rotor attained speed.

It was appreciated that the high-frequency rotor flux at starting could be damped to a great extent by using a high-reactance squirrel cage, and that the circular rotating field produced by the repulsion winding at synchronous speed would induce a low frequency in the squirrel cage which would minimize its reactance and cause it to develop appreciable running torque.

Experiments with various means of accomplishing these results proved the correctness of the theory, although several presented structural difficulties.

In order to secure power factor compensation to the marked degree shown in the paper, abnormally large magnetic parts are required so that saturation may be avoided.

By alterations in rotor design this type of motor lends itself to a variety of speed-torque characteristics and still maintains the other general characteristics mentioned by Mr. Bergman.

A line of motors of this general type, having a somewhat drooping speed-torque curve, has been on the market for three or four years and has been giving excellent service on such applications as pumps and compressors as well as in general service.

H. C. Specht (by letter): The motor with such a performance as described will necessarily be somewhat larger in dimensions than the ordinary repulsion-starting induction-running type. It also seems to me that the mechanical construction of the rotor laminations is such that very expensive equipment will be required and the punching cost will be high.

During the development of a similar motor various rotors were used, and it was found that those having a high reactance and low resistance in the squirrel cage showed a break in the speed curve at lower torques than those with relatively higher resistance and lower reactance. It was also found that the high-reactance rotors showed higher current and lower power factor at light loads than did the rotors of relatively higher resistance. However, the low-resistance rotors showed better speed regulation with better efficiency and power factor under overload conditions. This only goes to show the variations of some characteristics at the expense of others, and indicates the possibility of considerable choice in performance.

The improvement in power factor due to the use of the squirrel-cage winding with low resistance and high reactance becomes effective only after the load has caused the speed to drop below synchronism, whereas above synchronism the reverse effect is true. Therefore, it is not desirable to keep the speed of the motor above synchronism over a very large portion of the operating range. There is really very little object in comparing the power factor with that of a straight repulsion motor as this type is not

suitable for general application. If we compare the power factor of this motor with an induction motor having a short-circuited armature winding, the increase in favor of this type of motor is very marked due primarily to the lack of cross-field magnetizing current being reflected in the primary.

Mr. Bergman points out that the thin metal strip in the slit between the two windings improves the commutation under running conditions, and this is no doubt true, but, inasmuch as it is a very easy matter to secure excellent commutation near synchronous speed and the metal strip decreases the starting torque to some extent, as well as slightly increases the losses, it would seem to be an undesirable addition.

William Cramp (Communicated after adjournment): With reference to the article by Mr. S. R. Bergman in the JOURNAL of the A. I. E. E., July, 1924, it may interest your readers to refer to the *Journal* of the London I. E. E., Vol. 57, page 287, wherein I think they will find the prototype of Mr. Bergman's new machine.

Several motors working on this principle were designed and sold about 1904, but by his ingenious addition of metal plates in the slot openings to improve commutation, Mr. Bergman has undoubtedly improved the machine, especially when it is required for large horse power. The original motors gave no trouble at all as far as commutation was concerned, but they were built chiefly for driving fans, where the starting conditions are easy and the power comparatively small. I should like to add that my experience with these motors showed that the fall in speed from nothing to full load, was a good deal more than that of the ordinary induction motor. It is difficult to tell from Fig. 8 of the JOURNAL what the regulation on Mr. Bergman's machine is like, and it would be interesting if he could give further information on this point.

S. R. Bergman: In regard to Professor Karapetoff's statement, I pointed out in my paper that the reason for the good power factor in this motor was the action of the squirrel cage which is rather curious due to the fact that this squirrel cage possesses a high reactance. Professor Karapetoff is correct in his statement that the motor characteristics would be even better during running conditions if the squirrel cage possessed less reactance, a fact which I believe is illustrated in my paper by the description of the first motor having an adjustable reactance of the squirrel cage, this reactance being great in starting and low in running. Thus, I believe that Professor Karapetoff's conclusions are in full accord with the theory given in my paper.

Mr. Bretch has contributed a very interesting discussion showing that he, at a very early period, had some quite interesting ideas. Of course in the light of our present knowledge it may be readily understood why the motor built in accordance with the Bretch patent was abandoned.

The motor which is described in my paper is mechanically and electrically something quite different from the Bretch motor. It is, in my judgment, not possible to satisfactorily control the flux in the by-pass by proportioning the cross section of the iron between the two windings so as to depend upon the saturation of the iron for results.

Mr. Fynn discusses the novelty of this motor at some length, referring particularly to the Bretch patent. He forgets however, the very important fact that the Bretch motor has been discontinued in production. The motor proposed by Lundell I am not familiar with, but it seems from Mr. Fynn's description to be substantially different in principle.

Mr. Fynn seems to severely criticise the theory given in my paper. I wish to suggest that Mr. Fynn read the paper giving the details of the theory, which was presented at this Convention by Mr. West, entitled: "The Theory of the Squirrel Cage Repulsion Motor." Mr. West's theory is based on the general equations for the alternating current motor, single or polyphase, as first published by Steinmetz. Mr West's theory is carried out in complex quantities and agrees with the few graphical illustrations I have given in my paper. Results of careful tests at all speeds for both rotations, check our theory surprisingly closely. It seems therefore, plausible that such a theory is correct and it has well served our purpose of predetermining a complete line of motors of this type, which has recently been put on the market by the General Electric Company.

Mr. Fynn further states that the two windings into which we have resolved the field winding, do not exist and furthermore that field windings do not transfer energy. I wish to point out that we have built motors with two field windings and by inserting wattmeters in these windings it is an easy matter to check our theory.

Mr. Fynn also states that he cannot see how the flux, which acts as self induction, can possibly produce torque. The flux which penetrates the space between the two windings of the armature may be considered leakage flux with respect to the squirrel cage winding and mutual flux with respect to the repulsion motor winding. This is in accordance with the general accepted views on leakage and mutual flux. Hence, the flux which acts as self induction with respect to one winding, acts as torque producing with respect to the other winding.

Mr. Fynn also seemed to criticise the name of "Repulsion Motor" which I have given to the commutated winding. The brushes on this winding are short circuited and therefore, conform to that type of machine which was first brought out by Professor Thomson and called by him "Repulsion Motor." Professor Thomson's contribution in inventing the repulsion motor is one of the most notable contributions to the electrical art and in recognition of this contribution, I think we should maintain the name "Repulsion Motor."

Finally, Mr. Fynn has again brought up for discussion, his paper called "A New Self Excited Synchronous Induction Motor." This paper, which was presented at the Spring Convention in Birmingham, Ala., describes a polyphase induction motor possessing a commutator as well as slip rings having two armature windings in addition to two field windings. I merely have pointed out that in the case of polyphase motors which do not need to depend upon a commutator for operation, it certainly is a complication to add a commutator as well as slip rings, as well as four separate windings. A polyphase motor starts very satisfactorily with a squirrel cage and all these complications have been added to a polyphase motor in order to improve the power factor. As is well known, a single phase motor is not self starting, hence there is a good reason in order to start such a motor, to add a compensator. I wish to emphasize that in my motor the armature possesses only a single wire winding and the field also only a single winding. Furthermore, my motor does not possess any slip rings. It is, therefore, obvious that this new single phase motor is much simpler than Fynn's polyphase motor.

Turning now to Mr. Lincoln's inquiry as to the commutation in this motor, the theory of commutation is given at some length in my paper. The commutation in this motor is perfect during running conditions and as stated, is as good as that of a direct current motor with commutating poles. The reason for the good commutation is the fact that the motor runs near synchronism and the leakage flux is damped out by the squirrel cage and the metal wedges. The effect of the squirrel cage and these metal wedges is therefore, similar to the action of commutating poles in a direct current machine, since both of these devices take care of the self induction of the coils undergoing commutation.

As to Mr. Lincoln's inquiry about the cost of this type of motor, I may state that the material is efficiently utilized and that due to the simple mechanical arrangement of the windings, the process of manufacture is attractive.

As to how large a motor we can build in this manner is a question which is rather difficult to answer. There is nothing in the

theory of this motor which would indicate that size would be a limiting feature, which I believe will answer Mr. Lincoln's question.

Mr. Garcelon states that a few years ago he brought out a line of motors similar in principle and operating characteristics to this new motor. I believe Mr. Garcelon is referring to a motor built on the principle of using a squirrel cage in the same slots as the repulsion motor, this squirrel cage consisting of high resistance magnetic bars. This motor will give quite different operating characteristics from the motor I described. I go so far as to state that, in my opinion, the underlying principle is dissimilar in these two motors and the operating characteristics certainly justifies this statement.

There is one statement made by Mr. Specht which I wish to briefly touch upon. Mr. Specht states that the metal strips decrease the starting torque and the core loss and furthermore, as it is an easy matter to secure perfect commutation near synchronism it would seem undesirable to add these wedges. Of course, before standardizing such wedges we built numerous motors of identically the same design with and without such wedges. The efficiency and the starting torque showed no difference, but the commutation was markedly different inasmuch as the omission of these wedges made the commutation unsatisfactory. I agree with Mr. Specht that these wedges introduce small additional losses but as they improve the commutation, the commutation losses are eliminated and thereby counter-balance the losses in the wedges. Therefore, this is the explanation why the efficiency is not affected by these wedges.

Theory and Calculation of the Squirrel Cage Repulsion Motor

BY H. R. WEST
Associate, A. I. E. E.
Electrical Engineer, General Electric Co., Pittsfield, Mass.

Review of the Subject.—*A brief history of the development of the squirrel cage repulsion motor and a physical explanation of the principles of its operation have been given in the preceding paper "A New Type of Single Phase Motor" by Mr. S. R. Bergman. It is the purpose of the present paper to give the results of an analytical study of the operation of the motor. The derivation of the method of calculation is outlined and some of the more interesting results are given.*

THE only known method that has thus far been worked out for the calculation of the performance characteristics of the squirrel cage repulsion motor is a method which has been derived from an analytical solution of the fundamental voltage equations in a manner similar to the method given by Steinmetz[1] in his general equations for a-c. motors. The method that has been developed differs somewhat from that given by Steinmetz in the form and arrangement of the results. As a result of this difference in the treatment, not only was a workable method worked out for the calculation of the performance characteristics of the squirrel cage repulsion motor, but it was also found that accurate and useful methods for calculation of performance characteristics of different types of a-c. motors, such as, for instance, the double squirrel cage induction motor, could be worked out along similar lines. The derivation of the method of calculation will therefore be explained in the hope that similarly derived methods may be found useful in the study of other types of machines.

The squirrel cage repulsion motor, as described by Mr. Bergman, consists of a repulsion motor with a squirrel cage placed well below the commutated rotor winding. The brushes are set at a larger angle, usually about 30 electrical degrees, from the neutral axis than in the case of the plain repulsion motor. The amount of copper in the commutated winding and the size of the commutator and brushes of a squirrel cage repulsion motor are less than in a repulsion motor, since the squirrel cage carries part of the rotor current. The construction is otherwise essentially the same as that of a plain repulsion motor. The relation of the squirrel cage to the commutated winding is indicated in Fig. 1.

In the following, it will be assumed that all m. m. fs. and fluxes are sinusoidally distributed in space. In order to further simplify the solution, the angle of hysteretic lag between flux and m. m. f., and the effect of the local currents in the coils short-circuited by brushes are neglected. In calculation of losses the core loss can be calculated separately and considered either as extra input, or as a frictional drag, or as partly extra input and partly frictional drag. The motor operates at speeds near synchronism throughout its normal operating range where the currents induced in the coils short-circuited by the brushes are negligible. The effect of these currents is therefore neglected in the general equations. These assumptions effect a considerable simplification in the solution of the equations, which in its present form is at best too complicated for general routine design work.

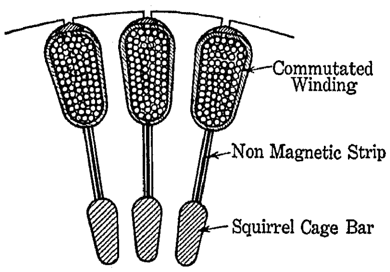

FIG. 1

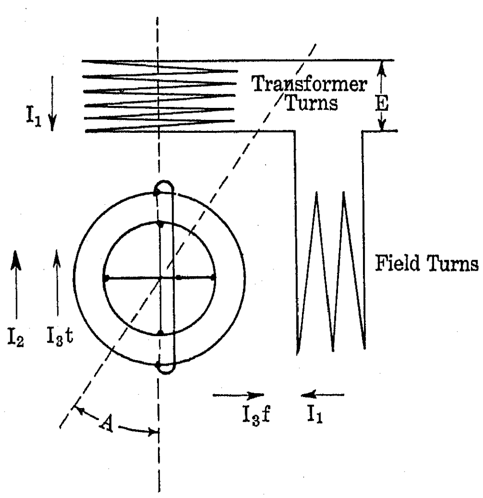

FIG. 2

Following the usual treatment of the plain repulsion motor, the stator winding of the squirrel cage repulsion motor is resolved into two component windings whose axes are at right angles to each other; the transformer winding whose axis, called the transformer axis, coincides with that of the commutated winding as deter-

1. Theory and Calculation of Electrical Apparatus, Chapter 19.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

mined by the brush position; and the field winding whose axis is at right angles to that of the commutated winding. In accordance with the assumption of sinusoidally distributed m. m. fs., the number of effective turns in the transformer and field windings is equal to the effective turns of the stator winding as a whole, multiplied by the cosine and sine, respectively, of the angle formed by the magnetic axis of the commutated winding, as determined by the brush position, with the magnetic axis of the stator winding.

The squirrel cage can be considered as equivalent to a commutated winding, the corresponding brushes of which are short-circuited in two rectangular axes. For purposes of analysis, the motor can therefore be considered as consisting of four simple circuits; the stator circuit, the commutated winding, and the two equivalent circuits of the squirrel cage. The motor can be represented diagrammatically as in Fig. 2. By applying Kirchoff's Law to these four circuits, we obtain four simultaneous equations, from the solution of which the performance characteristics of the motor can be determined.

Symbols

E = voltage applied.
r_1 = resistance of stator winding.
r_2 = " " commutated winding.
r_3 = " " squirrel cage winding.
X_m = mutual inductive reactance corresponding to flux mutual to all three windings.
x_1 = leakage reactance of stator winding.
x_2 = leakage reactance of commutated winding (which is mutual to the squirrel cage).
x_3 = leakage reactance of squirrel cage (corresponding to the permeance of the leakage path between the commutated winding and the squirrel cage).
A = angle of brush setting from neutral.
I_1 = current in stator winding.
I_2 = current in commutated winding.
I_{3t} = current in squirrel cage in the transformer axis.
I_{3f} = current in squirrel cage in the field axis.
f = frequency of applied voltage.
N = effective turns in each of the windings.
S = speed as a fraction of synchronism.
s = slip.
ω = $2\pi f$.
σ = $S\,\omega$ = "angular speed."

The resistances and reactances should all be expressed in terms of the number of turns in the stator winding. The symbols for voltage and current all represent time vector quantities. The positive senses of the currents are indicated by the arrows in Fig. 2.

The fluxes linking the four circuits of the motor can be resolved into mutual and leakage components which can be expressed in terms of the various reactances and currents as follows:

The transformer flux ϕ_{mt} which is the component of the mutual flux of stator and rotor in the transformer axis,

$$\phi_{mt} = \frac{X_m}{2\pi f N}(I_1 \cos A - I_2 - I_{3t}) \qquad (1)$$

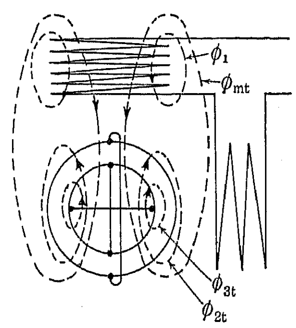
The field flux ϕ_{mf} which is the component of the mutual flux of stator and rotor in the field axis,

$$\phi_{mf} = \frac{X_m}{2\pi f N}(I_1 \sin A - I_{3f}) \qquad (2)$$

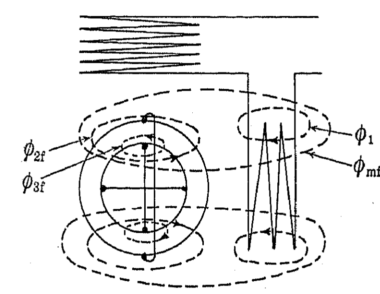
The leakage flux of the primary,

$$\phi_1 = \frac{x_1 I_1}{2\pi f N} \qquad (3)$$

The leakage flux linking the commutated winding in the transformer axis,



(a)



(b)

Fig. 3

$$\phi_{2t} = \frac{x_2(I_2 + I_{3t})}{2\pi f N} \qquad (4)$$

The leakage flux cut by the conductors of the commutated winding in the field axis,

$$\phi_{2f} = \frac{x_2 I_{3f}}{2\pi f N} \qquad (5)$$

The leakage fluxes in the transformer and field axes respectively, linking the squirrel cage conductors only,

$$\phi_{3t} = \frac{x_3 I_{3t}}{2\pi f N} \qquad (6)$$

$$\phi_{3f} = \frac{x_3 I_{3f}}{2\pi f N} \qquad (7)$$

The relations of these flux components to the circuits and to each other are indicated in Figs. 3a and 3b.

Voltage applied to the stator terminals must overcome the resistance drop $r_1 I_1$ and the voltages induced by alternation of ϕ_1, ϕ_{mt} and ϕ_{mf}. That is,

$$E = r_1 I_1 + j\,2\,\pi f\,(N\,\phi_1 + N\,\phi_{mt}\cos A + N\,\phi_{mf}\sin A)$$

Substituting for the fluxes their values given in equations (1), (2) and (3), we have,

$$E = r_1 I_1 + j\,x_1 I_1 + j\,X_m \cos A\,(I_1 \cos A - I_2 - I_{3t}) + j\,X_m \sin A\,(I_1 \sin A - I_{3f}) \qquad (8)$$

In the commutated winding, voltage is induced by transformer action of ϕ_{2t} and ϕ_{mt}, and by rotation through ϕ_{2f} and ϕ_{mf}. The vector sum of these voltages must equal the resistance drop $r_2 I_2$. This gives the equation,

$$O = r_2 I_2 - j\,2\,\pi f N\,(\phi_{mt} + \phi_{2t}) + S\,2\,\pi f N\,(\phi_{mf} - \phi_{2f})$$

or

$$O = r_2 I_2 - j\,X_m (I_1 \cos A - I_2 - I_{3t}) + j\,x_2\,(I_2 - I_{3t}) + S\,X_m\,(I_1 \sin A - I_{3f}) - S\,x_2\,I_{3f} \qquad (9)$$

Similarly, for the squirrel cage in the transformer axis,

$$O = r_3 I_{3t} - j\,X_m\,(I_1 \cos A - I_2 - I_{3t}) + j\,x_2\,(I_2 + I_{3t}) + j\,x_3 I_{3t} + S\,[X_m\,(I_1 \sin A - I_{3f}) - (x_2 + x_3)\,I_{3f}] \qquad (10)$$

and in the field axis,

$$O = r_3 I_{3f} - j\,X_m\,(I_1 \sin A - I_{3f}) + j\,(x_2 + x_3)\,I_{3f} + S\,[-\,X_m\,(I_1 \cos A - I_2 - I_{3t}) + x_2\,(I_2 + I_{3t}) + x_3 I_{3t}] \qquad (11)$$

The above four equations, (8), (9), (10) and (11) containing the four unknowns I_1, I_2, I_{3t} and I_{3f} can be solved giving equations from which the performance characteristic curves of the motor can be calculated.

It will be noted that these equations differ in form from the general equations of Steinmetz[2] for a-c. motors having any number of windings in both stator and rotor, in that his equations do not contain terms corresponding to $S\,x_2 I_{3f}$ in equation (9), $S\,(x_2 + x_3)\,I_{3f}$ in equation (10), and $S\,[x_2\,(I_2 + I_{3t}) + x_3 I_{3t}]$ in (11). In his treatment of polyphase motors, he took care of the phenomena involved by considering the leakage reactance of the rotor windings as being proportional to the slip. This gives exactly the same results, and is an exactly equivalent method when applied to polyphase motors. However, in cases where the mutual flux of stator and rotor is resolved into two components at right angles to each other in space, it seems preferable to treat the leakage flux in the same way and not to consider it as a flux revolving at synchronous speed. This applies particularly to the case of commutator motors where the current in the individual conductors is of line frequency. In single-phase motors where the leakage reactances of the rotor windings cannot in general be considered proportional to the slip, the omission of the terms representing voltages induced by rotation of rotor conductors through leakage fluxes results, in the usual case, in slight and negligible inaccuracies, but in the case of the squirrel cage repulsion motor would result in inaccuracies so great as to completely destroy the value of the results.

It is of interest to note that the reasoning on which the above equations are based is exactly similar to that followed by Arnold[3] in formulating the fundamental equations from which he developed the equivalent circuit for the single-phase induction motor according to the cross field theory.

Rearranging terms in equations (8) to (11) and solving for I_1, I_2, I_{3t} and I_{3f}, we get equations of the following forms:

$$I_1 = E\,\frac{F_1 + (1 - S^2)\,F_2 + j\,[F_3 + (1 - S^2)\,F_4]}{U + j\,W} \qquad (12)$$

$$I_2 = E\,X_m \cos A \left(\frac{G_1 + S\,G_2 + (1 - S^2)\,G_3 + S\,(1 - S^2)\,G_4 + j\,[G_5 + S\,G_6 + (1 - S^2)\,G_7]}{U + j\,W}\right) \qquad (13)$$

$$I_{3t} = E\,X_m \cos A \left(\frac{H_1 + (1 - S^2)\,H_2 + S\,(1 - S^2)\,H_3 + j\,H_4}{U + j\,W}\right) \qquad (14)$$

$$I_{3f} = E\,X_m \cos A \left(\frac{S\,J_1 + (1 - S^2)\,J_2 + j\,[J_3 + (1 - S^2)\,J_4]}{U + j\,W}\right) \qquad (15)$$

where $U + j\,W = F_5 + S\,F_6 + (1 - S^2)\,F_7 + j\,[F_8 + S\,F_9 + (1 - S^2)\,F_{10} + S\,(1 - S^2)\,F_{11}]$ (16)

and F_n, G_n, H_n and J_n are functions of the motor design constants, r_1, r_2, r_3, X_m, x_1, x_2, x_3, and A, and are independent of the speed. The complete expressions for these functions will be given in the appendix.

The torque produced by the motor at any speed can be considered as made up of three components produced respectively by interaction of the currents I_2, I_{3t} and I_{3f} with the fluxes $(\phi_{mf} - \phi_{2f})$, $(\phi_{mf} - \phi_{3f})$, and $(\phi_{mt} - \phi_{3t})$ through which the corresponding conductors rotate. The torque of the motor at any speed is, in synchronous watts:

$$T = 2\,\pi f N\,\{\,[\,(I_2\,(\phi_{mf} - \phi_{2f})\,] + [I_{3t}\,(\phi_{mf} - \phi_{3f})\,] + [I_{3f}\,x\,(\phi_{mt} - \phi_{3t})\,]\,\} \qquad (17)$$

where the expressions $[I_2\,(\phi_{mf} - \phi_{2f})\,]$ etc., represent the products of the in-phase components of current and flux. Substituting for the fluxes and currents

3. Wechselstrom technik, V. I. Chapter 8.

their values according to equations (5), (6), (7), (13), (14) and (15) we get the following equation.

$$T = \frac{E^2 X_m^2 [M_1 + S\, M_2 + (1 - S^2)\, M_3 + S\,(1 - S^2)\, M_4 + (1 - S^2)^2 M_5 + S\,(1 - S^2)^2 M_6]}{U^2 + W^2} \tag{18}$$

where M_1, M_2, etc., are functions of the motor design constants. The complete expressions for these functions will be given in the appendix.

By the use of suitable calculation forms, the torque developed and the current taken by the motor at any speed can be readily calculated from equations (12)

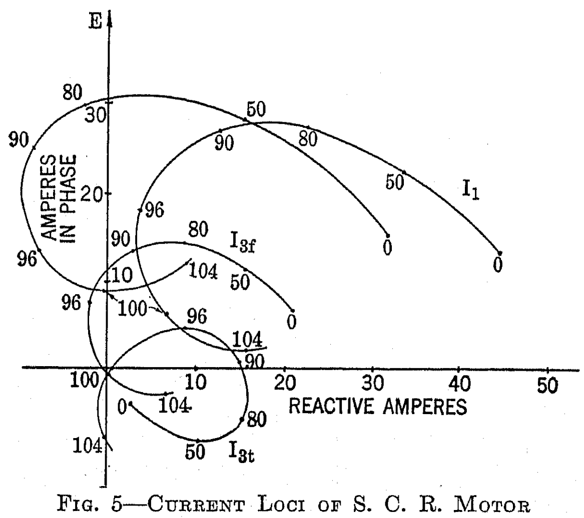

FIG. 5—CURRENT LOCI OF S. C. R. MOTOR

and (18). Since the value of current obtained by solution of (12) is given in terms of its power and reactive components, the power factor and input can then be determined. From the torque and speed, the output is determined; then after allowing for friction and core losses the efficiency is determined. If it is desired, the currents I_2, I_{3t} and I_{3f}, and the corresponding components of the torque can be calculated in a similar manner.

In Fig. 4 are shown the performance characteristics of a 3-h. p. 1800-rev. per min. 60-cycle squirrel cage repulsion motor as calculated from equations (12) and (18). Tested values are shown for comparison in the broken curves. It will be observed that the motor has a starting torque of approximately three times full load torque, and for speeds from standstill up to about 90 per cent of synchronism has a speed torque characteristic similar to that of a plain repulsion motor. For speeds in the neighborhood of synchronism the speed torque characteristics are those of an induction motor, from no load to double load. The motor therefore combines the characteristics of a repulsion motor and of an induction motor in operation, as well as in mechanical construction. The power factor at full load and overload is seen to be from ten to fifteen per

cent higher than would be obtained from either a plain repulsion motor or a plain single-phase induction motor of the same rating.

In Fig. 5 are shown the loci of the current vectors of the same motor, calculated from equations (12) to (15). The speeds corresponding to the different values of current are indicated in terms of synchronous speed on the curves. It will be observed that the stator current has its minimum value at synchronous speed, and that the variation in power input with change in speed in the close neighborhood of synchronism is accounted for principally by variation in power factor and not by variation in the magnitude of the current.

At full load, the current in the commutated winding is equal to approximately 85 per cent of the current in the stator winding.

The current I_{3t} in the transformer axis of the squirrel cage is very small for starting conditions, the squirrel

cage in this axis being effectively shielded by the commutated winding. In the field axis, the squirrel cage current I_{3f} has its maximum value at standstill. For normal operating speeds, these currents I_{3f} and I_{3t} are approximately equal in magnitude and 90 deg. out of phase in time, I_{3f} leading I_{3t}.

The division of the torque between the commutated and squirrel cage windings is shown in the calculated curves of Fig. 6. The speed torque curves of the motor when running with only the squirrel cage in the rotor, and with only the commutated winding, are shown in the dotted curves. It will be noted that the torque developed in the squirrel cage is roughly twice that which would be developed if the commutated winding were removed. In a general way, this is explained by the fact that for speeds in the neighborhood of synchronism, the motor has a nearly uniform revolving field like that of a polyphase induction motor. The explanation for this revolving field is the same as for the plain repulsion motor. That is, since the brushes bearing on the commutator are short-circuited, it follows that the voltages induced in the commutated winding by alternation of the transformer flux and by rotation through the field flux must be approximately equal. The transformer and field fluxes must therefore be 90 deg. out of phase in time as well as being at right angles in space. The resultant flux is therefore a revolving flux produced largely by the m. m. f. of the stator and commutated winding currents, independently of the squirrel cage currents. The squirrel cage therefore operates much the same as if it were in a polyphase motor, and it may be said to develop polyphase motor torque, the maximum torque thus developed being, roughly, twice the maximum torque that would be developed if the commutated winding were not used. For this reason the squirrel cage is much more effective at speeds in the neighborhood of synchronism than at standstill, and although the squirrel cage reactance is high enough so that the standstill conditions are comparable to those in a plain repulsion motor, the torque developed at speeds near synchronism is sufficiently large to give excellent speed regulation and to hold the no load speed to a value very slightly above synchronism.

The curve of torque developed by the commutated winding currents is of the same general shape as that of a plain repulsion motor, excepting in the neighborhood of synchronous speed where it has a definite maximum and minimum. The peculiar shape of this speed torque curve in the region of synchronous speed is of little practical significance or interest, except that it calls attention to the fact that the action of the commutated winding is greatly affected by the action of the squirrel cage current and vice versa, and that it is associated with the question of phase relations of the field flux, which, in turn, determine the power factor. This variation in torque is not due to any material change in the magnitude of the commutated current I_2 or the flux, $(\phi_{mf} - \phi_{2f})$, with which it reacts to produce torque, but is caused almost entirely by variation of the phase difference between the current and the flux.

When the motor is running at exact synchronous speed, the current in the squirrel cage can, for all practical purposes be considered equal to zero. The motor is therefore operating with the same current, power factor, efficiency, and torque as though the squirrel cage was removed, or, in other words, as a plain repulsion motor. If the load on the motor is increased so that the speed drops slightly below synchronism, currents are induced in the squirrel cage and induction motor torque is developed. The effect of these currents, as pointed out by Mr. Bergman, is to cause the field flux to lag the line current in time phase, resulting in power-factor compensation. That this phase difference is considerable for loads in the neighborhood of full load is shown by the fact that the torque produced by the commutated winding drops to a very low value.

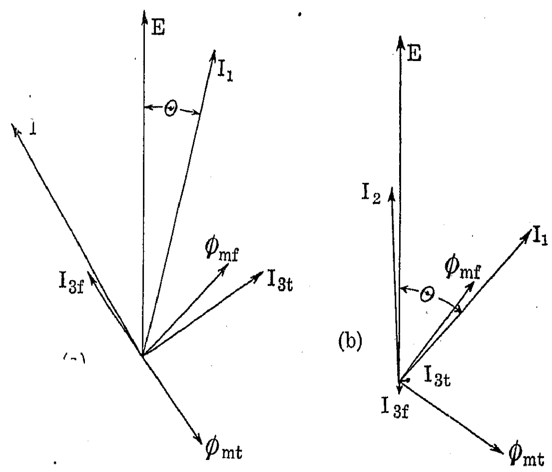

FIG. 7—VECTOR DIAGRAMS OF S. C. R. MOTOR
a. Full Load.
b. Synchronous Speed (Approximately Half Load.)

At exact synchronous speed, the squirrel cage repulsion motor may be said to operate exactly the same as a plain repulsion motor, since the current in the squirrel cage is then practically zero. A plain repulsion motor operating with the same brush position will be found to develop at synchronous speed a torque equal to approximately 50 per cent of the rated full-load torque of a squirrel cage repulsion motor of the same design constants. It is evident then that the squirrel cage repulsion motor develops approximately 50 per cent of full-load torque at exact synchronous speed, and for all loads greater than half load, the speed is below synchronism, so that power-factor compensation is obtained for all loads throughout the most important range.

Vector diagrams showing the phase relations at synchronism and at full load are shown in Fig. 7.

In a properly designed squirrel cage repulsion motor

the ratios of the resistance and leakage reactance of the squirrel cage to the resistance and leakage reactance of the commutated winding must be held within fairly close limits. In order to obtain the best starting torque per ampere of starting current, the squirrel cage reactance should be as high as possible. On the other hand, the higher the impedance of the squirrel cage, the higher will be the running free speed at which

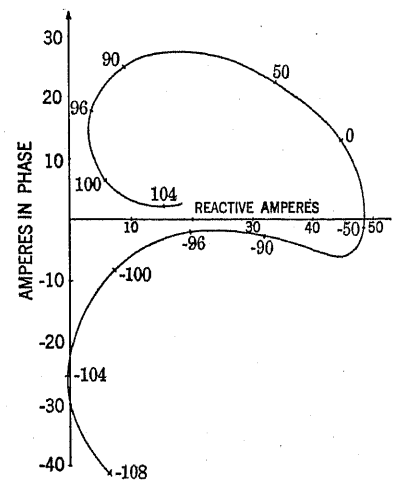

Fig. 9—Locus of Line Current—S. C. R. Motor

the generator torque, developed by the squirrel cage, will neutralize the motor torque, developed by the commutated winding. The currents, and therefore the losses, will be found to be correspondingly higher, so that we may say that the higher the squirrel cage reactance, the higher the no-load losses. There is a narrow range of values of squirrel cage reactance for which the starting conditions are comparable to those of a plain repulsion motor, and the no-load losses will be well within reasonable limits.

Since the full-load torque of the motor is furnished largely by the squirrel cage, it is evident that the speed regulation must be roughly proportional to the slip. The resistance of the squirrel cage should therefore be reasonably low in order to give good speed regulation.

A squirrel cage repulsion motor for reversing service may be obtained by providing a stator with distinct transformer and field windings, one of which can be reversed; or if desired, reversal may be accomplished by shifting the brushes. The reversing characteristics of the motor are shown in Fig. 8, which is the speed torque curve for both positive and negative speeds, and in Fig. 9, which is the locus of the stator current vector.

The current locus shows that although the motor does not return power to the line when driven at a speed above its no-load speed, it does operate as a generator with good characteristics, if driven at approximately synchronous speed against its normal direction of rotation as a motor. Its efficiency as a generator under these conditions is practically the same as its efficiency as a motor in normal operation, and as shown by the current locus, the power factor may be very high. The commutating conditions in this region also compare with those in normal motor operation, the explanation being the same as in the case of motor operation, that is, the voltages in the commutated winding induced by transformer action of and rotation through the transformer and field fluxes are approximately equal, and therefore the transformer and field fluxes must be approximately equal in magnitude and 90 deg. out of phase in time, giving as a resultant a rotating field, revolving with the rotor and therefore giving practically the same commutating conditions as in normal motor operation. A squirrel cage repulsion motor can therefore be reversed while running at full speed with no trouble from commutation. As shown by the current locus, the current taken by the motor is only very slightly greater at certain speeds during reversal than at starting.

It is well known that the current in an individual conductor of the rotor of a plain single-phase induction motor consists of two components of different frequencies, one component being of slip frequency and the other of approximately twice line frequency. The amplitude of the double frequency component is greater than that of the slip frequency component. In the squirrel cage repulsion motor, the current in an individual squirrel cage conductor also consists of two components, but in this case the double frequency component is small in comparison to the slip frequency component. This is to be expected, since the mutual flux of stator and rotor is, roughly speaking, a revolving field produced largely by the m. m. f. of I_1 and I_2 independently of the squirrel cage currents. The conditions affecting the squirrel cage can be compared

with those affecting the rotor of a polyphase induction motor with slightly unbalanced voltage applied to the stator; that is, the mutual flux of stator and rotor consists of a uniform revolving flux with a small pulsating flux superimposed in one axis. The ratio of the amplitude of the slip frequency component of current to the double frequency component, which is, roughly, the same as the ratio of the revolving component of flux to the pulsating component, can be determined for any particular speed from the calculated values of I_{3t} and I_{3f}. This nature of the squirrel cage current is of interest, in view of the fact that metallic strips or wedges are placed in the narrow slits connecting the squirrel cage slots with those of the commutated winding. These metallic strips serve the purpose of improving commutation by furnishing to the coils undergoing commutation local secondary circuits which absorb the energy that might otherwise appear in the form of very slight sparks at the brushes. The question of commutation and the action of the squirrel cage and these metallic strips in improving commutation has been rather fully discussed in the preceding paper by Mr. Bergman.

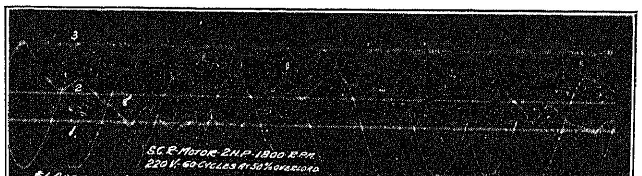

FIG. 10

Alternation of the leakage flux which threads these thin metal strips induces eddy currents in the strips, which has the effect of reducing the effective leakage reactance of the squirrel cage. The metal strips are therefore designed with sufficiently high resistance so that the eddy currents induced in them by the full-line frequency alternation of leakage flux at standstill will be so small as to be practically negligible. Otherwise, the effective leakage reactance of the squirrel cage would be appreciably reduced and the starting torque per ampere of starting current would be decreased.

When the motor is running at normal speed, the leakage flux threading the strips varies in the same manner as the squirrel cage current, *i. e.*, with a large slip frequency component and a small double frequency component. The effect of the slip frequency component in producing eddy currents in the strips will be entirely negligible on account of the very low frequency. The double frequency component can have only a very slight and practically negligible effect, on account of the small amplitude. The total effect of the metal strips on the operation of the motor is therefore quite negligible except for the improvement in commutation, and as is evidenced by the close agreement between the tested and calculated values shown in Fig. 4, it is perfectly legitimate to ignore the presence of the strips in calculating the performance characteristics of the motor, provided the strips are so designed as to properly take care of the standstill conditions.

In Fig. 10 are oscillograms showing the nature of the currents in the squirrel cage bars, the eddy currents in the metal strips, and the current in an individual coil of the commutated winding. In order to get an oscillogram showing the equivalent of the eddy currents in the wedges, an exploring coil was wound in the rotor with one side in the bottom of a commutated winding slot, and the other in the upper part of the corresponding squirrel cage slot. The wave shape of the voltage induced in this coil shows that the eddy currents in the metal strips consist largely of irregular high-frequency pulsations, which represent energy that is transferred during commutation from the commutated winding to the metal strips.

ACKNOWLEDGEMENT

The writer wishes to acknowledge his indebtedness to S. R. Bergman and to P. L. Alger for helpful suggestions in connection with the development of the theory and the method of calculation.

Appendix

Let $X' = X_m + x_2$

$X'' = X_m + x_2 + x_3$

Using these abbreviations, the complete expressions for the functions in equations (**12**) to (**18**) are:

$F_1 = r_2 r_3^2 - 2 r_3 x_3 X'$

$F_2 = - r_2 X''^2 - r_3 X'^2$

$F_3 = 2 r_2 r_3 X'' + r_3^2 X'$

$F_4 = - x_3 X' X''$

$F_5 = r_1 F_1 - x_1 F_3 - r_2 r_3 X_m (X_m + 2 x_2 + 2 x_3) - r_3^2 x_2 X_m - r_3^2 X_m^2 \sin^2 A$

$F_6 = - 2 r_3 x_3 X_m^2 \sin A \cos A$

$F_7 = r_1 F_2 - x_1 F_4 + x_2 x_3 X_m X'' + x_3^2 X_m^2 \sin^2 A$

$F_8 = r_1 F_3 + x_1 F_1 - 2 r_3 x_2 x_3 X_m - 2 r_3 x_3 X_m^2 \sin^2 A + r_2 r_3^2 X_m$

$F_9 = r_3^2 X_m^2 \sin A \cos A$

$F_{10} = r_1 F_4 + x_1 F_2 - r_2 (x_2 + x_3) X_m X'' - r_3 x_2 X_m X'$

$F_{11} = - x^2_3 X_m^2 \sin A \cos A$

$G_1 = - 2 r_3 x_3$

$G_2 = - r_3^2 \tan A$

$G_3 = - r_3 X'$

$G_4 = x_3 X'' \tan A$

$G_5 = r_3^2$

$G_6 = - 2 r_3 x_3 \tan A$

$G_7 = - x_3 X''$

$H_1 = - r_2 r_3 \tan A$

$H_2 = - r_2 X''$

$H_3 = - x_3 X' \tan A$

$H_4 = r_2 r_3$

$J_1 = H_4$

$J_2 = - [r_3 X' + r_2 X''] \tan A$

$J_3 = r_2 r_3 \tan A$

$J_4 = H_3$

$M_1 = [2 r_2 r_3^3 X' + 4 r_3^2 x_3^2 X' + r_3^4 X'] \sin A \cos A$

$$M_2 = r_2\, r_3^2\, [-\, r_2\, r_3 + 2\, x_3\, X' \cos^2 A - r_3^2 \sin^2 A - 2\, x_3\, X'' \sin^2 A - 2\, x_3^2 \sin^2 A]$$
$$M_3 = r_3\, x_3\, X' \sin A \cos A\, [r_3\, X' - 2\, r_3\, x_3 + 2\, r_2\, X'']$$
$$M_4 = r_3\, [2\, r_2\, r_3\, x_3\, X'' \sin^2 A + r_2\, r_3\, X'^2\, (1 + \sin^2 A) + r_2^2\, X''^2 + 2\, x_3^2\, X'^2 \sin^2 A + r_3^2\, X'^2 \sin^2 A]$$
$$M_5 = x_3^3\, X'\, X'' \sin A \cos A$$
$$M_6 = -\, x_3^2 \sin^2 A\, [r_2\, X''^2 + r_3\, X'^2]$$

The first step in calculating the performance characteristics of a squirrel cage repulsion motor from its design constants is to calculate the constants F_1 to F_{11} and M_1 to M_6 given above. Using the constants thus obtained, the calculation of current, power-factor input, torque, etc., can be carried out for all desired speeds simultaneously. Taking advantage of the fact that the constants to be calculated contain many terms and combinations of terms in common, and by using suitable calculation forms, the calculations can be completed in much less time than would be expected, judging from the lengths of the equations.

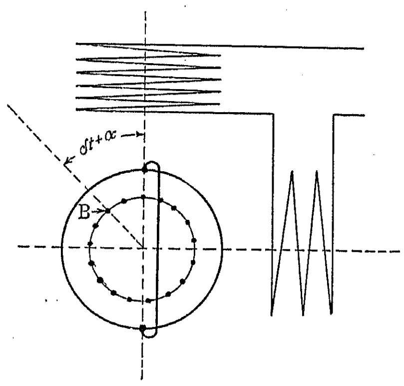

FIG. 11

An analytical expression for the instantaneous value of the current in an individual conductor of the squirrel cage would undoubtedly be so complicated as to be entirely out of the question. If it is desired to determine the wave shape of this current for any particular speed, it can be readily determined from the calculated values of I_{3t} and I_{3f}. Referring to Fig. 11, the instantaneous value of the current in the bar B is given by the equation

$$i_B = \sqrt{2}\, [\, |I_{3t}| \sin(\omega\, t + \theta_1) \sin(\sigma\, t + \alpha) + |I_{3f}| \sin(\omega\, t + \theta_2) \cos(\sigma\, t + \alpha)\,]$$

where $|I_{3t}|$ and $|I_{3f}|$ represent absolute values, θ_1 and θ_2 are the phase angles of I_{3t} and I_{3f} referred to the line voltage and α is the angular position of the bar when $t = o$. Transforming this equation into one involving functions of the sum and difference of two angles, we get the equation,

$$i_B = I_B' \sin[(\omega - \sigma)t + \beta_1] + I_B'' \sin[(\omega + \sigma)t + \beta_2]$$

or $i_B = I_B' \sin(s\,\omega\, t + \beta_1) + I_B'' \sin[(2 - s)\, \omega\, t + \beta_2]$

where I_B', the amplitude of the slip frequency component is given by the equation,

$$I_B' = \sqrt{\tfrac{1}{2}\, [|I_{3t}|^2 + |I_{3f}|^2 + 2\, |I_{3t}|\, |I_{3f}| \sin(\theta_2 - \theta_1)]}$$

and I_B'' the amplitude of the component whose frequency is $(2 - s)\, f$, is given by the equation,

$$I_B'' = \sqrt{\tfrac{1}{2}\, [I_{3t}^2| + |I_{3f}^2| - 2\, |I_{3t}|\, |I_{3f}| \sin(\theta_2 - \theta_1)]}$$

and β_1 and β_2 are constants.

Discussion

H. C. Specht (by letter): The calculation method shown by Mr. West will, without doubt, interest all motor designers. The way of demonstrating the different fluxes gives a very clear picture which can be easily understood. On the other hand, such a method of calculation without the use of diagrams and saturation curves seems to me rather complicated for routine design work, in spite of the fact that the effect of short-circuit current under the brushes and iron losses have been neglected. It is also assumed that all m. m. f. and fluxes are sinusoidal, which does not often correspond to the type of winding usually employed in a commercial motor. Another assumption is that of constant reluctance, whereas this will vary inversely with the saturation, which will have a very marked effect on the characteristics of the motor at overloads and when starting.

Possibly the neglect of these items is responsible for a discrepancy in the calculated curves shown in Fig. 6. Curve No. 4, as drawn, indicates that the starting torque of a repulsion motor will be increased by the addition of a squirrel-cage winding. This cannot possibly be the case, and Curve No. 4 should cross Curve No. 1 somewhere below synchronous speed, and show a starting torque considerably larger than that shown by Curve No. 1 representing the combined windings.

Using diagrams, in connection with the saturation curve for magnetizing voltage and flux, simplifies the calculation method, particularly when the motor is first calculated as the straight repulsion type and thereafter corrections are made for the effect of the squirrel-cage winding, short circuit current under the brushes, iron loss, etc. This method also gives a clear picture of the effect of the different items and any errors in calculation may be more easily noticed.

P. L. Alger (by letter): The element in design of the squirrel-cage repulsion motor that is all-important is the choice of the constants of the squirrel cage, and this is the point in which the new motor described by Mr. Bergman differs most from all previous motors of the same class.

Theory shows that in so far as starting is concerned, the squirrel cage should have the highest possible impedance, together with the lowest possible ratio of resistance to reactance. The ratio of resistance to reactance must be low in order to hold the axis of the squirrel-cage current as far away from the axis of the cross-field flux as possible, since this will give the least possible reduction of cross-field flux for a given squirrel-cage current. During normal operation, the squirrel cage should have the lowest possible impedance and a fairly definite, but rather low, ratio of resistance to reactance. This is true because maximum power factor at normal load is secured with a particular value of squirrel-cage reactance and because suitable values of pull-in torque and of losses are obtained with a particular value of resistance. Finally, in so far as commutation is concerned, the squirrel cage should have the lowest possible impedance, and a high ratio of resistance to reactance, since in this way the energy of commutation is most readily and completely dissipated without sparking.

Consideration of methods of securing these diverse values of the squirrel-cage impedance shows that it is very important to have no saturation in the reactance flux paths for the squirrel cage, since any such saturation would reduce the ratio of starting reactance to running reactance, which ratio should be made as large as possible. Also, the squirrel cage should have a low

d-c. resistance, with eddy currents of such a magnitude as to be inappreciable up to double line frequency, but considerable at commutation frequency. As the eddy currents give the effect of a reduction of reactance as well as an increase of the effective resistance, they are altogether objectionable at starting and altogether desirable for commutation.

In the new motor, these requirements have been met in a way which seems theoretically the best possible. The squirrel-cage leakage flux path has an air gap in it calculated to be of such a magnitude as to avoid all saturation at starting, and this air gap is filled with a metal wedge of such a resistivity as to give eddy currents that are inappreciable at operating frequencies, but are considerable at commutation frequency.

K. L. Hansen (by letter): Although Mr. West has made use of certain simplifying assumptions with reference to the angle of hysteretic advance and the effect of eddy currents in the shielding commutating strips, it must be conceded that the agreement between the tested and calculated values is sufficiently close to justify these assumptions, especially when the complexity of the calculations is taken into consideration. It is rather unfortunate, however, that neither design constants nor dimensions are given in the paper, thus making it impossible to compare the results with those obtained by a method differing somewhat from that of the author.

It is clearly set forth in the paper that the ratio between the constants of the squirrel cage and the constants of the commutated winding must be held between close limits, otherwise the no-load losses become excessive or the starting torque per ampere will be too low. The fact that at no load the motor develops two torque components neutralizing each other instead of just sufficient torque to overcome the friction losses, as is usually the case, tends to make the no-load losses high. The no-load losses of the particular machine discussed in the paper appear to be approximately 25 per cent of the full-load output. That may not be excessive in a 3 h.p. motor, but the same percentage losses in a larger machine would be excessive, and it would be of interest to learn what results have been obtained on motors of say 10- or 15-h.p. capacity.

The analysis of the squirrel-cage repulsion motor may be approached from a different viewpoint from that which Mr. West has chosen as his starting point. About thirty years ago Professor Ferraris suggested that single-phase induction-motor operation could be explained by considering the single-phase alternating field as made up of two components revolving in opposite directions. It seems that this method has not been looked upon with favor as a starting point for quantitative analysis, but I have found it exceedingly useful in the solution of just such problems as that discussed by Mr. West.

Analysis of the squirrel-cage repulsion motor from this viewpoint also leads to four equations with four unknowns, so the numerical calculations may not be much simplified, if any, but the forming of the equations from physical considerations is made more simple and direct by this method. It is not necessary to resolve the primary winding into two components at right angles to each other, nor to consider the transformer and rotational voltages separately. Equally, there is no need of considering the squirrel-cage as the equivalent to a commutating winding with the brushes short-circuited in two rectangular axes. From the viewpoint of two oppositely rotating fields the squirrel cage is considered as a polyphase circuit with two current components flowing in it of frequencies proportional to s and $(2-s)$, where s = slip. These current components are physical realities and are plainly shown on the oscillogram in Mr. West's paper. The reactances which these current components meet are likewise proportional to s and $(2-s)$.

I have not derived the formulas of the squirrel-cage repulsion motor from the viewpoint of two rotating fields, mainly because the constants are not given in the paper so that results can not be compared anyway. Another reason is that I have applied this method in considerable detail to a number of similar problems in a paper entitled "The Rotating Magnetic Field Theory of Alternating-Current Motors," which will be published in the JOURNAL at some future time.

I am indebted to Mr. Specht for calling attention to a point which should perhaps have been explained more fully in the paper. It is natural to believe that Fig. 6 of my paper is wrong as has been claimed by Mr. Specht, because at first thought it would seem that the addition of a squirrel-cage to a repulsion motor must necessarily reduce the starting torque. Paradoxical as it may seem, however, this is not true, and it is a fact that if the squirrel cage is removed from a properly designed squirrel-cage repulsion motor, the starting torque will be materially reduced unless the brush position is changed.

The explanation is that although the ampere-turns of the squirrel cage partially neutralize the field ampere-turns of the stator winding, and thus reduce the field flux per ampere of line current, the starting impedance is much reduced so that the starting current is greater. The starting torque is roughly proportional to the product of the starting current times the field flux, and therefore may or may not be decreased by the

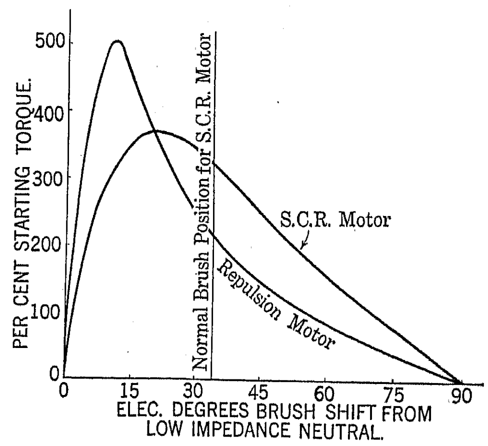

FIG. 1—CURVE OF COMPARISON BETWEEN STARTING TORQUES OF A REPULSION MOTOR AND A SQUIRREL-CAGE MOTOR FOR DIFFERENT BRUSH POSITIONS

addition of a squirrel cage, depending on the relative design constants of the motor and squirrel cage, and the angle of brush setting.

The curves of Fig. 1 give in a general way a comparison between the starting torques of a repulsion motor and of a squirrel-cage repulsion motor for different brush positions. It will be noted that for brush positions close to the low-impedance neutral, the plain repulsion motor has the higher starting torque, but as the brushes are shifted farther from neutral a point is reached beyond which the squirrel-cage repulsion motor has the higher starting torque.

It is of course true that the maximum torque obtainable is less for a squirrel-cage repulsion motor than for the corresponding plain repulsion motor. It should also be noted that the starting torque of the squirrel-cage repulsion motor is less sensitive to slight changes in brush position than is the plain repulsion motor.

The omission of certain minor factors in the derivation of the equations is, in my opinion, fully justified. If all factors that affect the motor operation were taken into consideration, assuming that it were possible to do so, the results would differ from those obtained by the method given in the paper by percentages in comparably smaller than the percentage difference between the starting torque values of curves 1 and 4 of Fig. 6 which Mr. Specht mentioned. In calculating starting torque, it is sometimes necessary to make certain allowances, such as those for saturation and the effects of the currents in the short-

circuited coils. The calculation of starting torque is so very much easier and shorter than the general calculation that the necessary allowances can easily be made.

I feel safe in saying that it is impossible to make a reliable quantitative predetermination of the performance of a squirrel-cage repulsion motor by first calculating the performance of a plain repulsion motor and then making allowances for the effect of a squirrel-cage unless experimental or other accurate data for motors of somewhat similar design characteristics are available. For example, I do not believe that the design of a 2-pole, 25-cycle motor could be most advantageously worked out on that basis if experimental or other reliable data were available for 4-pole, 60-cycle motors only. The conclusion which Mr. Specht arrived at concerning the curves of Fig. 6 might be said to be characteristic of the results that might be expected from the use of that method, for as I tried to show by the curves of Fig. 6, the action of each rotor winding is altogether different from that which it would have if the other winding were removed.

The method of calculation which I have outlined in the paper is too complicated for general routine design work, but, in my opinion, the design of a motor of which many thousands will be built, is of sufficient importance to justify the carrying out of a number of complete calculations so as to determine the most economical use of materials, to get a better idea of the best proportions of the design constants, and to learn how the operating characteristics of a motor will be affected by a change in any one of the design constants.

I am in complete agreement with Mr. Alger except in regard to the way in which squirrel-cage resistance affects the starting torque. At standstill, the current in the squirrel cage is almost all in the field axis, since the commutated winding effectively shields the squirrel cage in the transformer axis. The effect of the squirrel-cage resistance is to cause the field flux to lag the line current in time phase, thus making it less effective in producing torque.

In reply to Mr. Hansen's question about the no-load losses, it may be said that the no-load losses need never be objectionable. The larger the motor, the lower the percentage no-load losses may be made. For a 10-h. p. motor, the no-load losses are approximately 11 per cent of the full-load input.

I am glad that Mr. Hansen has succeeded in working out the theory of single-phase commutator motors by the revolving-field method, for it seems that it is necessary to use the revolving-field method in order to allow properly for the effects of eddy currents in the squirrel-cage bars.

The revolving-field method and the cross-field method both have their advantages, and in my opinion neither method should be used to the exclusion of the other. The revolving-field theory allows for the variation of inductance and resistance with frequency variations in the rotor conductors and would give the slip-frequency and double-frequency components of the rotor current directly. On the other hand, the cross-flux theory is, in my opinion, easier to work with, especially for commutator motors, and in the case of the squirrel-cage repulsion motor gives a clearer picture of the effect of the squirrel-cage currents on the power factor than would be obtained from the revolving-field point of view. The "current in the transformer axis of the squirrel cage" and the "current in the field axis of the squirrel cage," which are given directly by the cross-field method, have definite and very useful physical meanings.

I regret that Mr. Hansen has not completely worked out the equations for the squirrel-cage repulsion motor following the revolving-field method. I believe that the equations which he would obtain by that method, starting with the same assumptions, would be identical in form with mine. At least it should be possible to transform the equations obtained by one method into those obtained by the other. Possibly his final equations would appear in a form that would give an easier method of calculation than mine. A direct comparison of equations would be more convincing and probably easier than a comparison of calculated data.

Technical Committee Annual Reports 1923-1924

TRANSMISSION AND DISTRIBUTION COMMITTEE

To the Board of Directors:

The increasing demand for electrical energy has made necessary the interconnection of present systems and the development of additional hydroelectric power projects. These new developments are in many cases at points remote from load centers, and the transmission problems involve distances, amounts of energy, reliability, and voltages for their economic transmission in excess of previous operating practise.

The insulator problem continues to be one of the chief sources of difficulty in overhead transmission, and although considerable progress has been made, both in the design and manufacture of suspension type insulators, there still remains room for additional investigation on the electrical and mechanical effects influencing leakage resistance, deterioration, etc. Some flashovers of insulator strings are still unexplainable and research work is being done to try to determine the cause and cure of these flashovers. The cause of the flashover possibly has a bearing on many of the so-called lightning disturbances.

The successful automatic operation of oil switches with relay protection at voltages as high as 220 kv. is an accomplished fact and this prevents the damage to insulators on account of flashovers. It may be said that the transformers and switches operate satisfactorily at these high voltages. The improvement of the insulation to prevent flashovers and many of the so-called lightning disturbances seems necessary, as the flashovers do not seem to be caused by high-frequency or transient voltage, since the rise in voltage (sometimes double voltage) due to switching, does not of itself cause flashovers. The mechanical stress, due to continued loading, vibration of aerial spans, temperature, humidity, and atmospheric conditions, in particular, require further study.

The result of experience this year on the 220-kv. transmission lines in California is very encouraging. In the northern and southern California systems 220-kv. transmission seems now an absolute necessity, as a result of the large power loads to be transmitted. The leading charging kilovolt-amperes supplemented by synchronous condensers is proving a valuable asset in voltage maintenance.

Transmission research work is being carried on in California and at other places, to determine all the factors entering into a system of transmission that will give the greatest practical reliability of service and the greatest stability and efficiency. Those responsible for financing and cooperating in carrying out this work are to be commended.

In the eastern section of the United States, various companies have, or are contemplating, changing their distribution systems from 3-wire 3-phase 2300-volt, or ¼ phase, 2300-volt, to 3-phase, 4-wire, 2300-4000-volt. The special problems involved in such change-overs include, in general, arrangement of wires, identification of neutral wire and phase wires, transformer connection, re-winding motors, etc.

The increased demands for electrical energy in urban districts are likewise tending towards the use of higher distribution voltages in order that larger amounts of energy may be delivered more economically, and the congestion of overhead routes avoided. This increase of distribution voltages makes necessary the development more of economical and efficient types of lightning arresters, fuses, switches, and other protective apparatus.

The demand for rural service continues to be felt throughout the country, and types of construction and material economically suited for this service are being given careful attention. The low-load factor, in general, experienced in rural service has made advisable some form of transforming equipment which will reduce the core loss during light or no-load periods, and progress is now being made in the development of equipment for this class of service. Also research work is being done to see how much power can be used by the rural areas in different sections of the country.

Continued progress is being made in the work of standardizing materials used for aerial construction the economical principles of which are apparent to both the producing and consuming branches of the industry. In order that the benefits of such standardization may be realized, the consumers should, in so far as possible, use such standardized equipment, and the manufacturer should continue to cooperate in the production and improvement of these various types of material. Where manufacture has been stabilized, such standardization can be accomplished through the American Engineering Standards Committee.

CABLE RESEARCH

The most important development during the past year has been the evidence that the cable specifications of the N. E. L. A. and the present Standards of the A. I. E. E. do not insure a satisfactory cable for the higher operating voltages.

This subject is now receiving attention from the manufacturers as well as from the users of high voltage cable and as a result of these studies, it is hoped that it will be possible: *First*, to make the necessary changes in manufacturing processes and materials so as to secure a satisfactory cable for operation at the

higher voltages, and *Second*, to devise a method of testing high voltage cable which will determine its operating characteristics in advance of its installation.

The Cable Research Subcommittee is cooperating with similar committees of other organizations in the development of the necessary tests and specifications for this purpose.

During the past year a 500,000-cm. single-conductor underground cable installation has been made from the Sherman Creek Station of the United Electric Light & Power Company in New York City northward a distance of about eleven miles into Westchester County, which is intended for operation at 44 kv. 3-phase. An eight-mile line of similar size has been installed by the Cleveland Electric Illuminating Company for operation at 66 kv. 3-phase. These are the first high-voltage single-conductor underground transmission lines to be installed in this country and the results of their operation will be watched with considerable interest.

The committee is cooperating with the technical colleges in connection with their researches into the properties of impregnated paper insulation, as follows:

Massachusetts Institute of Technology.

The effect of heat on impregnated paper insulation.

Harvard Engineering School.

Dielectric loss and ionization.

Cornell University.

Dielectric loss, ionization and the mechanism of cable failures of impregnated paper insulation.

Similar investigations are now under consideration by Washington University (St. Louis, Missouri).

FRANK G. BAUM, *Chairman.*

LIGHTING AND ILLUMINATION COMMITTEE

To the Board of Directors:

Pursuant of the recent practise, the report of this committee is submitted in two principal sections; the first being an outline of the committee's plan and work, and the second a brief resumé of the advance in lighting for the year.

COMMITTEE ACTIVITIES

The Committee held an investigation meeting at the A. I. E. E. Headquarters, October 11, 1923, in which the plans for the year were generally formulated. Mr. Skiff was reappointed in charge of Illumination Items, and Dr. Shackleford in charge of solicitation of convention papers.

Various plans were discussed, and it was understood that the Chairman would continue the discussion among the membership of the committee by correspondence.

Illumination Items. The Committee has kept the Editor of the JOURNAL continuously supplied with articles for inclusion in this section. Some of these are original contributions, others are reviews of papers or reports published elsewhere. Concerning the latter, it often happens that information of value to practising engineers is accompanied with much mathematics or involved discussion of theory. The committee has endeavored to extract the essential conclusions and data in convenient form for the use of the membership. Inquiries concerning various topics indicate that the articles are read with considerable interest.

In connection with this work the committee supplies the Editor with short notes, for use as fillers.

Convention Papers. The analysis of the situation by members of the committee, leads to the conclusion that it is not desirable at the present time to submit many papers on lighting at general conventions. Relatively little material of note, in the strict field of the committee, has come out in the past year.

It seems to be the general opinion, and that of the committee, that pure lighting practise papers are more suitable for the Illuminating Engineering Society. Most of the material of this sort is better suited for Illumination Items than for the convention programs.

Guided by these considerations, and the congested condition of convention programs, the committee has found it expedient to arrange for only one paper—namely an authorative treatment of the general subject of street lighting, which is being submitted for the June convention.

Lighting Publicity. It has been suggested by C. F. Scott, that the material published in Illumination Items was of sufficient value to warrant steps to encourage wider use. Several plans for encouraging the copying of Illumination Items have been investigated. The following procedure was finally adopted as the most expedient. The committee will submit to the Editor of the JOURNAL, with each piece of copy, a list of periodicals likely to be most interested. The Editor thereupon will secure a few extra proofs, and forward to designated publications, with memo of release date. It is expected, of course, that in using such material credit will be given to the JOURNAL, as the source. This program is just being started, so that it is not yet practicable to judge how effective it will prove.

Cooperation with Sections. It has been the desire of the committee to cooperate with sections, to encourage and assist them in securing high-grade discussions of lighting questions.

No practicable way has yet been found for initiating such an activity on a large scale. However, a plan has been formulated for starting in to cooperate with college sections, under the direction of collegiate members of the committee. Owing to lateness of this development it was not found expedient to undertake this during the current year, and it is commended to the attention of next year's committee.

Designation and Scope of Committee. A communication has been received suggesting a change of name for the committee, and a definition of its scope.

This proposal is under discussion within the committee, and it is hoped to make suggestions in this connection before final action is taken.

PROGRESS IN LIGHTING AND ILLUMINATION

Based upon the radical improvements in illuminants, there have for several years been many improvements in lighting equipments, which have not been taken full advantage of in practise. Therefore, at the beginning of the Institute year, the development of lighting equipments was far in advance of their application. This was especially true of economic features, in that practise was far behind in taking advantage of the value available.

As a result of a growing realization of this condition, there has been a rapid accelleration in the application of improved lighting, in both new and revised installations; so that the year stands out as one of raising standards, successful commercial campaigns, etc., more particularly than as one of engineering development.

While this is regarded in the lighting industry as a commercial achievement, it is also interesting because it represents a growing tendency to apply good engineering principles to lighting practise.

As mentioned in last year's report, the sale of incandescent lamps provides the best numerical measure of the advance in extent and intensity of artificial lighting.

The sale in the United States of so-called large incandescent lamps for 1922 as reported last year was 203,000,000, a gain of about 22 per cent over 1921. The sale for 1923 is reported to be approximately 245,000,000, or a further gain of over 20 per cent.

The lamps are those used upon power circuits and as such are reported annually by the Lamp Committee of the National Electric Light Association to indicate the growth of that phase of electric lighting in which the central station industry is interested.

In addition, there has been growing up a very large use of lighting supplied by batteries and other sources, usually separate from central station lines, as for example, automobile lighting, flashlights, surgical lamps, etc.

Lamps for these services have been considered as a separate class, designated as miniature lamps. Previous information has been less complete and accurate with regard to these lamps. Last year's report carried an estimate that 85,000,000 miniature lamps were sold in this country during 1922. More complete estimates now show that nearly 130,000,000 were sold in 1922. The latest compilation shows the sale for 1923 to have been approximately 175,000,000, nearly all being tungsten lamps. The remarkable extent of the lighting represented by miniature lamps has not been generally appreciated.

This is no doubt due to the fact that growth has been of such recent date. The earliest records now available are for the year 1908 when a little less than 2,000,000 miniature lamps, mostly carbon, were sold. The widespread use of electric-lighted automobiles and of flashlights are the largest factors in this growth.

Illuminants. There have been no outstanding developments during the past year, though many minor improvements have been or are being made.

In the manufacture of incandescent lamps, the improved machinery referred to in last year's report has been further improved and more widely applied. Besides increasing the flexibility of adapting manufacture to meet the demand, these developments have shown an influence in reducing cost. It is reported that tungsten lamp prices are now at least 30 per cent less than in 1920, in spite of increased costs of labor and materials.

Last year's report also referred to the fact that it had been found practicable to make tipless lamps. This has now progressed to a point where practically all the more common types and sizes of tungsten lamps are being made without tips.

There have been a number of changes in filament form. For example, the 200-watt 110-volt lamp is now made with a ring-shaped rather than a saw-tooth or loop filament.

Bowl-frosted lamps of the vacuum type have been widely used in open reflectors and shades for home lighting. When this finish was adopted an all-frosted lamp was considered extravagant, due to the loss of light through internal blackening of the bulb. Recent tests with various types of equipment in common use indicate that the all-frosted lamp is nearly as efficient. Where the bowl-frosted lamp was used in connection with open reflectors and some styles of frosted globes, the filament was exposed to view. The all-frosted lamps are therefore being recommended in place of the bowl-frosted lamps in order to insure diffusion and better appearance.

In the focus-type miniature lamps used for motor vehicle headlighting, an effort is being made to reduce the tolerance of dimensional variations, with the view of forming the basis of avoiding the necessity of refocusing upon replacement of lamps. The improvement should render practicable a fixed focus lantern. Such equipment if properly constructed, would do much to improve headlighting practise, which is today suffering from the failure of the motorist to focus.

Arc lamps have practically disappeared from all of the ordinary classes of lighting, with the exception of street lighting. In the ornamental form, a considerable number of arc lamps with magnetic electrodes are being used, especially in "white way" districts. It is reported that electrodes of increased efficiency have been developed during the year.

Arc lamps are, of course, still used extensively, for projection and photographic work.

Mercury arc lamps are used in photographic and industrial lighting and the quartz tube lamps for sterilization, fading and other chemical applications. No radical improvements have been reported.

The fact that the efficiency of present day illuminants falls far short of the theoretical ideal, is a continual incentive to investigators to search for improved methods of light production.

Much attention is being given to arcs and dis-

charges in gases. While some interesting experiments have been tried, no results giving immediate promise of practicability have been reported.

Lamp Equipments. There are a multitude of light-modifying equipments for use in connection with incandescent lamps. New types and improvements are continually being developed. Many of the improvements have to do with artistic appearance or mechanical convenience. No developments have been reported which incorporate radically new engineering principles.

The most distinctive development of the year is in connection with street lighting luminaires, following up the idea suggested by the recent highway lighting units.

Various characteristics of asymmetrical distribution have been incorporated in equipment for residence streets and thoroughfares, for the purpose of concentrating more light in useful directions, and reducing the light where useless or undesirable. The problems involved are rather complex, requiring consideration of degree of redirection, as well as relative values of light in different directions. There is still considerable difference of opinion as to what is most desirable in various classes of streets, with and without foliage, and considerably more practical experience is necessary before a general agreement among engineers can be expected. It seems likely, however, that some degree of asymmetry of light distribution will be found desirable for certain classes of streets, while on the other hand, symmetrical distribution will predominate in others, for example, "white ways" and business streets.

A number of new types of traffic signals has been developed both in those used for the control of traffic and those which simply warn drivers of busy intersections. The former group are practically all electric lighted. Owing to the recent improvements in electric equipment, a growing proportion of the warning signals are electric lighted, either from central station circuits or self-contained batteries.

Lighting glassware by its very nature is subject to certain variations as to light transmission and diffusing qualities. Such variations affect both the efficiency and appearance of luminaires. These variations can be minimized by care in manufacture and in some cases by grading. This, of course, means additional cost, so that unless there is a criterion for evaluating superior glassware, there will be a tendency for the cheaper products to predominate. An association of glass manufacturers has been making a study of the problem with the view of providing more suitable methods of specifying the desirable characteristics.

Practise. Standards of lighting are advancing in practically all fields; notably homes, streets, stores, show windows, signs and schools. The improvements involve both higher levels and better diffusion.

Home lighting, involving as it does the elements of art and tradition, has been found a difficult problem for the illuminating engineer. Too often the application of modern incandescent lamps and higher levels has been rendered ineffective because the equipment has not been suited for the more brilliant and powerful light sources.

About a year ago, the shallow diffusing globe unit was found to provide a considerable improvement in kitchen lighting. This application found a remarkable acceptance, and under aggressive commercial campaigns, this practise has spread so that over 300,000 of such equipments are now reported to be in use. The indications are that there will be even greater activity in this field in the near future. Moreover, by educating the home-maker to the possibilities of good illumination, it seems likely to facilitate the improvement of illumination in other portions of homes.

From the humane viewpoint, it is important that hospital operating rooms be as well lighted at night as in the daytime. During the year a number of installations have been made which supply not only a high level of diffuse illumination but also light of a color approximating closely to daylight. This is reported to have advantages in identifying particular classes of tissue, and so facilitating accurate work on operations.

Certain athletic sports, such as tennis, have for years been carried on under artificial light. Artificial lighting has also been tried for baseball and football, but little has been heard of it after the first try-out. During the past year unusually good results have been reported in several games of each, the method of illumination being floodlighting.

Considerable experimentation has been carried on by the Government Air Mail Service, toward the improvement of airplane landing lights, field lighting and beacons for mail routes. Considerable advance is reported and new beacons are now being set up.

For a number of years considerable interest has been shown regarding the question as to whether or not there is something related to light as music is to sound.

Most of the attempts along this line have been the projection in sequence of various light colors, in varying intensity, without definite form. Some experimenters have used the effect to supplement musical productions.

One development which has attracted considerable attention during the past year has employed colors in more or less indefinite form, without musical accompaniment. Another development along similar lines, but for which no musical analogy has been claimed, automatically projects interesting kaleidoscopic patterns on a screen.

Various surveys and tests of lighting practise have been made and reported. A very important and extensive test of industrial lighting is now projected.

Codes and Standards. The state of Massachusetts has adopted an industrial lighting code similar to the American Engineering Standard. This is the ninth

state to adopt such a code. The Pennsylvania Industrial Lighting Code has been revised.

Last year reference was made to the organization of a sectional committee of the American Engineering Standards Committee to consider the project of a School Lighting Code, under the sponsorship of the Illuminating Engineering Society and the American Institute of Architects, (the A. I. E. E. being represented). This project has been carried on by the sectional committee and is understood to be ready for the final action of the American Engineering Standards Committee.

Another lighting standard referred to last year is the project relating to colored signal lights for traffic and other purposes. This question, which has many ramifications, is understood to be still under consideration.

American Engineering Standard on Illuminating Engineering Nomenclature and Photometric Standards, under the sponsorship of the Illuminating Engineering Society is receiving preliminary study for revision and further coordination with the corresponding European Standards.

Educational. For a number of years leading lamp manufacturers have conducted courses in illuminating engineering and lighting practise for representatives of the lighting industry. The past year has witnessed a considerable increase of interest in this direction.

Arrangements have been made by the National Electric Light Association for a course to be conducted under the auspices of the Illuminating Engineering Society for the purpose of training illuminating engineering specialists for central stations. This is to be held in the summer and fall of this year and is to include visits to a number of the larger cities.

Another educational undertaking about to be launched by the National Electric Light Association is a nation-wide movement to teach better lighting of homes.

American success in improving the practise in lighting has attracted much attention abroad and many visitors from various foreign countries have come to study our methods. Recently, a group of eight engineers from European lamp manufacturers inspected lighting in the large cities as far west as Chicago, and studied the American practises. Lighting demonstrations similar to those established in this country during the last two or three years have been installed in London and Paris.

In the United States the demonstration method of teaching good lighting seems to be firmly established. Various types of portable demonstrations are used in connection with lighting lectures.

A notable permanent exhibit, covering the principal applications of incandescent lamps, is attracting considerable attention.

A cooperative street lighting demonstration, covering about one-half mile of street has been installed in Cleveland to show the effect of various heights, spacings, locations, types and sizes of street lighting units. This has proved very helpful to municipalities studying methods of improving their street lighting.

At the Illuminating Engineering Society Convention at Lake George, New York, in September, 1923, one of the interesting presentations, was the solution of a hypothetical street lighting problem, by eleven different engineers representing a number of viewpoints. A similar method is being applied to an office-lighting problem with three contributors. The scheme seems to have possibilities of coordinating ideas on lighting practise.

The 1924 meeting of the International Commission on Illumination referred to in last year's report, is to be held at Geneva, Switzerland, Supplementing the usual reports, it is planned to have papers from various countries.

The United States National Committee will present a group of American contributions in this connection.

Research. That scientific research is still giving considerable attention to light, is evidenced by a few of the outstanding discoveries reported.

A new primary standard of light has been produced and described by Herbert E. Ives. While candlepower standards are carefully preserved in the form of incandescent lamps at several national laboratories, it is highly desirable that an accurate means of primary check be available lest there be a tendency over a considerable period of years for the standards to drift. The primary standards of the past have lacked accuracy of reproduction at the hands of different experts and under different local conditions. The new standard seems likely to insure greater accuracy in this connection.

An improved quality of transparent optical quartz has been reported as produced in a laboratory at Lynn, Massachusetts, by E. R. Berry.

The gap in the radiation spectra, between the infrared and the electric waves has finally been investigated by E. F. Nichols and J. D. Tear.

It was the final victory of Dr. Nichols' useful life, and he passed quietly away while presenting his results in an address before the National Academy of Sciences.

Conclusion. The remarkable accomplishments of electric lighting, are all the more notable when it is remembered that this art is so new and that many of the original pioneers are still alive and in active service. It, however, has reached the age at which losses may be expected to be numerous.

It does not seem suitable to close this report without mention of those outstanding Americans who have concluded their valuable contributions in this field, namely, Louis Bell, Charles P. Steinmetz and Ernest L. Nichols.

G. H. Stickney, *Chairman.*

MARINE COMMITTEE

To the Board of Directors:

The committee was organized, subcommittees were appointed and the first meeting was held November 8th. Three subsequent meetings were held. A good portion of the time of the committee's members has been devoted to the work of the Sectional Committee of the American Engineering Standards Committee for Electrical Installation on Shipboard.

The shipbuilding industry, while slightly improved from a year ago, is far from normal. The activities of your committee can only be reflected in proportion to that industry and greater improvement is hoped for during the coming year.

Owing to the success attending past installations of electric motors on shipboard, it is now almost universally recognized that electricity will be the future power for ships' auxiliaries outside of machinery spaces for all vessels, for all auxiliaries in Diesel engine propelled vessels and a portion of engine room auxiliaries in steam vessels.

Perhaps the most important and urgent work of the committee is the licensing of engineers, electrical, for vessels. The ship owners and operators must continue to bear the expense of educating the personnel, as no steps have been taken by the licensing authorities to improve the present conditions and, furthermore, the licensing authorities have candidly stated they can see no necessity for a change, although your committee has labored earnestly with them and presented what was thought to be conclusive evidence warranting action in that direction.

Your committee realized the importance of some action to insure proper maintenance of electrical apparatus on shipboard. We believe the matter has been presented to the shipowners and operators in such a manner that they are also convinced that some changes are desirable and your committee proposes to continue its activities, until some relief is obtained. It is to be regretted that developments did not warrant the presentation of the paper on the subject at the November 1923, meeting of the Naval Architects and Marine Engineers, as anticipated.

The Power Apparatus Committee is preparing, and no doubt will complete next year, some definite detailed recommendations for the kind of current, type of apparatus and control for various auxiliaries for several types of vessels.

The depression in shipping and shipbuilding has not given the Propulsion Committee the opportunity expected to collect and compile data from electrically propelled ships. There have been a few Diesel electric ships completed during the past year and some data should be available in the near future.

The Publicity Subcommittee have issued several interesting articles relative to marine electrical installations.

The other subcommittees on Standard Appliances, Historical, Radio, Wires and Cables, Interior Communication Apparatus and Editing have taken care of current work with nothing special to report.

The committee as a unit has worked harmoniously. The coming year will tax the committee with matters pertaining to the licensing of engineers and considerable energy will be require to have the Marine Rules adopted as an American Engineering Standard.

The committee is to be congratulated for its consistant efforts and achievements.

G. A. PIERCE, *Chairman*.

INDUSTRIAL AND DOMESTIC POWER COMMITTEE

To the Board of Directors:

During the past Institute year this committee had charge of an Institute Session at the Midwinter Convention in Philadelphia where two papers on the "Electric Elevator" were presented followed by a very interesting discussion of this important topic.

The committee assisted the New York Section in arranging a meeting on "Electric Drive for Ventilating Fans" which was held in New York, November 14th, 1923.

At the present time increasing interest is being taken in the application and control of motors for industrial purposes. Commercial motors are limited to relatively few types, but the control apparatus is capable of wide variations and in many cases control can be designed which will permit the use of a standard motor for most applications. The control system has, therefore, been receiving an increasing amount of attention, as it is realized that the success of many applications of electric drive depends upon selecting suitable control equipment.

Surface indications would lead one to believe that the type and variety of control is being greatly increased; the contrary, however, seems to be the case. As every art develops, engineers at first solve each problem in a new way as standard apparatus is limited and it is necessary to broaden their experience; as these accumulating data are analyzed it becomes possible to group the various problems and develop apparatus which will take care of the more frequent applications. It is also possible to subdivide the problem into units which can be standardized, so that where special systems are necessary they can be assembled from standard units.

Control engineering is working in the second stage where standardization is becoming of increasing importance. To a very great extent, the unit parts of

control equipment are being standardized and a number of combinations is being eliminated as it is found that during the earlier developments of the art systems were listed with only minor differences. By consolidating similar systems of control, a number of combinations now listed as standard can be eliminated. This standardization is a direct benefit to the art, as it reduces the new combinations and new apparatus developed on customers' orders; it enables the customer to obtain prompt service; and it enables the apparatus to be produced in a more economical manner, thus reducing the first cost of the installation and making electric drive more popular.

During the past year there has been some interesting applications and some new apparatus placed on the market.

The following is a partial list of new applications:

Silk Spinner Drive—In Textile Mill

The first commercial installation of a three-motor automatic drive for combination spinning, doubling, and twisting machine drive was placed in operation during this year. Each one of the three decks is driven by a one-horse power vertical motor, all three of which are mounted on the same end stand of the frame and in the proper location to drive the spindle belt.

An automatic magnetic trip throws the feed rolls out of action when the power is shut off or when it fails, and a fly-wheel on the motor, which drives the upper deck, continues the twisting on this deck for a short period, after the lower deck stops, sufficient to take up the slack in the yarn and thus prevent kinking.

The feed rolls are driven by a gear from the upper deck motor, thus insuring a positive twist.

The method of drive practically eliminates all kinks and broken ends due to failure of power and shutting down of the machine and also insures a positive and uniform twist.

Individual Motor Drive for Cotton Card

The first commercial installation of an individual motor drive on cotton cards was accomplished this year. The installation consists of 63 of the latest type of cotton cards installed in a new cotton yarn mill, each driven with a 1¼ h. p. gear-connected motor, mounted as an integral part of the machine. Control is accomplished with a special combination of snap switches in one cabinet to give normal forward operation and reverse direction of the machine for grinding the card clothing. Stripping is taken care of by rope and sheave drive, direct from the motor shaft.

The method of drive insures freedom from specks, dirt or oily lint, usually present with the line shaft and belt method of drive.

Electric Elevators

During the past year, there have been a great many installations of passenger elevators in office buildings, equipped with automatic leveling devices. The leveling being accomplished principally through the medium of an auxiliary motor which drives the hoist rope sheave through a set of spur and worn gears.

There has also been developed, a system for automatically leveling the elevator car at floor landings without the use of auxiliary motor, use being made of the main motor operating at a slow speed when leveling and controlled automatically when running at this slow speed. When the operator desires to stop at a floor, he moves his car operating switch to the neutral point when within a given distance of the floor at which he wishes to stop and the controlling mechanism then functions automatically to slow down the main motor and bring the elevator car to practically a level with the floor sill.

Another system of elevator control has been developed and has just been put in operation which has been termed, the Signal Control. This control operates somewhat on the order of the automatic push button elevator in that a passenger desiring to go up or down from any given floor in the building, presses the push button for the desired direction and the first approaching car will then automatically stop at that floor without any action on the part of the car operator, providing the elevator car is not loaded to capacity. When the passenger has entered the car, the operator closes the door and presses a push button in the car corresponding to the ground floor or the top floor and the elevator automatically starts off and runs to the terminal landing unless stopped by another passenger who has pressed a button on another floor. The operator in the car, when asked to stop at a particular floor, presses the button in the car corresponding to that floor and the car then automatically stops at that floor. This signal control system is also designed to automatically open and close the hatchway doors and the car gate.

These automatic leveling and automatic stopping elevators, can be operated on either direct or alternating current, as the motive power is usually supplied from a small motor-generator set which can be driven by a d-c. or an a-c. motor. The generator end of the set always being direct current.

The cars of these elevators are now in successful operation at 600, 700 and 800 ft. per min.

There has also been developed and put in operation recently, a new type of worm gear traction elevator, consisting of a *V* groove traction sheave driven by two worms operating on one gear wheel. The two worms being mounted vertically and each directly connected to the armature of a vertical-type d-c. motor. The acceleration and retardation of this type of winding machine when used with field weakening motors having a speed range of one to two or one to three, is remarkably smooth and rapid and is practically free from back lash.

Oil Well Drilling

One of the most interesting developments in the petroleum industry for many years is the Hild System of oil well drilling. This system is especially adapted for rotary drilling and makes use of practically standard "draw works" but introduces several features which have been previously lacking. The electrical equipment consists of two wound-rotor induction motors with suitable reversing controllers and regulating resistance, together with a gear unit which combines a speed reduction and a differential unit.

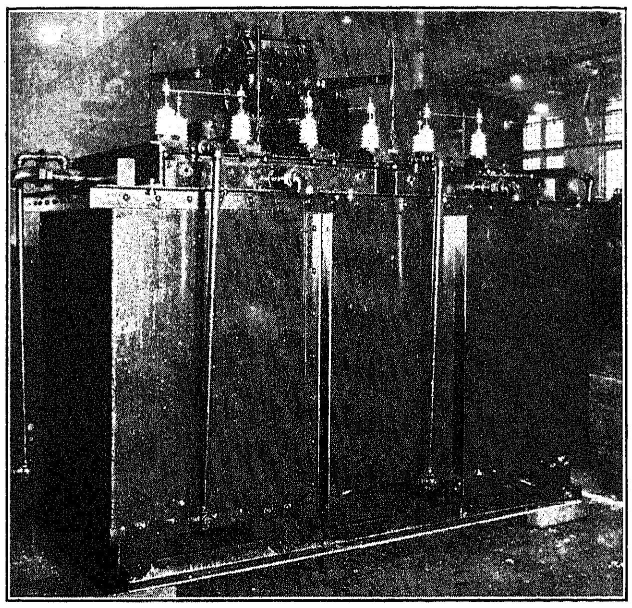

Fig. 1

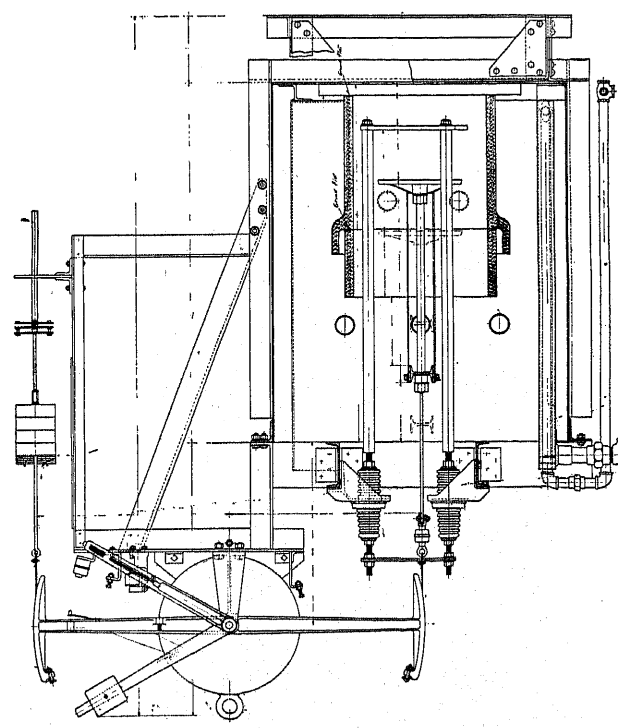

Fig. 2—Lewis Type Slip Regulator

This combination of motors, control and gears provides automatic feeding of the bit so that in sand or soft rock a high rate is obtained, while in hard or sticky formation the feed is slow, thus insuring a straight hold and reducing or eliminating the chances of twisting off the drill pipe. The forcing of the bit with no knowledge of the pressure on the bottom has probably been the cause of most of the trouble with rotary drilling; the Hild System eliminates this guess work.

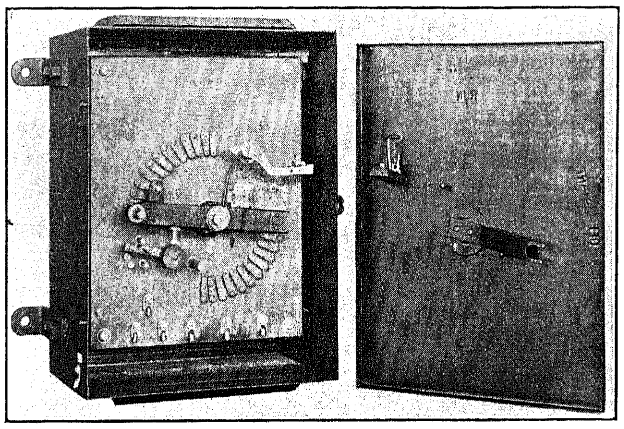

Fig. 3—Safety Starting Rheostat for Slip Ring Induction Motor

Some of the new electrical equipment placed in service during the past year is as follows:

Slip Regulator. Figs. 1 and 2 show a 1500-h. p. slip regulator for a wound-secondary induction motor. This regulator is of the liquid type and differs from the previous regulators in the construction and arrangement of the cells constituting the resistor element for each of the three phases. These cells are located within the electrolyte tank and have the terminals of the stationary electro brought out at the top of the tank.

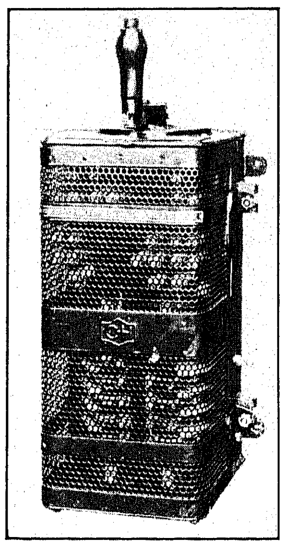

Fig. 4—Reversible Compound Drum Controller

This arrangement avoids leakage of the electrolyte, either through the connections at the bottom of the cells or by reason of failure of the cell walls.

Starter for Wound Secondary Induction Motors. This starter introduces resistance in the secondary of the motor during the starting period, its general features are illustrated in Fig. 3.

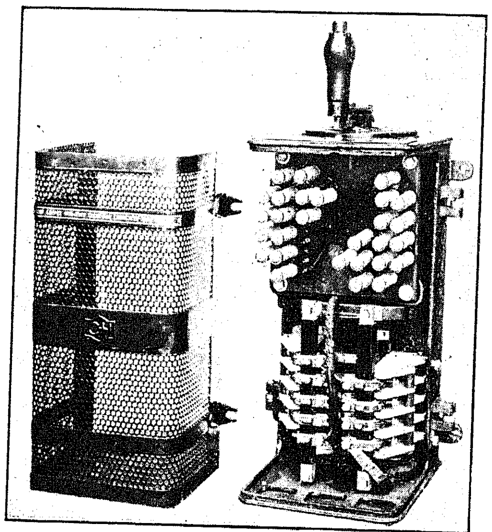

FIG. 5—REVERSIBLE COMPOUND DRUM CONTROLLER

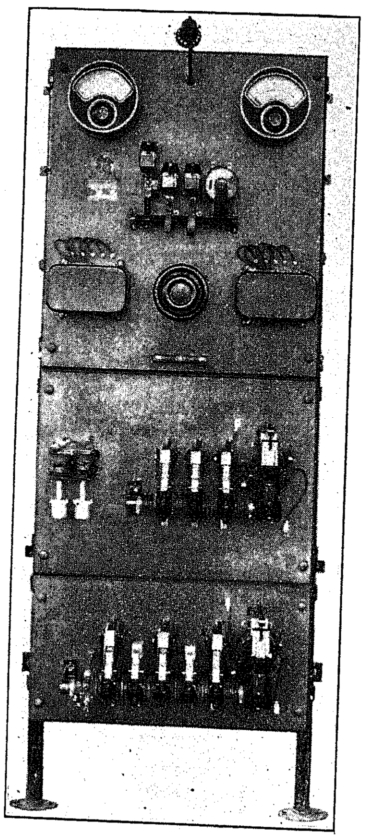

FIG. 6—AUTOMATIC STARTER FOR 3-PHASE SYNCHRONOUS MOTOR 150-AMPERES 550-VOLTS

Machine Tool Control. The distinctive feature of this controller is the mounting of the field controlling resistors within the case and adjacent to the drum fingers for commutating it. Both the resistor units and the controller fingers connect to this resistor and are mounted on a single slate base; this eliminates lead wires. The resistor units can be removed by loosening one nut at the end of the stud on which they are mounted.

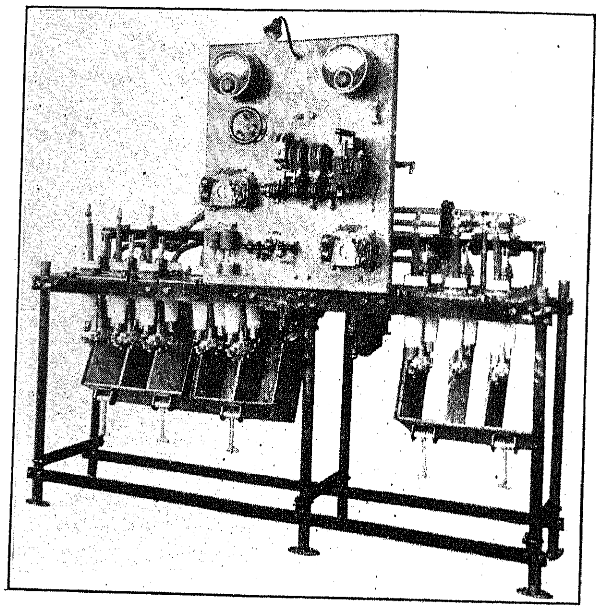

FIG. 7—AUTOMATIC SYNCHRONOUS MOTOR STARTER

Synchronous Motor Starters. These starters somewhat resemble the auto-transformer starters used for squirrel-cage induction motors. A starter of the 550-volt class is shown in Fig. 6, and for 2200-volt service in Fig. 7. The special features of these controllers are two motor-driven time relays, one for controlling the contactors which connects the motor to the auto-transformer to give reduced starting voltage, afterwards changing the motor connections to full voltage and the

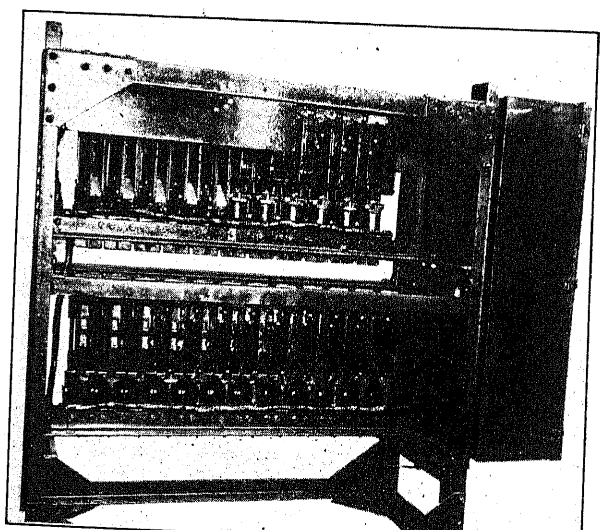

FIG. 8

other relay closes the field contactor after the motor has reached full speed.

Logging Donkey. The control illustrated in Figs. 8 and 9 uses pneumatic contactors for handling the main motor circuits. These particular controllers operated a 300/200 h. p., 2-speed yarding motor and two 250-h. p. loading motors. The illustration shows only one

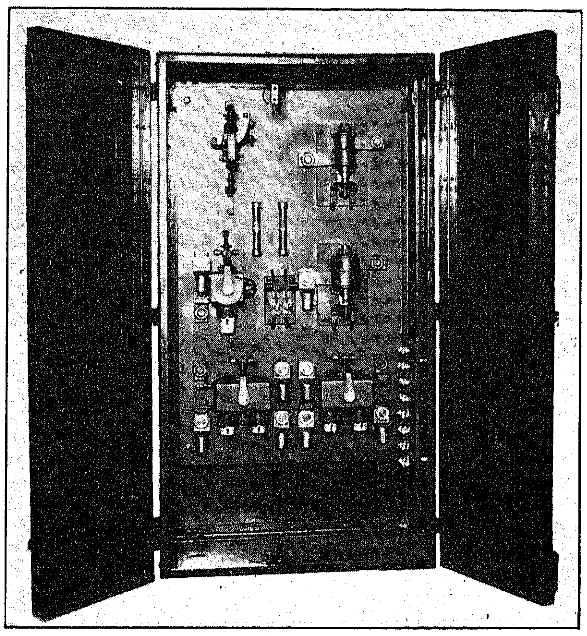

Fig. 9

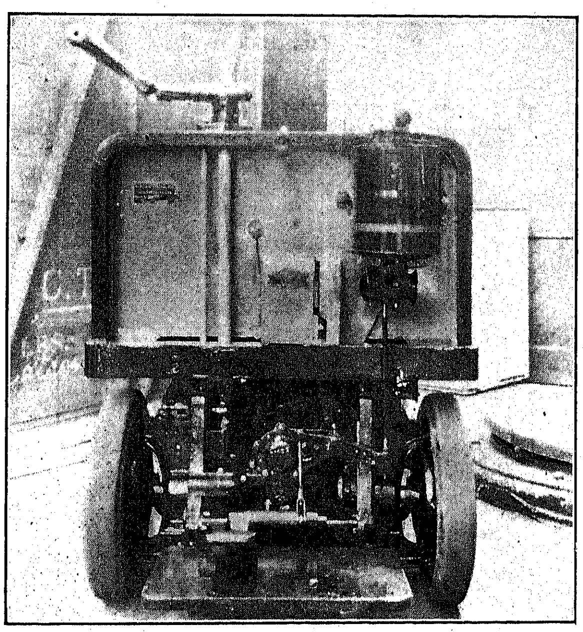

Fig. 10—Controller Mounted on Industrial Truck

controller. Air-operated contactors of this type are held open by a heavy spring and closed by an air cylinder. Their operation is still free from shock or jar and it is not necessary for them to be mounted in any definite position.

Industrial Truck. The control equipment shown in Fig. 10 is very interesting, not only from the apparatus standpoint but because it shows an application that is rapidly increasing in favor, namely, the storage battery. The control proper is of the drum-type, having mounted within the case a line switch interlocked with the brake pedal in such a way that the line switch is open if the operator applies the brake when the controller is in the running position. It is

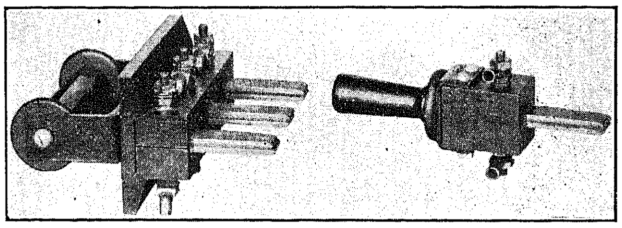

Fig. 11—Plugs for Use with Safety Type Jack Disconnecting Switch

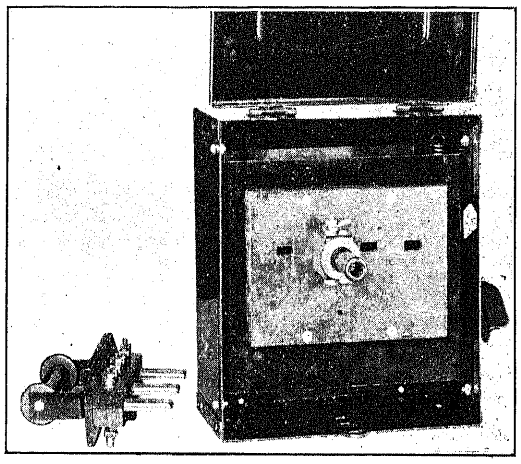

Fig. 12—Safety Type Jack Disconnecting Switch

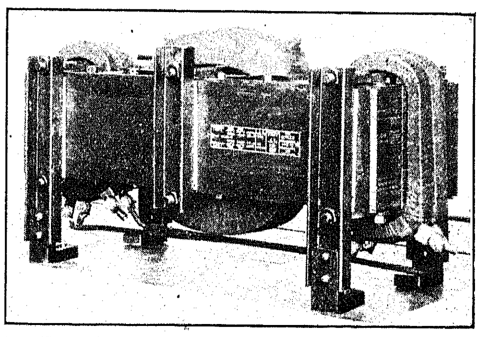

Fig. 13—Ten Kilowatt Magnetic Dimmer Element

then necessary to return the controller to the starting position before the line switch can again be closed.

Jack-Type Disconnected Switch. This device is illustrated by Figs. 11 and 12. The jack switch can be used for disconnecting control equipment and can also be used with ammeter and wattmeter jacks to connect these instruments in circuit without opening the line. Arrangements are made which permit this switch to be locked in the closed position, to prevent interference by unauthorized persons.

Magnetic Dimmers. A three-wire dimmer of the

magnetic type is shown in Fig. 13. This device is similar to a transformer, the central coil being connected to a source of d-c. power; the outer coils are connected in circuit with the lamps to be controlled. The power delivered to these lamps is varied by changing

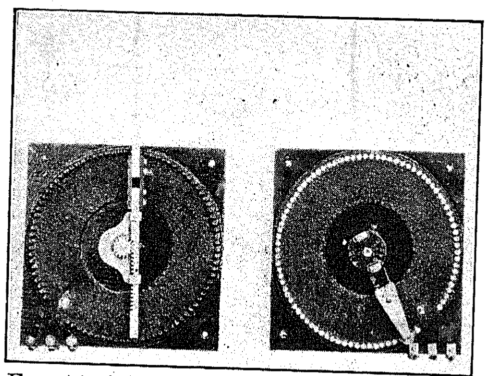

Fig. 14—Magnetic Dimmer Control Plate

the current in the d-c. coil, which changes the reluctance in the magnetic circuit of the a-c. coils. Fig. 14 shows the control plate for this magnetic dimmer.

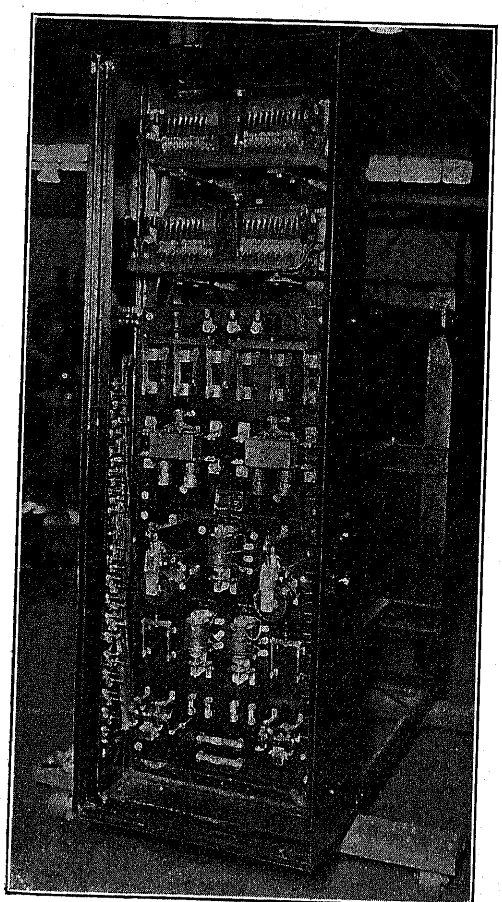

Fig. 15

A-C. Shovel. This is another application of the pneumatic contactor for industrial uses. This type of contactor was originally developed for railway service and is well adapted for industrial applications subject to continual vibration and shock. The design is made very compact and relatively light in weight. The electric shovel is similar to a large freight car filled with machinery; it is self-propelled and is often moved over rough and uneven surfaces. In many cases it is not practicable to operate the shovel with the floor level on account of the nature of the ground. The particular control illustrated is part of the equipment which

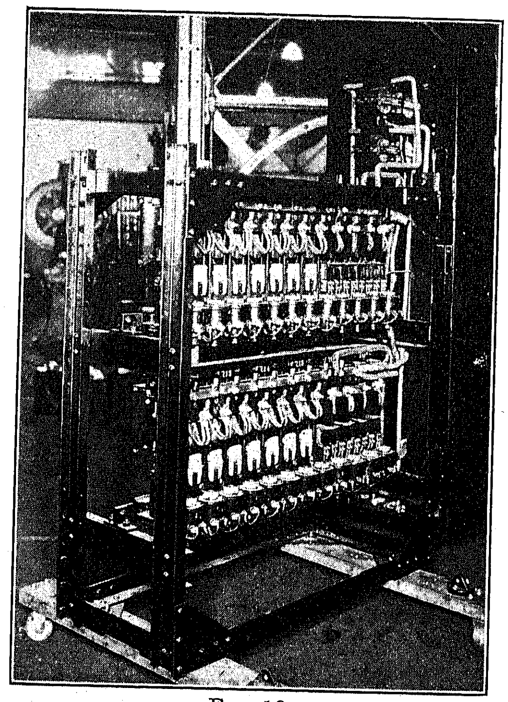

Fig. 16

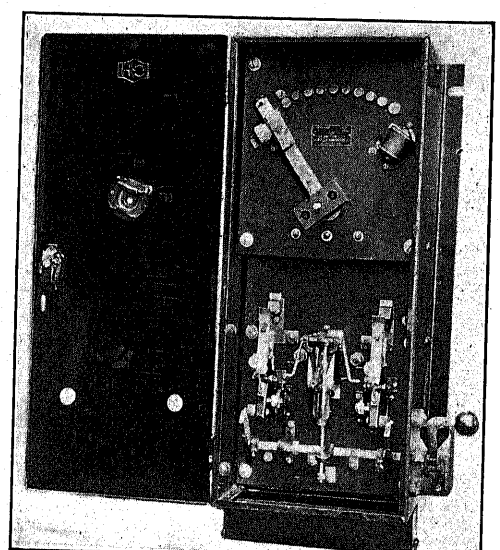

Fig. 17—Enclosed Manual Motor Starter with Circuit Breaker

consisted of two 150 h. p. hoist motors, one 80-h. p. thrust motor and one 80-h. p. swing motor.

D-C. Selenoid Brakes. These brakes are of the standard shoe type, the braking pressure being applied by a single spring and released by a solenoid magnet. They can be adjusted by hand and are so arranged that

the proper position of the adjustment is indicated by a pointer on the brake arm. The brake coils are weatherproof and have type B insulation which will withstand high temperatures. The travel of the magnet core is short, which increases the life of the working parts.

Controller for Building Equipment. The controller illustrated in Fig. 17 consists of a line switch and a starting rheostat, both operated from the outside of the case. The rheostat arm is held in the "off" position by a spring, it is operated in the usual manner after the line switch is closed and is held in the running position by a magnet. The arm automatically returns to the "off" position when the line switch is open. The line switch is so arranged that only one pole is closed at a time. If a ground or short circuit existed during the closing period, one pole would be free to trip open and relieve the circuit at the time the second pole was closed.

Definite Time Accelerating Relay. This relay is designed to give a maximum interval of approximately five seconds and is for use on a-c. circuits. The principle of this relay is an armature energized by an alternating magnetic flux. This armature is drawn across the face of the magnet under spring pressure. Each time the magnetism passes through zero, the armature moves a small distance. The repeated moving and gripping of the armature by the magnetic flux results in a ratchet movement and introduces the desired time element.

H. D. JAMES, *Chairman.*

POWER STATIONS COMMITTEE

To the Board of Directors:

SCOPE OF THE COMMITTEE

The Committee has not departed in the year past from the four main activities outlined in last year's report as:

First. Routine analysis and recommendation of papers submitted by the Meetings and Papers Committee.

Second. Securing of papers on subjects related to the Committee's jurisdiction for publication in the A. I. E. E. JOURNAL.

Third. Special research investigation with reports and papers resulting therefrom.

Fourth. Resumé of the year's progress on power station work.

In connection with the foregoing and the subject matter, as well as the treatment of the report, which follows your attention is directed to the extract from the "Tentative Report (touching this committee) of the Committee to Review Technical Activities of the Institute" as follows:

COMMITTEE OF POWER GENERATION

Field: Cognizance of all matters in which the dominant factors are the requirements, selection, relation, installation and operation of machinery and devices necessary to the generation and supply of electrical energy, including the economic questions thereto.

Note: The expectable functioning of this committee should be initiatory and determinative in the matters within its province. Subject to the approval of the Board it would have power in all matters arising therein, except such formulation of standards as is the function of the Standards Committee, including those of contact with other bodies and of arrangement for joint action where such is indicated.

Mention is made of this point because of certain criticism of two sorts which has come to the attention of the committee:

1st. That in previous years it has rather perfunctorily duplicated some of the reports of the organizations avowedly chiefly interested in operation, and

2nd. That the character of the reports has not been consistent with the dignity of the Institute primarily as a scientific body.

It is difficult to see how compliance with the procedure applied by the latter criticism can be made consistent with the field proposed for the realignment of the committee activity, if indeed there are sufficient matters of purely technical and scientific interest arising yearly within the scope of this committee to justify its continued existence without in any way treating of practical operating conditions.

As to the first criticism it may be sufficient to say that there is a feeling among several members, at least, of the committee that such practical operating reference as have heretofore appeared would be of value to a certain portion of the Institute not connected with associations of operating companies in various kinds of power station activity.

It would seem desirable that your body take under advisement from year to year the questions whether the active functioning of a committee like this could to advantage be, at least temporarily, discontinued; whether the committee is functioning along the most desirable lines; whether the committee is functioning in these lines to best advantage both intensively and extensively?

ACCOMPLISHMENT

During the year there has again been routine consideration of papers submitted by the Meeting and Papers Committee.

As to initiating the publication of papers, some progress has been made and is still in the making.

The idea of interesting manufacturers and colleges equipped with suitable laboratories in special research investigation along lines kindred to the activity of this committee has been considerably advanced. Several such laboratories are in a position to make at least initial analysis of the requisites of the problem as soon as specific cases can be laid before them. This calls for initial action from the members of the Institute through this committee. It must not, however, be expected that such research, except in special cases, can be carried on without providing the necessary funds for it. But it is much to know that facilities in both equipment and personnel actually exist for carrying on many problems, for which many might suppose a

considerable period of preparation and large expense would be necessary.

Résumé of the Year's Progess in Power Station Work

It is scarcely possible to attempt to review power station progress without trenching upon ground covered by the 1923 reports of the Electric Apparatus and Prime Movers Committee of the N. E. L. A. and the Power Generation Committee of the A. E. R. A. to which particular reference is made for a wealth of information and detail. Certain points, however, deserve special mention and are given with somewhat definite treatment.

In the preparation of this portion of the report each member of the committee was made responsible for certain topics; failure of presentation of any subject that might appear important in a report of this character is to be attributed to the inability of the individual to furnish the appropriate data. Several members of the committee have expended no little time and energy in the preparation of their contributions.

General

The most impressive feature of the year's power station work was the unusually large building activity of both steam and hydraulic plants, amounting to approximately 5,000,000 kv-a. of generating capacity and the continued tendency toward larger stations and larger units.

Hardly in any other year than during 1923 have so many schemes been introduced to increase the steam power plant efficiencies. The insecure and the varying grades and qualities of coal have given fuel oil and pulverized coal a very strong impetus. With fuel oil there happened to be a heavy over supply, therefore bringing a low price, and with pulverized coal the recognized advantage of being able to use various grades of coal within the same furnace without great trouble, its flexibility and ability to maintain high efficiencies were the major inducements for so many changes and new installations. It appears that although for some time pulverized coal had been used, no uniform practise has developed. The mode of firing, especially, appears to lack satisfactory solution. On the other hand a considerable number of improved stokers has been installed, and may be still further developed in the future under the pressure of the competition of pulverized coal. The sizes of boilers and furnaces have rapidly increased to considerable dimensions and it has been proposed to build a single boiler to supply a 30,000 kw. turbine-generator unit. Such a boiler would have a heating surface larger than the biggest boiler now used, by about one third. Recent boiler designs show a tendency to increase the heating surface exposed to radiant heat and some contemplate lining the entire furnace with heating surfaces. Should this be successful, the difficulties with refractories would be overcome, and the operation of boilers at high rating with preheated air would gain increased impetus. Investigations of superheated steam temperatures in connection with varying boiler loads have led to various superheater developments. Hand in hand with high ratings the furnace volumes have so rapidly increased in size and cost that future growth may be limited by economical considerations. High ratings brought higher flue gas temperatures and therefore the economizer was brought to the front again. For the same reason the demand for better feed water developed more efficient water treatment plants, evaporators and deaerators.

The striving for high efficiencies has brought higher steam pressures and with it various new cycles and larger capacities of generator units which have increased to 62,500 kv-a. These larger units are mostly of cross or tandem compound arrangement, especially where higher steam pressures are contemplated in connection with a reheating cycle.

With the innovation of bleeding main turbines for feed water heating, the house turbine direct connected to the main unit has been developed. As for steam pressures, installations are being made for 400 and 500, 1200 and 3200 pounds, the last one by the English Electric Company, at Rugby, England. The maximum temperatures considered for the above pressures are between 700 and 800 deg. fahr. With these high steam pressures and temperatures the reheating or Ferranti cycle, the regenerative cycle and the combined reheating and regenerative cycle are given most attention.

Toward the end of the year much was heard of the mercury turbine which has been under development by the General Electric Company since 1914.

As far as valves and fittings are concerned, it has been reported that tentative standards for pressures up to 900 lb. per sq. in. and at a temperature of 750 deg. fahr. have been agreed upon. Besides this rapid departure from established steam practise, the economic success of which only time can prove, the leading manufacturers have carried on research and improvements on established equipment. Two out of the three largest builders of equipment are giving turbines resonance tests before leaving the shops, and much thought is given to generator cooling, of which the closed system of ventilation appears to be gaining in favor. The operating results of modern steam turbines have improved markedly.

The development in hydraulic plant equipment has followed the general trend of steam plants, both in improvement of design and construction, and in size of units. The tendency toward large sized vertical units continued, and more attention was given to the question of suitability of design for the hydraulic conditions and load requirements, and careful working out of the details of design of auxiliary equipment required for the proper control and protection of the main units. The operation of the various control mechanisms electrically from the switchboard has come into more general use, and the details of switchboard control mech-

anisms as well as refinements in the setting, and the adjustments of such mechanisms have been worked out successfully.

The tendency in large hydroelectric stations, consisting of two or more vertical units seems to be in favor of a single floor station, with the main floor at approximately the elevation of the top side of the turbine casing, or about the center line of the main turbine steady bearing. With this type of station layout the generator is generally supported on reinforced concrete piers and the switchboard and remote control mechanism are located in a gallery off the main generator room, at about the elevation of the generators. This arrangement gives the operator vision of the generators, turbine equipment, governors, and all auxiliary apparatus.

Outstanding, as to size, are the 70,000 h.p. hydraulic turbines for the Niagara Falls Power Company, operating under a head of 213½ feet, at a speed of 107 rev. per min., and connected to a 65,000-kv-a., three-phase, 25-cycle, 12,000-volt generator. These units are also equipped with air brakes for bringing them to a stop quickly when shutting down.

The hydraulic turbine of the Oak Grove plant, of the Portland Railway Light & Power Company, at Portland, Oregon, has the highest head reaction wheel built to date. This is a 35,000 h.p. vertical turbine designed for operation under an average net effective head of 875 feet, the static head being 960 feet. The unit will operate at a speed of 514 rev. per min. and is complete with governor operated, automatic water economizing pressure relief valve; 72-in. water and electric motor-operated remote control butterfly valve; Moody type spreading draft tube and special oil pressure governor. The penstock providing power water for this unit is comparatively short but on account of its combination with a flow line several miles in length, the regulation problem involved has been solved by the installation of a Johnson differential surge tank hewn from the solid rock. A Johnson plunger type valve is provided at the upper end of the pipeline just below the surge tank, equipped with remote control and with emergency control features to provide for its mechanically closing down in the event of rupture to the pipeline or for any other reasons which would increase the velocity of the flow within the line above normal.

A notable improvement in hydraulic turbine design during the year, has been the use of the rubber seal rings or clearance rings in a number of large turbine installations. Former constructions have required metal rings at the clearance spaces between the rotating runners and the stationary portions of the casing. Usually these rings have been made in pairs, of which the rotating part is steel and the stationary, bronze.

The governor problem has been given special attention, and much improvement in speed control and regulations has resulted. Present-day governors are made with various accessories and auxiliaries, the use of which affords practically absolute safety and protection to the generating equipment under all phases and conditions of operation. Owing to the large size of the present-day electrical systems and extremely large inherent flywheel effect available for speed regulation, it is now very seldom that it becomes necessary to require that any additional flywheel effect be provided in the generator, or the hydraulic prime mover, to satisfy speed regulation requirements, as the inherent flywheel effect of the machines added to that of the system into which they will be connected is generally more than ample. With this condition there is also a strong and proper tendency on the part of the operators to simplify their pipeline and surge problems by increasing the length of time required for the governor stroke. With modern governors the stroke time may be regulated to meet conditions exactly, and the time for the opening stroke may be made different from that of the closing stroke.

Considerable progress was made during 1923 in various design features and in the control mechanism of butterfly valves. The remote electrical control of such valves when placed at the upper end of a pipeline or at the outlet of a surge tank has been quite generally adopted. A system of distant control has been developed which insures the correct operation of the valve at times of emergency without danger of the valve being operated inadvertently by accident to the control circuit through lightning or mechanical injury from falling trees, etc. Such valves can, of course, be readily operated by means of the controller at the valve and by means of suitable relay mechanism can also be operated from the powerhouse. Most installations are arranged to allow closing of the valve from the powerhouse but not opening it from that point, thus providing for the necessity of closing the valve in case of a serious accident at the power house, or to the pipe line, but not allowing the automatic opening of the valve from the power house with the pipe line empty, as this might cause serious damage or even loss of life. Indicating lamps are provided to show at the power house switchboard the open or closed position of the butterfly valve, and the operating motor of the valve is equipped with limit switches to prevent overtravel of the valve at either end of the stroke.

Attention has been given to increasing the life of generators as well as improving their stability. Use of relays for protection, particularly of the thermal type, has been quite a factor.

More confidence in extremely high-voltage transmission has developed from the results of the 220,000-volt systems put in operation during the year by the Southern California Edison and the Pacific Gas & Electric Companies. Transformers and switching gear for such service contributed much to the success and indicate that distinct progress has been made in the design and construction of such equipment.

For the higher voltages, switching apparatus and transformers are generally installed outdoors on ac-

count of excessive housing costs, and there is a tendency for the lower voltages to isolate the phases and isolate the entire switch house from the main power station building.

Mention should be made of supervisory control of generating stations from a central point which is generally in the load dispatcher's office, where is located the system diagram board on which switches are indicated by small colored lamps which at all times give complete information concerning operating status of the entire system. The development of the carrier-current system of telephony, which effects communication by means of high-frequency currents superimposed on the power conductors of the transmission lines, has increased the scope of usefulness of supervising control, particularly of hydroelectric stations located in remote districts.

Switches and Circuit Breakers

During the last few years the rapid increase in capacity of a number of large systems has reached the point where it has become a difficult matter to secure satisfactory oil circuit breakers of sufficient interrupting capacity to protect the system even when current-limiting reactors, to limit the short-circuit current, are used in every way practicable. The manufacturers of oil circuit breakers are making herculean efforts to keep pace with the requirements of the industry but to date no breaker with an interrupting capacity greater than 1,500,000 kv-a. has been installed.

The manufacturers have been handicapped in their design on account of their inability to test their breakers to destruction due to lack of generator capacity. To date very few large central stations have been willing to allow high capacity tests to be made on their system. It is believed that oil circuit breakers of very much greater interrupting capacity than have been manufactured, can be successfully made providing the need is great enough to justify the cost.

In order to limit the number of short circuits in power stations and minimize the damage done in case trouble occurs on the bus or switching equipment, a segregated phase scheme, either horizontal or vertical, is used in a number of the latest and largest stations built during the last two years.

Gang-operated disconnecting switches interlocked with the oil circuit breakers are to a great extent replacing single pole switches operated by a switch hook. In one of the newest large central stations practically no disconnecting switches are used for disconnecting the oil circuit breakers from the bus or line. The disconnection of the breakers is accomplished by lowering them below their normal position, thus breaking the connections and isolating the breakers.

The use of truck type panels for controlling station auxiliaries is increasing. A number of the latest large stations have installed or are contemplating the installation of equipment of this type.

Waterwheel Type Generators 1923 Development

The outstanding developments regarding capacity of units are:

a. 65,000-kv-a., 107-rev. per min., 25-cycle, 12,000-volt generators for the Niagara Falls Power Company.

b. 55,000-kv-a., 187½-rev. per min., 25-cycle, 12,000-volt generators for the Queenston Development of the Hydro Electric Power Commission of Ontario.

c. 28,000-kv-a., 428-rev. per min., 50-cycle generators, suitable also for 60 cycle operation at 514 rev. per min. with a guaranteed overspeed of 85 per cent for the Southern California Edison Company.

Some features worthy of mention in the case of one design for the 65,000-kv-a. units, are the elimination of the lower guide bearing on the generator, and the incorporation of a 650-kv-a. 2200-volt service generator within the main unit, the rotor of which is immediately above the main rotor and the stator suspended from the main upper bracket. The main rotor spider is made up of two wheels each consisting of seven cast steel sectors bolted to cast steel hubs. The main upper bridge is also of cast steel with ten radial arms bolted to a central hub.

The 55,000-kv-a. generators are very similar to the 45,000-kv-a. units built a year or two ago. In the design of one of the manufacturers an extra wide space is provided in the stator iron to facilitate removal of the armature coils. The first of these units went into operation in slightly less than one year from date of placing the contract.

There has been considerable change in the general design of smaller units; generators have been developed with the thrust bearing located immediately below the rotor spider with the top bracket eliminated entirely. With this type of construction reducing the turbine pit diameter to an absolute minimum there should be a considerable reduction in the cost of the unit. This type of design should also require considerably less head-room for erection, with a consequent saving in power house superstructure cost. In fact, it might be possible to dispose of the power house superstructure entirely by providing a weather-proof housing over each unit, which could be readily removed if necessary, and all operations carried on by chambers provided in the substructure.

Automatic generating stations are receiving more attention, as evidenced in the increasing number of installations such as some developments of the Hydro Electric Power Commission of Ontario, where in each case two generating stations each containing three 2000 kv-a. generators will be operated from a third station located four and six miles from the automatic station respectively.

A contract for generators placed during the year and worthy of mention is that placed by the Quebec Development Company for eight 30,000 kv-a., 13,000-volt, 112-rev. per min. units. This is notable not alone on

account of the size of the units but on account of the large number included in the contract.

Fly-Wheel Effect of A.-C. Waterwheel Generators

In connection with the design of waterwheel generators the question as to the most suitable flywheel effect of generator usually comes up for discussion, as very frequently the flywheel effect which is inherent in a normal design of generator is not considered sufficient from the point of view of waterwheel speed regulation and the advisability of adding extra weight to the generator rotor must be taken into consideration. It was thought therefore, that a brief study of this feature might well be considered in the present report of your Power Stations Committee.

The basic formula generally used for computations of speed regulation of water wheels is as follows:

$$d = \frac{800{,}000 \times H.\,P. \times T}{W\,R^2 \times (R.\,P.\,M.)^2} \tag{1}$$

Where T is the governor time in seconds, *i. e.* the time taken to operate the gates, h.p. is the change in horse power load which causes the governor to act; $W\,R^2 =$ flywheel effect of the rotating elements including the water wheel runner and shaft (expressed in lb. $-$ feet^2); rev. per min. the initial speed expressed in revolutions per minute. The resulting speed regulation d as given by this formula is expressed as a decimal; ($100 \times d =$ per cent speed change). This formula is approximate but sufficiently accurate for average conditions.

Formula (**1**) is more frequently used in another form as follows:

$$d = \frac{800{,}000 \times T}{K} \tag{2}$$

$$\text{Where } K = \frac{W\,R^2 \times (R.\,P.\,M.)^2}{H.\,P.} \tag{3}$$

K is known as the regulating constant and h. p. is the full load rating of the water wheel.

The constant K may range from 2,000,000 with small machines, particularly direct current generators, to 10,000,000 or more with large capacity, medium, or high-speed units. Flywheels or extra weight in the rotor are sometimes added, but K in commercial plants rarely, if ever, exceeds 12,000,000. There is some difference of opinion as to the desirable minimum value of K for governor operation; some makers have gone as low as 3,000,000, but in general 4,000,000 may be taken as a reasonable lower limit. A value of 3,000,000 is suitable only for open flume conditions where there is no large moving column of water to handle as in a closed penstock.

If the governor time on the average is taken as 2 seconds and $K = 4{,}000{,}000$, Formula (**2**) gives d a value of 0.4 or 40 per cent for a full horse power load change. This figure is of course, rarely reached in practice while the unit is operating on load, but serves as an indication of the extreme that might be reached if the unit were suddenly disconnected from the line. It is also a rough indication of the regulating characteristics of the unit. It should be remembered that the majority of waterwheel units are not isolated, but are tied in on a system with a number of other generators. The system is, therefore, usually sufficient to make the load changes on any one unit small in comparison to its rating, and the total connected flywheel effect of the system is such that the load changes have relatively little effect from the standpoint of speed change. Modern systems are becoming so large that the governor as such is practically inoperative under usual conditions and serves mainly for convenience in starting and stopping the unit, for adjusting the load from the switchboard, or as an emergency shut-down device in case of emergency. With isolated units the governor is, of course, necessary for regulation in most cases.

Plant operators and operating departments have, however, handled units to such a great extent with governors, that as a rule they are of the opinion that governors are inherently required for the control of hydroelectric units. This general attitude has resulted in the requirement of a regulating constant of 4,000,000 or more in most modern plants, in spite of the fact that the generator frequently works out with such flywheel effect as to give normally a smaller regulating constant. Naturally weight added to the generator rotor increases the cost and with vertical machines increases the weight on the thrust bearing, thus in many cases increasing the size and cost of the latter. Increased $W\,R^2$ over and above that inherent in the normal design will also result in most cases in a slight reduction in generator efficiency owing to the increased windage and friction loss.

Some hydraulic engineers as well as those engaged in the operation of hydroelectric plants are of the opinion that the usual hydroelectric unit arranged for an extended interconnected power system of considerable magnitude, particularly such systems as have a portion of their generating capacity in steam, do not require a governor, at least not one as usually built, and that it is not necessary to load the generator with extra weight for purposes of regulation. The reason for this viewpoint is found in the fact that a hydroelectric unit is intended primarily for the purpose of delivering the maximum possible number of kilowatt-hours per year to the system from the flow in the river and at the available head. A governor, as such, defeats this purpose to a greater or less extent, as any movement of the gates away from the point of best efficiency, decreases the net kilowatt-hour output; and a governor can regulate only by moving the gates. This loss of output is overcome in plants where the operation is most closely watched by running the governor on what is known as the load limit device. When the governor is so operated, it is ineffective from a speed regulation standpoint

unless the load is reduced so as to cause the governor to close the gates either partially or wholly. In large systems, such as are becoming prevalent, the regulation of an individual unit is of little consequence and, on this account, excess WR^2 in generator is becoming of less and less value. This factor together with the feature of maximum kilowatt-hour production will doubtless influence the design of units for operation on extended networks, in the direction of a gate opening device rather than a governor of usual type, this device being combined with an emergency shut down mechanism which would become operative in case the unit should lose its load or the speed tend to increase unduly. Such an arrangement would be much simpler than the regular type of governor. With control of this kind the gate mechanism would be controlled by hand from the switchboard and by float from the head water level. A number of units are at present operated successfully in this way.

Assuming that no extra weight is added to the generator rotor to increase the flywheel effect, the question arises as to what WR^2 may be reasonably expected in a generator of normal design and of given kilovolt-ampere output at given speed. Can a formula be developed from which the WR^2 can be determined? From the nature of the problem it is plain that no general formula can be developed that will give the WR^2 because a machine of given kilovolt-ampere output at given speed may be designed with different diameters of rotor. One design may use a rotor of relatively large diameter, high peripheral speed, and short axial pole length. The same kilovolt-ampere rating might on the other hand be made with a rotor of relatively small diameter, lower peripheral speed and longer axial length of pole. Both machines might be entirely satisfactory as generators, but their flywheel effects would be quite different. Again, the mechanical design of the rotor may have a decided influence on the WR^2, so that on the whole there can be a wide variation for machines of the same rating, even if the generators are equally good in other respects.

It has been felt by the Committee that some information as to the normal WR^2 of waterwheel generators as actually built would be of value as it would at least give an approximate idea as to what might be expected in machines of various ratings. With this in view, information was collected on quite a large number of units covering a wide range in speed and output and designed by three leading manufacturers. These flywheel effects have been plotted, using the ratio $\frac{\text{kv-a.}}{\text{R.P.M.}}$ as abscissas, and WR^2 expressed in lb.-ft.^{2} as ordinates. The kilovolt-ampere rating in each case was taken as the maximum rating of the generator and the WR^2 is that inherent in the design of the machine; *i. e.* it includes no extra added weight in the rotor. The curve shows an approximate average but this is added as a matter of interest only, and Fig. 1 is chiefly of value as indicating values of flywheel effect as they worked out in waterwheel machines as built and in operation. The general tendency seems to be to eliminate added WR^2 especially for machines used on large systems so that generators built in the future will doubtless correspond more nearly with those indicated in Fig. 1, as having the lower values of flywheel effect rather than the higher except in cases where a high WR^2 may be the result of mechanical features necessary to take care of overspeed, etc.

Temperature Standards

The question of temperature standards has been for some time in the hands of a subcommittee of the Institute Committee on Standards and the American Engineering Standards Committee for official action, to the progress reports of which as well as to the Committee on Electrical Machinery reference should be made for details of the present status of the recommendations.

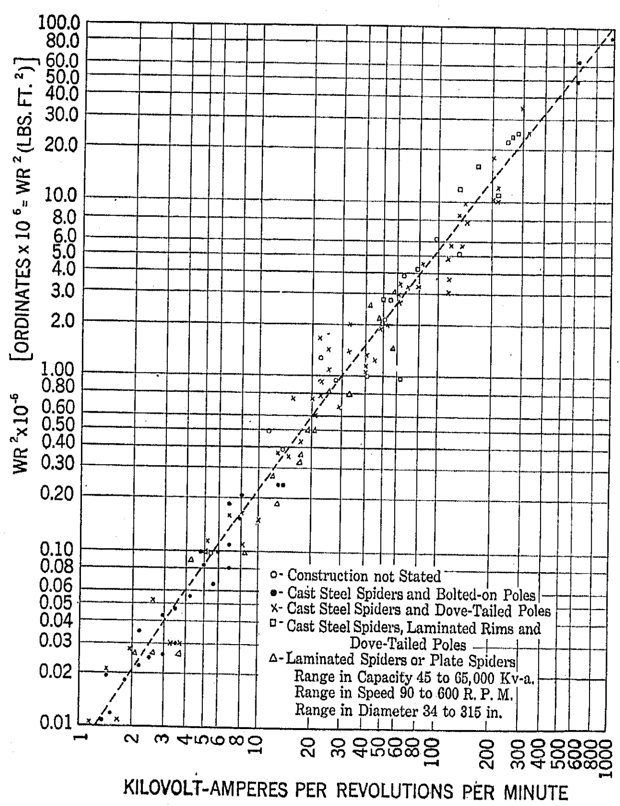

Fig. 1

Electric Drive and Control of Auxiliaries

Practically all the auxiliaries at the new station of the Edison Electric Illuminating Co. of Boston now under construction on the Weymouth Fore River will be driven by a-c., 60-cycle motors. The use of alternating current for this service, was decided upon after a careful comparison with direct current.

Motors and control that are essential to continuous

plant operation are designed to be automatically started, upon restoration of power, after an interruption.

On the larger constant-speed motors, a double squirrel-cage winding is used which reduces the starting current to approximately one-half that of the usual squirrel-cage design and allows the motor to be thrown directly across the line.

Maximum reliability and efficiency of the station service energy supply are obtained by the use of a 2500-kv-a., 2300-volt auxiliary generator direct connected to the main generator shaft and supplying power to a definite group of auxiliaries. Relay service is provided from buses which connect through transformers to the main 14,000-volt buses. An automatic face plate voltage regulator is used with each auxiliary generator.

It is intention of this report to describe the motor and control equipment of the station auxiliaries giving the reasons which led to its selection. No attempt will be made to compare electric with steam, or steam electric drives, as it seems to be generally recognized that station auxiliaries should be as completely motorized as possible.

Description of System

Fig. 2 shows a one-line wiring diagram of the auxiliary power system. There is a 2500-kv-a., 2300-volt auxiliary generator H on the same shaft as the main generator. This auxiliary generator is connected to a 2300-volt group bus J to which are connected all the auxiliaries required for the main unit, and in addition, a portion of the auxiliaries in the boiler house. This group bus is relayed from two 2500-volt buses K and L which are supplied with power from two 2000-kv-a. transformers M and N connected to the main 14,000-volt buses and also from a spare 1250-kv-a., 2300-volt turbo-generator U. These 2300-volt buses are designated "Common Station Service Buses" and supply power normally to all auxiliaries, such as cranes, elevators, and coal handling equipment, the operation of which may be temporarily interrupted without affecting power production. The boiler house auxiliaries and also the important auxiliaries for the main units, have selector breakers which allow them to be supplied with power from either their own generator group bus or from one other generator group bus. The only auxiliaries in this station that are steam driven are a high-pressure-boiler feed pump, a low-pressure-boiler feed pump and a steam-driven exciter. Normally, the steam-driven units will not be running. All other auxiliaries are driven by alternating current motors. The valves, however, are operated by 220-volt, direct-current motors.

The design is laid out to afford an independent system of two common station service and four generator group buses for every four main turbo-generators.

ALTERNATING VS. DIRECT CURRENT

One of the first considerations in determining the type of electric drive, was the choice between alternating-current and direct-current motors. Determination of the relative economy of the two types of equipment depended largely upon the duty cycle assumed for the various auxiliaries and also upon the load factor of the plant. Comparative figures were made for both, using various schemes for obtaining the power supply.

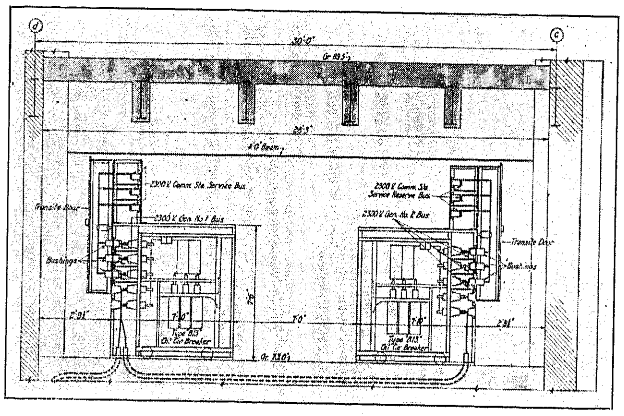

FIG. 3—CROSS SECTION-STATION SERVICE ROOM WEYMOUTH POWER STATION

and the layout was simpler. Smaller cables and conduits could be used and thus possibly wall and floor thicknesses could be reduced. Alternating-current motors were, therefore, adopted.

POWER SUPPLY

The auxiliary generator on the main generator shaft not only offers a power source of maximum efficiency but also allows unit operation through the group bus, thus securing a very high degree of reliability. It is estimated that the normal auxiliary power required by each 30,000-kw. unit will be about 800 kw., with about 450 kw. additional for the boiler house auxiliaries necessary to operate one turbine generator, making a total of approximately 1250 kw. for one main unit. One-half of the boiler room auxiliaries for three high-pressure generators add 300 kw., making a total of about 1550 kw. under normal conditions. Under emergency conditions, when it may be necessary to force some boilers up to their maximum rating, it is estimated that the load on one auxiliary generator will be approximately 2100 kw., which it will carry for a period sufficiently long to start other boilers.

The auxiliary generator is capable, not only of supplying power for its own auxiliaries and its portion of

*This figure is not the product of the efficiencies in the table on account of the common station service.

The most economical direct-current scheme seemed to be one having an auxiliary alternator on the main generator shaft feeding direct to a 550-volt direct-current synchronous converter. The most economical alternating current scheme appeared to be the one adopted. A comparison of these schemes is shown in Table I.

This analysis indicated that for this station, alternating current was at least as economical as direct current

the boiler house load, but also under normal conditions of carrying the auxiliaries required to start another unit. Such operation is provided for through selector oil circuit breakers as previously described. The transformer capacity between the 14,000-volt bus and 2300-volt bus has been made sufficiently large to supply the common station service load and in addition, to relay one of the 2500-kv-a. auxiliary generators. In case, however, of a complete power station shutdown it

would be possible to start the plant by means of the steam-driven exciter, the spare 1000-kw. steam-driven generator and the steam-driven boiler feed pump.

Excitation System

For each main turbo-generator there will be a 200-kw., 250-volt motor-generator set for excitation, the motor being connected to the 2300-volt generator group bus. In order to provide excitation in starting up the station independently of any source of power supply, a 250-kw. steam-driven exciter will be installed. The turbine of this exciter will supply low-pressure steam for heating. To insure a source of excitation which will be instantly available in an emergency, a 140-cell type *G*, exide storage battery and end cell switch is to be installed together with a 250-kw. motor-generator set for charging. This motor-generator set can also be used as a spare exciter. The battery has a discharge rate of 2106 amperes for thirty minutes. All exciters are connected through selector air circuit breakers to duplicate exciter buses. The fields of all synchronous generators are connected through selector breakers to these buses which are also provided with sectionalizing switches.

Power Distribution

Truck type switchboards are used to control the 2300 volt circuits. These trucks are equipped with oil circuit breakers of the *B*-13 type, redesigned, however, for finger type contacts and also for clearances of at least 5 in. between phases and 3 in. to ground. The rupturing capacity is ample to take care of the service.

Analysis indicated that the use of reactors with smaller circuit breakers in each station feeder would cost more than high capacity breakers without reactors and the latter arrangement was adopted. The reactors also have the disadvantage of introducing a very large voltage drop when motors are being started.

Operation

The switching arrangement adopted for the auxiliaries allows considerable latitude in the method of operation. At the present time, the following is contemplated:

In starting up the plant, the 2300-volt auxiliary bus will be energized either from the main 14,000-volt bus connected to the system or from the steam-driven auxiliary house turbo-generator. Assume that No. 1 main generator is to be put into service. When No. 1 main generator has been synchronized to the 14,000-volt bus, the No. 1 auxiliary generator oil circuit breaker *V* will be closed and the breaker *W* connecting the generator auxiliary group bus to the common station service bus will be open manually. In shutting down a unit, the auxiliaries that are required to remain in service can be transferred to another generator group bus. This is accomplished by means of a single control switch which automatically opens one selector breaker and closes the other after the first one has opened. If it is found undesirable, however, to interrupt power to the motors momentarily under normal operation, the generator group bus can be connected to the common station service and the circuit breaker between the auxiliary generator and its bus can then be opened. No difficulty is expected due to any phase displacement through the station transformers, as the auxiliary generator is so wound and constructed with respect to the main unit, that at no load, both generators are in synchronism. On account of the high reactance in the circuit, it is not expected that there will be any disturbance if it should become necessary to synchronize the auxiliary generator with the main generator through the transformers.

Reliability of Power Supply

Interruption of auxiliary power supply might be caused by any of the following conditions:

1. Failure of the auxiliary generator or loss of its field.
2. Failure of the main generator.
3. Overspeeding of the turbo-generator.
4. Failure of an oil circuit breaker on the auxiliary bus to function, or a short circuit on the generator group bus.

In case the auxiliary generator should fail, the differential relays would trip out the generator breaker and close a selector oil circuit breaker to the station service bus, thus keeping power supplied to the auxiliaries. In case the field of the auxiliary generator should fail a low voltage relay would trip out the oil circuit breaker of the generator and automatically close the breaker to the station service bus. Failure of the main generator would cause its differential relays to operate, which in turn would operate the differential relay of the auxiliary generator and close the selector breaker to the station service bus. In case of a severe disturbance on the system which would be sufficient to overspeed the generator and shut off the steam, it is estimated that the inertia of the rotor would be sufficiently great to keep the auxiliary generator running at sufficient frequency to supply power to the auxiliaries, while the main oil circuit breaker is tripped and the throttle again opened. It is expected, however, that the auxiliary load remaining on the unit will prevent overspeed sufficient to trip the throttle even though the main load be entirely lost. Failure of an auxiliary oil circuit breaker or a short circuit on the group bus, would affect only that particular group until such time as an operator can transfer to another bus.

Regulation

Each auxiliary generator is equipped with a face plate regulator, which automatically operates the field rheostat and maintains constant voltage. Relays are provided to ring an alarm in case of excess or low voltage due to sticking contacts.

Motors and Control

General Description. In general, all motors over 25 h. p., are rated 2300-volt, 60-cycle, 40 deg. All motors

of 25 h. p. or less are rated 550 volts. Motors that are fed through trolleys are rated at 550 volts. Motors for operating valves are rated at 220 volts direct current.

The motor and control equipment of all auxiliaries upon which continuity of station output is dependent is so designed that on restoration of auxiliary power after an interruption, the auxiliaries will automatically be restored to service.

This is accomplished on squirrel-cage motors of 25 h. p. or larger by means of a double squirrel-cage winding which permits the motor to be thrown directly across the line requiring a starting current of a little over four times the rating of the motor. On slip ring motors, this is accomplished by means of an automatic contactor, the opening of which inserts a block of resistance in the rotor circuit which resistance is automatically short circuited after the current has declined to a definite value. On brush shifting motors a pilot motor restores the brushes to starting position.

Forced Draft Fan. Each forced draft fan is driven by a B. T. S. 135-h. p., 2200-volt, 1200-rev. per min. commutator type, brush shifting motor. The motor is thrown on the line by means of contactors which are controlled from a push button station mounted on a control board located in front of the boiler and from a similar station located at the motor. The brushes are shifted mechanically by the Bailey combustion control system. Variations in the steam pressure or the furnace draft, cause the Bailey mechanism to increase or decrease the speed of the motor. Upon loss of power the main line contactors open and cut the motor off of the line. When power is restored, the brushes are shifted back to the starting position by means of the Bailey mechanism; the main line contactor closes and the motor comes to the speed required by the combustion control system. In order not to reduce the volume of air while transferring the motor from one bus to another a time-delay prevents opening the main line contactors or returning the brushes to the starting position during this operation.

Induced Draft Fans. Each induced draft fan is driven by a 100-h. p., 2200-volt, 600-rev. per min. slip ring motor, and a 225-h. p., 2200-volt, 900-rev. per min. slip ring motor. Each motor is connected to the fan by means of a flexible coupling. The 100-h. p. motor is thrown on the line by means of a contactor which is controlled from a push button station mounted on the control panel located at the boiler and from a push button station located at the motor. A drum controller with the necessary resistors in the secondary circuit, provides for speed control of this motor. This drum controller is operated mechanically by the Bailey combustion control system. When the load exceeds the capacity of the 100 h. p. motor, the line contactor in the 225-h. p. motor circuit is energized through contacts on the 100-h. p. motor drum controller and the 100-h. p. motor is disconnected from the line. The 100-h. p. motor is designed to withstand speeds up to 900 rev. per min. without injury. The drum controller for the 225-h. p. motor is also operated by the Bailey mechanism. Upon loss of power, the contactors open and the motor shuts down. Upon restoration of power, the drum controller is returned to the starting position by the Bailey mechanism, the 100-h. p. motor is energized and the fan comes up to speed in the normal way. As in the forced draft control, a time delay is provided in the control to allow for transferring the motor from one bus to the other without returning the controller to the starting position.

A description of the motor and control equipment for other auxiliaries is given in Table II.

Switchboards

Benchboards for a number of large installations have been made completely of sheet steel including panels which heretofore have been of slate. A new type of switchboard lamp has been developed, arranged for mounting on the front of the board. A resistance in series with it replaces the usual small fuse. For some installations in metropolitan districts where space is at a premium, control apparatus of unusually small dimensions has been used satisfactorily. In a number of instances asbestos board barriers have been installed between wiring of adjacent bench board panels. Such barriers serve to localize serious control trouble, and are a convenient mounting place for terminal boards.

Special care is being given to arrangement of switchboard equipment and wiring to eliminate congestion and provide a maximum of operating convenience and accessibility.

Circular benchboards have been used in the control rooms of several large stations. This type of construction usually involves extra expense, and must be justified by the benefit to be gained in any particular installation.

Terminal Rooms

In metropolitan stations from which large numbers of feeders are served, the multiplicity of control required has in some instances necessitated the use of terminal rooms directly beneath control switchboard rooms.

In the Hudson Avenue station of the Brooklyn Edison Company, now under construction, such a terminal room is provided. In this particular installation, conduits are of uniform size and come up through the floor in groups to steel terminal boxes located in a circle directly under the benchboard on the floor above. There is convenient access to all control and instrument wiring. Terminal rooms of this sort increase the over-all cost of the station where their use necessitates increase in cubic feet of building. If they can be fitted in without such increase in building cost, the over-all station cost should not be materially more because of their use. In stations where terminal rooms would have increased cost to an extent not justified by the benefits gained, the following method of construction has been used with satisfactory results. The floor underneath the bench-

board itself has been dropped approximately three ft. All conduits terminate in a steel trench box below the benchboard. Ample room is provided for all connections and terminal boards, and workmen can stand erect in the pit below each panel. Thus, repairs and changes in connections can be made almost as conveniently as in a terminal room. The question of whether or not a terminal room should be installed must be settled for each particular power station on the basis of the cost involved and the benefit to be gained.

Bus Structures

Practically all of the larger metropolitan companies have adopted, in their new stations, the isolated phase arrangement of switching equipment. This form of construction has been almost universally used where large numbers of feeders are supplied directly from the power station buses. With the continued increase in capacity of generating stations, it has become necessary to reduce the hazard of bus short circuit in every way possible.

The isolated phase scheme of construction has eliminated in some instances the conventional bus structure. The need of a totally enclosed compartment for the bus becomes of secondary importance. In many cases busses have been run entirely in the open. There are several companies that prefer to enclose the bus in the usual manner, and use through bushings for making connections to the bus.

Concrete or brick bus structures for auxiliary circuits are in many instances being eliminated by the use of truck type circuit breakers.

It should not be assumed that three-phase bus construction is obsolete for large stations or that it cannot be safely used where special attention is given to insurance against short circuit.

Where three phase bus construction is used, it has been found important to eliminate the passage of gases from one compartment to another in the case of breakdown to ground. All inspection openings in bus structures are enclosed by means of hinged or removable doors, and where conductors pass from one compartment to another through bushings, closure of the air passage is effected by various methods. In this way, with station neutrals grounded through resistance and all structures equipped with adequate grounding buses, disturbances on one phase, thus limited in severity, have little opportunity to involve the other phases and cause a bus short circuit.

The design of isolated phase equipment is now well through the development stage, and with the operating records of such equipment in service, which will be available within the next few years, a definite value can be placed upon the protection against short circuits which results from this type of construction.

The question whether isolated phase or three-phase bus construction should be used, must be solved in each particular case on the basis of the conditions to be met.

Turbo-Generator Units

The future of the electrical industry is now so dependent on steam turbo-generator development that advancement and improvement in design and construction of this type of prime mover is of extreme importance in every detail affecting the reliability of operation, the efficiency and the initial cost of the unit.

Improvements made and the most notable advances incorporated in the designs of several large power stations now under construction involve the use of higher steam pressures and temperatures, interstage reheating of steam, and stage steam bleeding.

The movement in the direction of higher steam pressures was initiated in 1917 at the North Tees power station in England where a gage pressure of 475 lb. per sq. in. and total steam temperature of 725 deg. fahr. was adopted. Interstage reheating was contemplated but was abandoned because of a few necessary modifications in turbine design and detail of piping which could not be undertaken during the war period. These improvements, however, have since been made. Although no consistent operating results are as yet available at this plant, the possibility and practicability of satisfactory operation at pressures of 500 lb. and 700 deg. fahr. have been demonstrated. A number of minor difficulties has been overcome and a great deal of valuable data and experience added to our knowledge of the use of higher steam pressures, all of which do honor to the pioneers who had courage enough to blaze a new trail in steam power-plant practise.

On the other hand, very little has been added to our knowledge of the properties of steam at high pressures, but the innovations adopted indicate clearly that an appreciable gain in economy should be expected in returning heat to the boilers, through stage bleeding, instead of carrying it out to the condensers.

Steam turbine designers do not anticipate any particular difficulty in producing machines adapted for pressures of 1200 or 1500 lb. per sq. inch. For these high pressures two or more cylinder machines will be used, the high pressure cylinder being small and operating with as good a factor of safety as the lower pressure cylinders.

Regarding steam temperatures, the limitations of strength of metals now available do not permit the use of temperatures in excess of 750 deg. fahr. Research for metals capable of safely withstanding higher temperatures for turbines, as well as for valves and fittings, is being conducted.

The rapid growth of turbo-generators to the sizes now being installed indicates the trend of development of the industry in general. Single cylinder units of 30,000 kw. have now become well standardized, and in answer to the demand for still larger sizes, 50,000-kw. turbo-generators of the single-cylinder type have been developed, and seem to be the next step indicated in size of single-cylinder units.

Considerable progress has been made in the last four years in turbine design and construction with a view to securing increased efficiency and reliability of operation, and, at the same time, to improving the steam cycle conditions. More stringent steam and vacuum conditions, in order to increase the heat-drop between the throttle valve and the exhaust outlet, have brought about many changes in turbine design and construction as well as in the selection and arrangement of plant equipment and layout.

With the increasing demand for larger sized units, and with the tendencies toward higher steam pressures and temperatures, there are indications that new designs will be adopted involving the subdivision of the turbine into two or more cylinders and shafts.

Single barrel units of 35,000 kw. and tandem compound units of 60,000 kw., both types for operation at 550 lb. and 750 deg. fahr., are now being installed; 2600-kw. and 4000-kw. turbines, designed for a steam pressure of 1000 and 1200 lb., are under construction. These machines are an entirely new departure and involve special boiler equipment and piping arrangement. The turbines themselves, however, are simple in design and present no obstacles to the ultimate success of the system adopted.

Tandem compound units with single shaft, both single- and double-flow types, in sizes ranging from 30,000 to 60,000-kw. have been successfully developed for speeds higher than for units of the single-cylinder type. Designs of large units with two shafts and three cylinders have been completed which reduce the number of alternators to only two.

Some increase in efficiency may be expected from these new designs or turbines, and the multi-cylinder arrangement will greatly simplify the application of steam reheating between high- and lower-pressure cylinders. The reheating cycle seems to be, of necessity, a feature of increasing importance, depending on the steam pressure adopted.

Quite a number of important problems remain to be completely and satisfactorily solved as further advance is made in the development of steam turbines, especially now that more severe operating conditions are imposed. Among these problems are; suitable material for blading and means to safeguard its reliability. The lack of an entirely satisfactory material that is sufficiently mechanically strong, that maintains its strength at high temperatures, that is reasonably cheap, easily machined, resistant to corrosion and erosion, and, most important of all, thoroughly reliable, is one of the limiting

factors in the designs for large outputs and high speeds. Chemical corrosion, due to air dissolved in the feed water, is now almost eliminated by the use of deaerators, evaporators and close circulation systems; but erosion is becoming more serious, since the present limit of safe initial steam temperature has been practically reached, and therefore, progress toward high initial pressures must result in larger moisture percentages in the last stages.

Next in importance are the questions of blade fastening to the wheels or barrels, the lacing or shrouding, the balancing of rotors, the keeping of length of blades, blade speeds and stresses within reasonably safe limits, while reducing and leaving losses to a minimum. To reduce the leaving losses, several methods have been recently developed, such as the "duplicate exhaust" and the "multi-exhaust" with directing steam vanes.

The bleeding of steam from one or more of the turbines stages for feed water heating has been advocated by turbine manufacturers for some time, but it is only recently that power station engineers have considered the subject with the interest which it deserves.

Stage bleeding is applied for the purpose of improving the efficiency of the heat cycle as a whole, but since this improvement is due in part to the effect of bleeding on the performance of the turbine unit, the subject is properly mentioned at this point. The diversion of a considerable fraction of the input steam at intermediate stages reduces the leaving losses and the effects of choking in the lower stages; a smaller quantity of steam is left to be condensed; the vacuum is improved, and less heat is passed on to the condenser.

To obtain the full advantage of stage bleeding, normal operation of auxiliaries must be almost entirely electrical.

The first commercial equipment which includes a mercury boiler and turbine exhausting into a condenser boiler which in turn generates steam for an existing steam turbine station, was put in service in the fall of 1923. The results which have been obtained confirm experimental tests and there is every reason to believe that this development will be of great value in reconstructing existing stations.

Generators

Improvements in design and construction of the generator have kept pace with those of the steam turbine. These simultaneous advances have made possible the supply of the demand for larger, more reliable and economical units. The additions made in 1923 to the generating capacity of the steam-electric plants in the United States totalled over 2,000,000 kv-a.

The progress made in recent designs is the result of efforts directed towards reducing the mechanical and electrical weakness of older machines, improving the ventilation, thus permitting the use of longer rotors and the production of generators of larger capacity. As to reliability, marked progress has been made in the insulation, both as to class of material and its application. There are more effective methods of holding the rotor coils, and bracing and clamping the stator end connections, thus increasing the reliability of the windings under stresses of short circuits or system disturbances.

As to size of generators, 62,500-kv-a. steam driven units are now being produced. The largest units built, however, are water-wheel generators having a rating of 65,000-kv-a., 12,000-volt, 25-cycle, 107 rev. per min.

The closed system of generator cooling, which has been installed in a number of large stations during the year, has many points of advantage. The air, having once been cleaned by the washer, filter or other device, remains clean indefinitely, reducing the deposit-forming material circulated through the windings practically to zero. By the closed system also, relatively little oxygen is available to support combustion, and the fire hazard, which has been quite serious with the open system, is greatly reduced.

In line with the general efforts to improve the economy of generating stations, some of the newer installations are equipped to cool the air discharged from the generators, using condensate as the cooling medium, thus retaining the heat lost in the generators.

With the trend in new generating stations towards stage bleeding for feed water heating, the use of electric driven auxiliaries is indicated for normal operation as to obtain the greatest advantage. To supply the essential auxiliaries, consideration has been given to the use of an auxiliary generator, connected to and driven directly from the shaft of the main unit. This method combines high reliability and economy. Several such installations with a-c. auxiliary generators and one installation with d-c. auxiliary generator are definitely planned.

Power Station Ventilation

With the growth in the size of power stations, the problems of ventilation, heating and lighting have increased and are receiving special consideration by both the architect and designing engineer.

Ventilation in the large modern power station presents entirely new and different problems involving the provision of features which were considered of trifling importance in the smaller power stations of the past.

Today the problem of ventilation involves the satisfaction of three main requirements:

1. Supply and movement of air for respiration.
2. Supply and movement of air for cooling apparatus.
3. Supply of air for combustion purposes.

These requirements must be satisfied at all times and under wide fluctuation of climate conditions. The conditions vary according to the geographic location and operation of the power station; *i.e.*, whether the station is continuously operated or subject to occasional shutdowns.

Ventilation and daylight illumination are closely allied, as well as problems of heating, where such requirements are necessary.

The first requirement; *i.e.*, providing a supply and movement of air for respiration, fortunately, offers no serious difficulty in the power station where large spaces are generally available and which, because of the relatively few men to be accommodated, do not require an active movement of air. In the modern power station however, dependence can no longer be placed on securing an adequate supply of fresh air for respiration through leakage around windows and doors. Other and more substantial means of ventilation must be provided. These, as far as possible, should depend on natural effects rather than artificial circulation of air, except where it is absolutely necessary to introduce purifying or conditioning devices.

The second requirement,—the provision of air movement for the cooling of apparatus—is a large item in power station design. This problem involves the absorption and dissipation of heat units generated and radiated by the station equipment. Future improvements, however, will doubtless serve to recover these losses and return them to the system.

At the present time, it is necessary to provide a sufficient volume of cool air for the removal of these heat units, not only from the electrical apparatus but also from steam and hot water piping and other apparatus.

One of the problems which has been practically solved is the prevention of condensation in the turbine room, and satisfactorily solved, too, under the very much more difficult conditions found in dye houses and paper mills, where tons of water are evaporated each day by the processing machinery used in these plants. Turbine room conditions, fortunately, are not so serious and by proper insulation of the roof structure and ventilation, it is possible to maintain the room atmosphere below its dew point, thereby preventing the condensation of warm, moisture-laden air which is found in the atmosphere of the turbine room.

The last requirement involves the supply of a large volume of air for combustion. It has been found in cases where no provision was made to meet this need that during the winter months the air supply for combustion was entirely insufficient. This condition would not exist in summer when the air could be admitted through open doors and windows. With the increased size of boilers, and with the tendency toward air preheating, this problem becomes one of great importance and requires special study for both the forced and induced draft. Ideal conditions will be met when the warm air is taken from the atmosphere of the boiler room and returned to the furnace, thus accomplishing the dual function of ventilation and heat-loss recovery.

Lightning Arresters

The Protective Devices Committee of the Institute has an efficient subcommittee actively at work on lightning arresters, and its report will thoroughly cover the ground in its technical aspects. A brief survey of the field, however, from the viewpoint of some of the manufacturers may be appropriate here in considerations of power station design. The manufacturers are of the opinion that they are furnishing apparatus which is quite effective, if properly installed and used; that their studies now under way will result in improvement, but they all point out the fact that a great deal depends upon intelligent cooperation on the part of the users.

Arcing grounds on non-grounded circuits, over-dynamic voltage, such as is caused by overspeeding of waterwheel generators, and faulty grounding of lightning arresters, are some of the causes of failures over which the manufacturers have no control. Doubtless, these sources of trouble will largely disappear when the users become aware of their seriousness and their undesirable effect upon an important piece of protective apparatus.

Two of the large manufacturing companies have testing equipment using the so-called lightning generator of Steinmetz. These devices afford excellent opportunities for studying the action of arresters under artificial lightning disturbances of an impulsive character.

Briefly, the lightning generator has revolutionized the testing of lightning arresters and their performance in actual service can be closely predicted. This fact should be emphasized and operating companies should more fully realize what fundamental characteristics a lightning arrester should possess and that these characteristics can now be determined in the laboratory. It is not essential to wait for data on hundreds of lightning arresters over a period of years before the true value of any particular arrester can be determined.

The lightning generator, however, shows chiefly the effect of the impedence of arresters to high current impulse of very short duration. They do not show the effect on arresters of all of the disturbance that may occur on transmission lines or distribution circuits. That disturbances other than impulses of extremely short duration do exist, is hardly a matter of doubt; they should be carefully studied. An arrester may be satisfactory from the standpoint of laboratory tests in discharging impulses and yet may be vulnerable to disturbances having an appreciable time element. At present this can be determined only by several years of service operation.

The real present need of the manufacturer for future progress with arresters is, as he says, not so much in actual apparatus development as in getting more specific and definite data on conditions to be met in service. He needs to know much more definitely not only what the surge voltages are, in magnitude, duration and frequency of oscillation and of occurrence, but also to what values these surge voltages may be reduced before reaching the apparatus to be protected. It is also necessary, since economics plays an important part

in the choice and use of arresters, to evaluate less than full protection in terms of average yearly injury to apparatus.

With this sort of information available, he believes he can add to the assurance that the characteristics of present designs actually meet conditions of service as fully as is now believed, and moreover that he can apply arresters with greater precision and with fuller assurance of obtaining the desired results.

Transformers

All the manufacturing companies disclaim any new radical changes in the design of transformers during the past year. A few things, however, have been done for the sake of protecting the transformer in case of breakdown. Changes have been made in construction methods and some companies still disagree in regard to polarity of distribution transformers.

The problem of protection of transformers from explosions has been attacked in various ways: a manufacturer placed on the market last year an "Inertaire" transformer which is claimed to be practically immune to explosions or internal fire. This is accomplished by equipping the transformer with an air tight cover and connecting the free space between the top of the oil and cover with an inertaire respirator which deoxidizes the air which passes through it. This respirator is filled with a substance which is said to be able to deoxidize the air as rapidly as it enters, allowing only nitrogen, an inert gas, to pass into the transformer.

The idea of using an inert gas in transformers to prevent explosions is not new; another manufacturer used CO_2 gas in transformers constructed several years ago, but later did away with the practice, developing instead the oil conservator.

So far as is known, there has been no trouble developed from the use of the "Inertaire" attachment. The following criticism might be offered, however. Since the deoxidation of the air is accomplished by chemical absorption of the oxygen by the compound in the respirator it follows that sooner or later the compound will depend upon the rate at which the transformer "breathes." The rate at which a transformer will "breathe" will depend upon varying load conditions, change of surrounding temperature, and seasonal changes. Two transformers alike in every respect, but working under different conditions, even on the same system, would have different rates at which the deoxidizing compound would be dissipated. This would make necessary frequent inspection of the compound in the respirators and irregular renewals. If a transformer were allowed to go a few days beyond the point of complete dissipation of the compound it would fill itself with ordinary air, which would mix with the gases from the oil and form an explosive mixture.

This device, however, offers a protection to the oil since it minimizes surface oxidation of the oil.

Winding of Disk Coils for Core-Type Transformers. During the past year one of the principal manufacturers developed a new method of winding flat disk coils for core-type transformers. This method makes it possible to wind a complete stack of either primary or secondary disk coils with one or more continuous conductors. The first coil in a stack is wound from the outside to the inside and so on until the complete stack is wound. There are two distinct advantages gained by this method. One is the elimination of all connections between coils and thereby eliminating the possibility of trouble arising from poorly soldered joints. The second benefit comes from lessening the handling of the coils, which reduces the possibility of injury to the insulation and insures better electrical conditions. Another advantage is that the new method speeds up production, which is to the advantage of the user.

Polarity of Transformers. Since 1922, when the N. E. L. A. transformer standards providing for standard polarity for single-phase transformers were adopted and put into use by the two largest manufacturers, some confusion in overhead distribution systems has been caused by diverse practise on the part of some of the smaller manufacturers. It is highly desirable that there should be uniformity of manufacturing practise in this respect.

Temperature Indicators

Several manufacturers were requested to supply information as to the progress made in the past year in the field of "Temperature Indicators." That no radical changes have occurred was admitted by most of them. In general, the progress consists in the addition of refinements or improvements by slight changes of construction to standard equipment.

One manufacturer has improved the optical system in his radiation pyrometer so that better accuracy can be obtained when used on small objects. Another has placed in production a Precision Portable Potentiometer for use with thermocouples, one scale division of which, is equivalent to approximately 1 deg. fahr. when used with an iron constantan thermocouple. Some minor improvements also have been added to instruments actuated by change of resistance of the bulb unit and also those actuated by expansion of gas contained in the bulb unit. Another manufacturer, in development of an instrument for indicating or recording temperatures at a distance, has reached the point where the instrument has been shown to be thoroughly practicable but he is not ready as yet to disclose the principle of operation or the type of construction.

Some tendency is evidenced to apply to commercial thermoelectric pyrometers and resistance thermometers, principles perhaps never so used before, although known and used in an experimental way twenty-five years or more ago.

Electric Drive in Fuel Preparation

Much interest was exhibited by the various public service and other companies, including some of the

TABLE III

No. Plant Reporting	A	B	C	D	E
1	Crushers bucket elevators, belt conveyors	6 motors, total 210 h. p., G. E. and Wagner 3-phase 25-cycle	1923 tons 187,002	Per ton 2.9 kw-hr.	Received by rail, 2 locomotive cranes, 2 locomotives, and 2 gondolas, used in handling storage.
2	100% electric drive	21 motors, total 1175 h. p. 3-phase 60-cycle	362,800	1.38 kw-hr.	Received by barges, clam shell bucket to crushers, conveying belts to bunkers, by rail for storage, clam shell bucket and crane.
3	100% electric drive	8 motors, total 175 h. p. a-c.	146,000	.65 kw-hr.	Received by rail, dumped to hopper, pan conveyor to crusher, inc. belt conveyor to top boiler room. Horizontal belt conveyor to bunkers, bridge crane for storage.
4	100% electric drive	6 motors, total 160 h. p., d-c.	146,000	Not given	Received by rail, dumped to pit, bridge crane with crushers. Transfer cars to coal bunkers.
5	100% electric drive	8 motors, total 145 h. p.	233,875	2.8 kw. (1) 5.7 kw. (2)	Rail-bridge crane to crushers from storage cars to crushers by winches, crushers to belt conveyors and bucket conveyors.
6	100% electric drive	11 motors, total 1339 G. E. Allis - Chalmers West. 3-phase 25-cycle	407,412	1.059 kw-hr.	Coaling, tower from scows at dock to crushers, 4 ton cars to bunkers, aeri cableway for storage.
7 Pulvzd. anthracite	100% electric drive	30 motors, total 1055 h. p. 3-Phase 60-cycle	63,352 Anthracite slush	See E	Recovery from storage pile to boiler bins, inc. drying, pulverizing, conveying 25.93 kv-hr. per ton.
8 2 plants combined	100% electric drive	22 motors, total 710 h. p. 2- and 3-phase 60-cycle	142,663	2.5 kw-hr.	Barge to coal tower, to coal car, to crusher by locomotive, to coal conveyors, to bunker bins, Gantry crane for storage handling.
9	100% electric drive	19 motors, total 677 h. p. a-c. 60-cycle 440-volt	479,750	No record	By rail to storage by locomotive crane, by cars to car dumper to shaking feeder, to conveyor belt to breakers, to crushers, to bucket conveyor, to boiler bunkers.
10 Pulverized bituminous. Not in operation	100% electric drive	13 motors, total 419 h. p. 3-phase 60-cycle 440-volt	Max. capacity 105,000 12 tons per hr.	Not operating under construction	Rail, track scale, to track hopper, skip hoist to crusher, to dryers, to pulverizers, to cyclones, to screw conveyor to boiler bins.
11 2 plants combined	1-50%, 1-100% electric drive	31 motors, total 1258 h. p. a-c. & d-c. motor	780,000	1.0 kw-hr.	Barges to coal tower to receiving hopper, to crushers, to weighing hoppers, to belt conveyors to bunker bins in boiler room.
12	100% electric drive	51 motors, total 2750 h. p. a-c. squirrel-cage and slip ring	300,000	3.0 kw-hr.	Steamer movable towers, to crushers, to cable cars, to station bunkers, or to storage lot. From latter reclaimed by skip hoist. From bunkers to weigh lorries to furnace hoppers.
13 2 plants combined	100% electric drive	No data	(1) 135,000 (2) 60,000	.75 kw-hr.	Cars to track hopper, to crushers, bucket conveyor belts, distributed to bunker bins.
14	100% electric drive	18 motors, total 837 h. p. a-c. 230 & 2200-volt	482,335	.43 kw-hr.	Cars to pits, conveyor to crusher, to carriers elevated above boilers, cross conveyor belts, distributed to bunker bins.
15	100% electric drive	9 motors, total 590 h. p. a-c. 220 & 2200-volt	108,797	.6175 kw-hr.	Ditto
16 Pulverized bituminous under construction	100% electric drive	32 motors, total 1558 h. p. a-c. 230 & 2200-volt	Pulvd. coal est. 78,126 7 months 1924	See E	Do.-Crushed coal, to coal preparation house, gravity to dryers, to pulverizer mills, then by Fuller-Kinyon Pumping System to boiler pulverized coal bins. All power estimated 22½ kw-hr. per ton.
17	100% electric drive	13 motors, total 1115 h. p. a-c. 2- & 3-phase, 60-cycle	276,032	.755 kw-hr.	Barge to crusher in tower, conveyor to top of building, cross conveyor to boiler bunkers, coal storage by locomotive cranes, capacity 3000 tons per day.
18	100% electric drive	9 motors, total 1060 h. p. 2-phase a-c. 60-cycle	174,408	.954 kw-hr.	Barge to crusher in tower, cable road to boiler bunkers. Coal storage by locomotive crane. Capacity 1000 tons per day.

TABLE III—*Continued*

No. Plant Reporting	A	B	C	D	E
19	90% electric drive	16 motors, total 900 h. p. 2-phase a-c. 60-cycle	249,456	1.00 kw-hr.	Ditto but coal is crushed twice.
20	50% electric drive 50% steam	6 motors 145 h. p. steam storage locomotive yard and 2 locomotive cranes	166,250	Not quoted	Rail-cars handled by steam locomotive, dump to hopper-hoist by movable tower to roof, to crushers, to boiler room. Storage by 2 locomotive cranes.
21 2 stations reporting	100% electric drive	6 motors 205 h. p. d-c. (no unloading inc.)	438,000 365,000	0.25 kw-hr. 0.31 kw-hr.	Barge-coal towers to crushers, to cable road belt conveyor, to boiler bunkers.
22	100% electric drive	2—700 h. p. m-g. sets towers, 24 motors, 1748 h. p. d-c. & a-c. 3-phase 60-cycle	Est. 226,000 1924	1.08 kw-hr.	Barge, 2 coal towers to crushers, sampled, to cars automatically operated, to boiler bunkers. Storage 50,000 tons—Staten Island, for emergency.
23	Hoisting by steam. Balance 50% electric drive	10 motors 140 h. p. d-c. 230 & 125-volt	336,000	No hoisting .161 kw-hr.	Barge, steam hoists to crushers, to electric driven coal cars, to boiler bunker bins. Storage mentioned No. 22 for this plant also.
24	Hoisting by steam. Balance 50% electric drive.	11 motors 161 h. p. d-c. 115 & 220-volt	197,000	No hoisting .161 kw-hr.	Ditto. Inc. transfer some coal by belt conveyor to boiler bunkers.
25	40% electric drive	3 motors 27 h. p. a-c. 60-cycle 3-phase	7,350	0.90 kw-hr.	Rail to crusher hopper, conveyor to bunker bins, locomotive crane for storage.
26	100% electric drive	3 motors 45 h. p. a-c. 3-phase 60-cycle	40,411	Est. 4.5 kw-hr.	Rail to derrick to crusher, to belt conveyors to bunker bins.
27	100% electric drive except for storage-locomotive crane	4 motors 150 h. p. a-c. 3-phase 60-cycle	50,400	.8 kw-hr.	Rail, skip hoist to crusher above bunker bins, belt conveyor to latter. Locomotive crane for storage.
28	100% electric drive	10 motors 480 h. p. a-c. 3-phase 60-cycle 2200 & 440-volt	240,000	.52 kw-hr.	Direct from mine, weigh baskets, to pan feeders, to crushers, to inclined belt conveyor, to bunkers. Drag conveyors for storage also locomotive crane. 71,000 tons storage.
29 Pulverized coal	100% electric drive coal from bunker bins	4 motors 300 h. p. a-c. 3-phase 220-volt	Capacity 2 mills, 10 tons hr. 36,000 tons	See E Pulverized coal	Coal from bunker direct to pulverized coal mills, to dryer, to cyclone, to burner feeders, 27 kw-hr. per ton, coal contains some bone and silica.
30	95% electric drive pulverized coal. Dryer fans by steam	22 motors 477 h. p. a-c. 440-volt 3-phase, induction	50,000 Steam heating operating 8 months per year	See E Pulverized coal	Electric cars to raw coal bunker, drying, conveying, pulverizing, conveying to boiler bunker bins, 22.3 kw-hr. Emergency storage several miles distant. Locomotive crane, clam shell bucket.
31	100% electric drive	14 motors 578 h. p. a-c. & d-c. 440 & 230-volt	540,000	.55 kw-hr.	Rail to bins, to crushers, bucket elevators, belt conveyors, to bunker bins. Gantry crane for coal storage.
32	100% electric drive	5 motors 105 h. p. a-c. 3-phase 220-volt	91,250	1.4 kw-hr.	Rail to hopper, to crusher, belt conveyor, to bucket elevator, to top of bunker scraper conveyor to bunkers. Storage-crane-clam shell bucket.
33	Unloading steam driven towers. Balance 100% electric	1495 h. p. 37 motors d-c. & a-c. 550-volt	389,623	1.734	Barge, belt conveyor to crushers, conveying belt to bunkers in boiler room. Storage from barge conveyor belts to field.
34	100% electric drive	11 motors 183 h. p. a-c. 60-cycle 3-phase 550-volt	276,000	No data	Rail, bridge crane, belt conveyor, bucket elevator to belt conveyor to bunker bins, slack coal, do not use crusher. Storage by steam, or electric cranes.
35	100% electric drive	5 motors 107 h. p. a-c. 3-phase 60-cycle 220-volt	75,000	0.6 kw-hr.	Rail to crusher, belt conveyor to bucket elevator, to scraper, conveyor to boiler bins. Storage by horizontal boom crane.

largest and most efficient plants in the country, in submitting to the Committee the accompanying tabulated data, the various plants being listed for obvious reasons by number only.

The plants reported in the tabulation had a total coal consumption for the year 1923 of 6,767,528 tons.

The average power per ton of coal handled is 0.98 kw-hr.

The total horse power installed averages 0.0019 h. p. per ton.

The following key is to be used with the foregoing data table:

A. Extent or use of electric drive in coal preparation
B. Number and size and characteristics of motors
C. Annual tonnage handled
D. Estimated kilowatt-hours per ton
E. System used in coal handling and storage equipment.

Automatic Equipment

The general trend in generating station design for the year 1923 has been to lean strongly toward automatic operation of apparatus where practical, particularly so where a personal hazard might otherwise be involved. The tendency has been toward:

A general increase in the size of automatic or remote-controlled hydroelectric generating stations; the elimination of the human element, by making automatic the sequence of operations in connection with high-tension switching, where a failure to follow the proper sequence might result in a serious hazard or damage to equipment;

the electrification of station auxiliaries with automatic restarting or remote control;

the providing of the system operator with automatic line and system load indication, for better supervision and control.

A considerable saving has been shown in the past by automatic operation of small hydroelectric generating stations, but the tendency now is toward making wholly automatic or remote-controlled stations of even larger capacity. Illustrations of this are Sprite Creek Station of the Adirondack Power Company, where a 7500 kv-a. generating station is automatically controlled, and an installation of three 1750 kv-a. units of the Wisconsin Valley Electric Company. There are some 60 installations of this kind with nearly 100 generating units.

While larger steam generating stations are not being made wholly automatic, every year records the addition of more automatic equipment. In the broader sense, where automatic operation includes interlocking to prevent a wrong sequence of operations, the advance is more marked, as illustrated in the Weymouth Station of the Edison Electric Illuminating Company of Boston, the Commonwealth Edison Company's Calumet Station at Chicago, and the Cahokia Station at St. Louis, where the disconnectors on the line-switches are interlocked with the oil-switch, to prevent wrong sequent operation. In some cases the disconnectors are automatically operated by the oil switch mechanism.

Station auxiliary apparatus is being electrified and the operation effected with remote automatic control. One feature of recent design is the automatic restarting of the essential auxiliary motors when power is restored after a shut-down.

Some of the larger systems are giving serious consideration to the question of providing the system operator with automatic indications of the system line and load conditions by means of automatic totalizing meters to indicate the load on the various generating stations, together with the total system load.

A further advance in automatic operation is the automatic indication at the system dispatcher's office of the open or closed position of the line-switches, and some thought has been given to the question of giving the system dispatcher control over some line-switching, independently of the station operator, so that the system dispatcher is not only a general supervisor of operations but has independent control of the general power system as well.

The manufacturers seem to be putting forth every effort to make their systems of remote and automatic control more reliable, so that the operating companies will have more confidence in this type of equipment and will undoubtedly find further use for it.

Nicholas Stahl, *Chairman.*

ELECTROCHEMISTRY AND ELECTROMETALLURGY COMMITTEE

To the Board of Directors:

This committee has during the past year continued the activity which was begun the previous year. As in 1923, it also in 1924 initiated a technical session held at the Spring Convention, devoted to electrochemical and electrometallurgical subjects. At this session, very excellent papers were presented which tended to indicate advances in the art and the status of the art in the respective fields covered. These papers were as follows:

(1) Maximum Demand Regulator for Electric Furnaces, by E. T. Moore.

(2) Manufacture of Phosphoric Acid in Electric Furnaces, by Theodore Swann and F. V. Andrea.

(3) Effect of Impurities on Battery Electrolyte, by G. W. Vinal and F. W. Altrup.

No regular committee meetings were held as all necessary business could be quite successfully conducted through correspondence. Four or five of the seven members of the committee have shown an active interest in the work. These were all unanimous in the belief that it would be a disastrous mistake to change the function and field of activity of this committee as proposed by the tentative report of the committee to review technical activities of the Institute, dated January 22, 1924. This committee also feels that the

tentative report referred to proposes an improperly narrow and restricted basis for the whole activities of the Institute and much prefers to support the higher conception of the Institute and its technical committees, as outlined in the general remarks on Technical Committee Activities which were approved and passed at a meeting of the Meetings and Papers Committee on May 2, 1924.

It is proposed to continue the activity of this committee during the next year by obtaining papers relating to the engineering requirements and operation of electrical equipment in electrochemical and electrometallurgical processes and to initiate a technical session at which such papers may be presented and discussed.

This committee especially provides the technical liason between the A. I. E. E. and the American Institute of Mining & Metallurgical Engineers and the American Electrochemical Society, so far as electrochemical and electrometallurgical applications are concerned. It is therefore the province of this committee to report that the two engineering societies mentioned have given considerable attention during the past year, and have, in fact, conducted several technical sessions at which a number of excellent engineering papers have been presented on subjects in which many electrical engineers, and accordingly the Institute, should be interested. As a matter of record, and for the sake of reference, a list of these papers is being included in this report. At the Midwinter Convention of the American Institute of Mining and Metallurgical Engineers held in New York on February 18th to 21st, 1924, the following papers of mutual interest to electrical and metallurgical engineers were presented:

(1) Direct Electrolysis of Black Copper Anodes of High Nickel-Lead Content, by M. H. Merriss.

(2) Electric Welding of Large Storage Tanks, by Harold C. Price.

(3) Greenwalt Electrolytic Copper Extraction Process, by Wm. E. Greenawalt.

(4) Electrolytic Zinc from Complex Ores, by U. C. Tainton.

At the Spring Convention of the American Electrochemical Society, Philadelphia, Pa., April 24th to 26th, the following papers were presented:

(1) Review of Progress in Electrolytic Refining of Metals, by S. Skowronski.

(2) Electrodeposition of Copper by the Union Miniere du Haut Katanga, by H. Y. Eagle.

(3) The Electrolytic Tank House, Chile Exploration Co., Chuquicamata, Chile, by C. W. Eichrodt.

(4) Electrolytic Silver Refining at Pachuca, by G. H. Clevenger.

(5) Electrolytic Tin, by Charles L. Mantell.

(6) Electrolytic Refining of Tin, by J. R. Stack.

(7) Progress in Electrolytic Iron, by Donald Belcher.

(8) The Electrolytic Production of Beryllium, by B. S. Hopkins and A. W. Meyer.

(9) Electrodeposition of Tellurium, by F. C. Mathers and H. L. Turner.

(10) An Attempt to Electroplate Tungsten on Iron, by C. A. Mann and H. L. Halvorsen.

There was also a session at which a series of seven papers on applications of organic electrochemistry was presented. The subjects were largely treated in a manner of value to the electrochemist, and therefore while they might be of interest to the electrical engineer if differently treated, a list of these papers is not being recorded.

Of all the electrochemical and electrometallurgical processes in which progress has been made during the past year or two, the one perhaps of greatest interest and possible future value to electrical engineers is that of electrolytic iron. It is worthy of record that the electrolytic production of high grade iron is receiving very great attention in a number of quarters in America, as well as in Europe, and that in America several small but commercial plants are already in operation, the latest of which has been started only within the past few months. Details will probably be available for publication later in the year.

J. L. McK. Yardley, *Chairman.*

IRON AND STEEL INDUSTRY COMMITTEE

To the Board of Directors:

At a meeting of this Committee in September, 1923, at which each member was present, plans for the ensuing year were discussed. It was agreed that the Annual Report should assume the form of either:

A technical paper prepared by members of the committee, dealing with some vital problem of the steel industry, for presentation at joint meetings of the Association of Iron and Steel Electrical Engineers and the American Institute of Electrical Engineers; or,

A Topical Report indicating briefly the progressive development of electrical applications in the steel industry.

The first suggestion had the enthusiastic and unanimous approval of the Committee. The subject selected for the paper, "Economic Balance of Thermal, Electrical, and Mechanical Energy" presents the greatest problem which the engineers of the steel industry have to face. A very comprehensive outline of this paper was prepared under such general subdivisions as:

A Sources of Heat and Power.
- a. Water Power.
- b. Natural Fuels.
- c. Prepared Fuels.

B Direct Application of Heat.
- a. Power Plant.
- b. Coke Ovens.
- c. Blast Furnaces.
- d. Open Hearth.
- e. Soaking Pits.
- f. Reheating Furnaces.

C Direct Application of Power.

D Heat Balance in Typical Steel Plant.

a. Energy requirements for steel plant of 100,000 net tons per month of finished and semi-finished steel.
b. Number of 600-ton blast furnaces.
c. Net tons of ore, coke, and limestone.
d. Cubic feet of gas evolved.
e. Cubic feet of gas required for stoves.
f. Cubic feet of gas available for other purposes.
g. Capacity of by-product plant to supply coke required by blast furnace.
h. Cubic feet of available coke oven gas.
i. Number of 100-ton open hearth furnaces required.
j. Quantity of gas, oil, or pulverized coal required.
k. Reclaimed energy from open hearth waste heat boilers.
l. Equivalent capacity in 50-ton electric furnaces.
m. Kw. hour and B. t. u. consumption of electric furnaces.
n. Number and capacity of soaking pits.
o. Pulverized coal, oil or gas required.
p. Tons of steel through Blooming Mill.
Kw. hours and B. t. u.
q. Tons of steel through 24 in. Billet and Bar Mill.
Kw. hours and B. t. u.
r. Tons of steel through two 18 in. Billet and Bar Mills
Kw. hours and B. t. u.
s. Tons of steel through 14 in. Merchant Mill.
Kw. hours and B. t. u.
t. Tons of steel through 10 in. Rod Mill.
Kw. hours and B. t. u.
u. Estimate of energy for all auxiliaries.
v. Summary expressed in terms of total B. t. u. in coal used for coke or as fuel for direct heating including B. t. u. value for fuel oil, also B. t. u. consumed or reclaimed in each application whether in form of heat or mechanical power.
w. Discussion of purchased power versus local generation.
x. Interconnection with Public Utilities.

Considerable work was done in the accumulation of data for this paper, and an effort made to arrange for joint meetings with the Local Sections of the A. I. E. E. in the more important steel centers. These efforts met with little success and the excellent work of certain members of the committee was rendered useless by the inability of all to devote the necessary time to this difficult but very important subject.

The committee, therefore, reluctantly gave up the preparation of this paper, and can only express the hope that under more favorable circumstances the work may be carried to a successful conclusion.

In place of this proposed technical paper the committee submits the following topical report of developments of the past year.

I. Generating Units

The steam turbine still holds first place as a prime mover in the steel plant power station, although excellent results are being obtained with the slow-speed gas engine using blast furnace gas under local conditions of high-load factor. A combination of gas engines and steam turbines often makes the ideal steel plant generating unit. In some instances the best economy is effected by the purchase of power during periods of low-load factor while carrying the base load of the steel plant at high-load factor on gas engines.

Much development work is being done with gratifying results in an effort to perfect the Diesel oil engine for small plants where these requirements do not exceed 5000 kw.

II. Distribution

It is almost impossible to appreciate fully the part which electricity plays in the steel plant of today. Cumbersome and inefficient steam and hydraulic lines are already largely replaced by a distributing network of electrical lines transmitting power to all parts of the plant in any desired quantity from local generating stations or from sources many miles distant. Instead of the many small and relatively inefficient prime movers formerly scattered about the plant, electricity has made possible the high economy of the modern central station, operating independently or in conjunction with other power systems.

If electric power is purchased from a source outside the steel plant, it is obtained at some high voltage such as; 22,000, 33,000, 66,000, etc., and is then stepped down through transformers to the working voltages of 6600 or 2200. The larger steel plants usually generate their own power at 6600 volts, as energy is easily transmitted about the plant with very little loss at this voltage. The 6600-volt power, either 60 or 25-cycle is commonly used for main-roll motors and stepped down through transformers to 230 volts a-c. or through motor-generators or synchronous converters to 230 volts d-c. for use on the smaller auxiliary motors.

Continuity of service through the distributing system, one of the most important, if not *the most important*, factors in a steel plant, seems to be best secured electrically through the use of the so-called loop or ring system, either overhead, underground, or a combination of both. This method of distribution lends itself to segregation of faults by the use of oil circuit breakers for the high voltages; of carbon circuit breakers or magnetic switches for the lower voltages. By controlling the breakers or switches with relays and interlocks, it is possible to isolate automatically any part of the system on which faults occur and without any material disturbance of the load on other parts of the system.

III. Yard Electrification

The economies found in the electrified yards of steam railway lines are found in even a greater degree in the steel yard system, due to the very intermittent nature of the work performed by a switching or transferring locomotive or car.

In a steam-operated yard there are individual self-contained units, generating motive power, handled more or less carelessly, and as a rule, with very low economies. The electrically-operated yard also has many individual self-contained units which, however, take their power from a central station fully equipped to produce power in large quantities at low cost. These electric locomotives with full automatic control are usually in the

hands of a single skilled operator and show a very fair operating economy.

The success or failure of an electrified yard depends to a large degree upon the method of getting power to the locomotive. Results obtained to date indicate that yard electrification is best secured through the use of the third-rail method, preferably the under-running type, of supplying power to the electric locomotive or car rather than the overhead trolley. The under-running third rail can easily be stepped over without personal danger. In a highly congested yard the use of a third rail demands a careful layout of switches, cross-overs, etc., but will adequately meet most requirements. In some cases a combination storage battery and third rail may be desirable.

One of our largest steel plants, after a year's experience with a 40-ton storage battery locomotive in general yard service reports most favorably. This locomotive is in operation during two 8-hour shifts and is charged during the third shift with occasionally one or two short-time high-current boosts during the 16 hours of continuous operation.

Among the many advantages of electrified yards over steam-operated yards are: one-man operation; no loss of time for getting coal and water or dumping ashes; cost of power about one-third that of steam; maintenance of electric locomotives on the order of one-ninth that of steam; two electric locomotives coupled together and operated by one crew; depreciation of electric locomotive materially less than that of a steam locomotive; greater flexibility in operation.

IV. Electric Furnaces

Thirty-seven new electric furnaces were installed during the year of 1923 in the United States and Canada, bringing the total number installed from 456 on January 1, 1923 to 493 on January 1, 1924. Of this number 442 are in the American industry and 51 in Canada. The new installations are mostly of small capacity, of 5 tons or less. Notable among the larger furnaces is one of 60-ton capacity. Development during the past year has been largely on the arc furnaces. Of the arc furnaces the three-phase, three-electrode type seems to be operating the most satisfactorily.

A number of repulsion-induction brass-melting furnaces was placed in commercial operation during the past year. This type of furnace utilizes the force of electro-magnetic repulsion existing between transformer high tension and low tension windings to cause a circulation of molten metal in the melting pot. A notable accomplishment of this type of furnace was the successful melting of pure copper on a commercial basis.

The largest horizontal single-ring type induction furnace in the United States has a maximum capacity of six tons and in normal service will melt three tons every three hours. It requires 800 kw. at 2200 volts, single-phase, 8½ cycles, supplied from a specially designed synchronous motor-generator. The motor of this set is rated at 1400 kv-a., 3-phase, and is operated at 80 per cent leading power-factor in order to compensate for low power-factor conditions in the electrical systems of the mill. In this way a low power rate is secured and the disadvantages of the inherent low power-factor of induction furnaces are avoided.

V. Electric Heating

Electric heating finds an important application in low-temperature heat treatment of small steel parts. Such installations, however, are more numerous in the steel-products industries than in the steel-making industry.

During the past year, a device has been developed for electrically pre-heating sheet-mill rolls preparatory to rolling hot steel sheets. Methods previously in use involved a series of gas flames, or hot-water jets played on the rolls during the warming-up period. By the use of electric heat, the rolls are more uniformly heated, the warming-up period is shortened, roll breakage is decreased, and a better steel sheet results.

Electric space heaters are now being installed in the frames of rotating machines in order to keep the windings warm and prevent sweating during long periods of idleness. This results in a materially longer life for the insulation, and lessens the danger of breakdown.

During the year 1923 electric ovens were, for the first time, successfully used for the bright annealing of copper wire. The oven is mounted on wheels and is moved back and forth over two hydraulic platforms, one of which can be loaded while the other is in the heating chamber. A water seal keeps the air from this chamber. The wire is uniformly annealed at all points in the oven and the product is bright and free from scale.

The connected load is 300 kw., 550 volts, 3-phase, and 7000 lb. of copper wire can be charged at one time and fully annealed in 75 min., the energy required averaging about 1 kw-hr. for each 25 lb. of wire.

VI. Automatic Control

During the past year there has been a steady movement toward simplified control and improved safety devices but no radical departures from past practise.

The ever-present demand for increased production has resulted in higher speeds for mill cranes and has consequently necessitated particular attention in design to secure safe and accurate control of the loaded hook, as well as high speeds for lowering the hook when empty. This is particularly the case with hot-metal cranes where dynamic braking is being extensively and satisfactorily used. Magnetic holding brakes are, of course, used in addition, one on the motor shaft and one on the intermediate shaft. The higher speeds coming into general use have also brought about the development of a safe limit switch, positive in action yet compact and admitting of mounting in various positions. There is a decided and increasing tendency

toward the use of enclosing features as a safety measure.

As mentioned elsewhere, the desirable characteristics of the synchronous motor have, in some few instances, overbalanced its objectionable features for steel-mill drives and a new type of automatic pushbutton starter has been developed for these motors which affords better protection and greater convenience than the older type of manual starter.

The use of automatic substations is spreading rapidly in the steel mills and during the last year several papers on this subject were presented before various societies. There is no doubt but that the automatic substation is an important item in the electrical net work of the mill. It is an excellent example of what can be accomplished safely and satisfactorily with automatic control.

Automatic hoists are being installed in the mills for handling coal, ashes and similar material. Balanced and unbalanced types are used calling for full reverse and dynamic lowering controllers. High-speed operation is provided with adequate slow-down features through automatic controllers. The use of two-speed a-c. motors has been an important addition to this field.

Two blast-furnace skip hoists have been installed recently using standard mill-type motors with mill-type shoe brakes of large size. One has a single motor equipment and is provided with full automatic push-button-operated control. The other uses two motors with a full automatic, series parallel controller to get high-speed operation with adequate slow-down and accurate stop. A large 36 in. shoe-type magnetic brake is used on each motor shaft.

The shoe type of magnetically-operated brake is fast replacing all others. A considerable number of brakes of a size larger than ever before attempted has been made with wheels 36 in. in diameter and 12 ½ in. face which have been very successful on blast-furnace skip hoists, large cranes, and car dumpers.

The application of magnetic type of friction clutch for use with synchronous motors and other power drives has been extended during the last 12 months.

Too little attention has been given in the purchase of control equipment to the duty cycle which it must meet. A more careful analysis of the time-torque-speed values is of utmost importance if the maximum of satisfaction is to be obtained under operating conditions.

VII. Main-Roll Drives

The reliability and high efficiency of what has come to be known as the steel-mill motor has given it a status such that only in rare cases is the steam engine ever mentioned as a competitor for main roll drives.

During the past year a very considerable part of the equipment sold for driving main rolls, reversing or non-reversing, has been for the purpose of replacing existing steam engines. Twelve units with an aggregate normal continuous rating of 55,500 h. p., including four d-c. reversing motors, supplied from suitable flywheel motor generators, have replaced engines, and one new 40-in. Blooming Mill has been equipped with a 6500-h. p., continuous rated, 50 rev. per min. d-c. reversing motor and flywheel set.

There has been the usual percentage of constant speed induction motors applied to continuous mills, sheet mills, bar mills and 3-high plate mills. Most of these installations are of interest only as an indication of the continuously increasing use of electric power. One installation comprising an 8000-h. p. 240 rev. per min., 13200-volt constant-speed induction motor, driving an interrupted continuous blooming mill, is notable as being the first steel mill motor for operation above 6600 volts.

The use of individual motors for the finishing stands of certain types of continuous mills, with the most exacting speed requirements, is increasing. Thus far the condition has best been met with d-c. motors in spite of their somewhat higher first cost and lower efficiency as compared with a-c. motors. The use of rolls in tandem, operating at high surface speeds and with but a short distance between stands, as in the case of continuous hot-strip mills, has made necessary a design of motor with close inherent regulation over a wide range of speeds. The success of such designs has been fully demonstrated in recent strip-mill installations.

In the normal expansion of an engine-driven plant, it is often desirable to disconnect a part of the rolls and drive them from one or more suitable motors. Due to the poor speed regulation of the engine, it is necessary to use adjustable speed motors provided with a special synchronizing control which will enable the motor automatically to follow closely all variations in engine speed. Several types of such control have been placed in successful operation.

Rolling mill engineers have long desired to apply synchronous motors to main rolls on account of the beneficial effect on the plant power factor. The deficiency of the usual synchronous motor in starting torque, has, however, almost entirely prevented such applications. The development of the revolving frame synchronous motor has overcome this objection and two such motors, each rated 580 kv-a. 70 per cent power-factor (500 h. p.) 360 rev. per min. have been installed for driving copper rolling mills.

An entirely new application and important development are the building of two BTA brush-shifting motors for driving rolling mills. One has a 3 to 1 speed range with 600 h. p. at maximum speed and the other 2 to 1 speed range with 500 h. p. at maximum speed. The operation of these machines will be watched with considerable interest, as they are expected to meet a long-felt need for an adjustable speed a-c. drive where the power required is too small to make Scherbius or Kraemer apparatus feasible on account of their high initial cost in small installations.

The largest Kraemer equipment in this country has been built during the year and will be used to drive a 14-in. Merchant Mill. This equipment is rated 4500/4500 h. p. 500/300 rev. per min. 2200 volts.

An interesting example of the attempt to secure the maximum flexibility in mill design is found in a 20-in. strip mill recently placed in operation. The roughing train is driven by a constant-speed induction motor, the intermediate train by a single adjustable-speed d-c. motor and the three finishing stands are driven by three independent adjustable-speed d-c. motors. The use of synchronous converters for supplying direct current for the adjustable-speed motors represents a departure from the usual steel-mill practise of using motor-generators for this purpose.

The following summary includes only main roll motors 300 h. p. and above, built by the three principal electrical manufacturers in this country.

		June 1923	June 1924
Continuous h.p.	60 cycle..........	452,840	478,390
" "	25 "	475,825	490,225
" "	direct current....	299,670	324,860
	Total.......	1,228,335	1,293,475

This shows an increase of 65,140 h. p. in the aggregate of main roll motors supplied by these three companies during the past year.

VIII. Arc Welding

Arc-welding processes and equipment are well standardized. The metallic arc has almost completely supplanted the carbon arc as it has been found that reliable welds can be made by a less skillful operator and the deposition of metal is just as rapid. Arc welding is being extensively used about the steel plant in the repair of worn pinions, wabblers, rolls, driving spindles, etc.

There appears to be a decided tendency toward the use of greater welding currents, and single-operator machines of high capacity are being produced to meet these requirements. The application of automatic arc-welding processes is expanding as the increased production and lower costs obtained become known.

One of the most important achievements has been a marked improvement in the construction of the electrode which makes it easy to combine the desired welding flux within the body of the electrode, thus securing all of the advantages which could be obtained with an externally coated electrode without its disadvantages. The flux is enclosed in an annular space between the core and a sheath, the amount being controlled by the thickness of the annular space.

It is customary to incorporate with the flux of coated electrodes, materials which merely serve as a binder. These materials add to the slag produced making it difficult to avoid inclusions in the deposited metal. The enclosed flux cannot flake off before it actually enters the arc.

The sheath, which receives the current and conducts it to the arc, always presents a clean surface to the holder or current-feeding device. This is particularly advantageous with the automatic welding machine where current is led in through the feed rolls or nozzle, as the electrode wire travels through in a continuous length.

* * * * *

There is a marked interest in the generation of electric power for sale as a means of realizing the benefit from the surplus gas from merchant blast furnaces. The single furnace of the Trumbull-Cliffs Furnace Company at Warren, Ohio has developed approximately 5000 kw. continuously over and above the power required for the plant itself and sold it to the local public service company. This sale of power materially affects the profit per ton of pig iron, placing the merchant furnace on a par with the furnace located at the steel plant, which in the past has been in better position to utilize the excess gas.

F. B. Crosby, *Chairman.*

PROTECTIVE DEVICES COMMITTEE

To the Board of Directors:

In addition to the five subcommittees which have been working during the past few years on protective devices, a new subcommittee on Automatic Stations was authorized and appointed last year and has been doing very active work.

Thus the committee's activities have been carried out along the lines of the six subcommittees, namely:

1. Lightning Arresters
2. Oil Circuit Breakers, Switches and Fuses
3. Relays
4. Automatic Stations
5. Current-Limiting Reactors
6. Grounding of Systems

The dependency on automatic devices on which the central station companies are constantly insisting is becoming stronger each year and the emergency functions are being taken away from the operator and placed with the properly selected equipment which is found more dependable than the human operator. The automatic features are found to be on the job twenty-four hours a day, 365 days in the year and can be relied upon to function in a moment's time and thereby maintain service at a higher standard with less operating cost than a completely manually-operated equipment.

During the past year the committee work has been very well supported and excellent results have been obtained, as indicated in the following subcommittee reports.

Subcommittee on Lightning Arresters

F. L. Hunt, *Chairman*

The work this year of the Lightning Arrester subcommittee has been chiefly that of preparing and agreeing on a statement which may be used as a basis of lightning arrester performance. This has been com-

pleted and was published in the June issue of the A. I. E. E. JOURNAL under the title "Basis of Comparison in Lightning Arrester Performance."

This statement is believed to be a start toward standardization in testing and classification of lightning arresters and it is the intention of the subcommittee to follow it up by the formulation of definitions of the features brought out in this statement.

The several different angles of lightning arrester design, performance and testing have been brought up in the papers fostered by the subcommittee and presented at the Spring Convention in Birmingham under the authorship of A. L. Atherton, E. R. Stauffacher, W. F. Young and C. E. Bennett.

During recent years there has been a steady increase in the emphasis which is placed on continuity of service by central stations and as the systems have grown in size and complexity, the results of failures become more serious. This has increased the emphasis and need of more effective protection against lightning and surges which has resulted in improved types of arresters being manufactured.

There is apparently some distance to travel before we find an ideal arrester, although the new developments in the Autovalve and Pellet type of arresters have gone a long way in bringing out an effective and simple arrester.

The necessity of good grounding conditions in connection with lightning arresters has been brought out forcibly this year, and attention is called to the fact that even an ideal arrester would be of little value on a system where good grounding conditions were not made effective.

Lightning arresters are very seldom installed today on completely underground systems and there is some question regarding their desirability on high-potential transmission lines of 200,000 volts and above.

Subcommittee on Oil Circuit Breakers, Switches and Fuses

E. C. STONE, *Chairman*

The subcommittee on Circuit Breakers, Switches and Fuses in cooperation with the representatives of the National Electric Light Association and the Electric Power Club have agreed on a definition of the interrupting duty of an oil circuit breaker. This definition as recommended to the A. I. E. E. Standards Committee is—

Interrupting Rating of Oil Circuit Breakers

The interrupting rating of an oil circuit breaker is a rating based upon the highest r. m. s. current at normal voltage that the breaker can interrupt under the operating duty specified.

The value of the current shall be taken during the first half cycle of arc between contacts during the opening stroke.

Operating Duty of Oil Circuit Breakers

(a) The operating duty of an oil circuit breaker shall consist of a specified number of unit operating cycles at stated intervals.

(b) Each unit operating cycle shall consist of a closing of the circuit breaker followed immediately by its opening without purposely delayed action.

Interrupting Performance of Oil Circuit Breakers

(a) An oil circuit breaker shall perform at or within its interrupting rating without emitting flame.

(b) At the end of any performance at or within its interrupting rating, the circuit breaker shall be in the following condition:

(1) *Mechanical*

The breaker shall be substantially in the same mechanical condition as at the beginning.

(2) *Electrical*

The breaker shall be capable of carrying rated voltage, and its main current-carrying parts shall be substantially in the same condition as at the beginning.

After performance at or near its interrupting rating, the interrupting ability of the breaker may be materially reduced and it is not to be inferred that it may be reclosing after such performance without inspecting, and, if necessary, making repairs.

Standard Operating Duty of Oil Circuit Breakers

The standard operating duty of an oil circuit breaker shall consist of two unit operating cycles at a two-minute interval.

The manufacturers are rating all new breakers in accordance with this definition and are also in position to give the rating of their old oil circuit breakers on this basis.

Although there have been no radically new developments in oil circuit breakers during the year and the largest breaker is still limited to 1,500,000-kv-a. rupturing capacity, the manufacturers are considerably advanced in the art and if larger breakers are required we feel reasonably sure that they can be supplied. There has been a marked improvement in the development of oil circuit breakers in the truck or quick removable type, allowing very much better facilities for inspection and repairs. This type of breaker is becoming very popular in the central station industry and will be of considerably greater use in the future.

A number of operating companies has started tests on oil circuit breakers to determine if the ratings guaranteed by the manufacturers are met. The operating industry expects to carry this very much further during the next year and a very definite set of specifications for testing oil circuit breakers so that the different sets of tests may be brought into a comparable basis, has been prepared. While it is expected that experience will possibly result in some modification in detail of this specification, it is believed that it covers the essential points and it is recommended that in order to secure truly comparative results, power companies conduct their oil circuit breaker tests in

accordance therewith. Copies of these specifications can be obtained at the A. I. E. E. headquarters.

There has been a distinct improvement in the satisfactory use of high-voltage current interrupting fuses and a number of tests has been conducted showing that it is possible to rely upon fuses in certain places where the short-circuit current does not reach excessively large values.

At a technical session of the Spring Convention at Birmingham, devoted completely to oil circuit breakers, papers were presented by H. J. Scholz, Alabama Power Company, A. J. D. Hilliard, General Electric Company and J. V. Jenks, West Penn Power Company.

Subcommittee on Relays

A. H. SWEETNAM, *Chairman*

The Relay Handbook is being published jointly with the National Electric Light Association, as mentioned in last year's report. It is practically completed and publication may be expected during this fall. We feel sure that this book fills a need throughout the industry and its publication will be welcomed by all. On account of the large number already subscribed for, there will be 10,000 volumes printed which reduces the price to N. E. L. A. or A. I. E. E. members to $4.00 per single copy with quantity discounts for 100 copies to one address at $3.00 per copy. The price to non-members is 50 per cent above these figures.

Development of greater accuracy of the transformer and the development of lower ampere windings on relay have made it possible to use bushing current transformer for relay protection, thereby saving considerable space and extra investment on new installations.

Greater use is being made of the indicating pointer and targets on the relays. Some companies are using the indicator pointer as an ammeter on the front of the control board. This not only gives them an indication of the load on the feeder but assures them that the relay circuit is intact. The targets have proven very valuable in analyzing troubles showing that a switch tripped out due to relay operation on certain phases.

Of the new type of relays that came out in production last year, the impedance relay is probably the most promising. This relay works on the principle of combining voltage and current with time so as to make the relay operate first which is next to the trouble. Two elements, one of potential and one of current, are so designed and arranged that the time of closing is inversely in proportion to the current and directly proportionate to the voltage or, in other words, depends on the distance between the relay and the fault.

A new relay designed to protect against open-phase, reverse-phase and unbalanced-phase in rotating machinery has been produced and shows promise of good application. This relay combines reactors and resistors in a network with an induction relay so that no current flows through the relay as long as the polyphase service is balanced and the phase rotation is correct. Upon the occurrence of the abnormal condition above mentioned, the relay received an appreciable amount of current and operates.

Greater care has been taken in the testing and maintenance of relays, and to the equipment available for this work has been added the portable phase meter which will indicate in electrical degrees the vector relationship between the current and voltage in any circuit. This addition to the testing equipment will make it possible to give greater assurance in the connections of directional relays.

The adoption of a-c. networks has made it desirable to install in certain places relays in manholes, and although the work in this connection is not very far advanced, there has been considerable emphasis placed on the development of relay cases for installation in moist or water-filled manholes and we can look forward to the development of real equipment for this work during the next year.

Subcommittee on Automatic Stations

W. H. MILLAN, *Chairman*

The newly organized Subcommittee on Automatic Stations has put in a year of very active work and has brought before the industry the dependability of protective devices for automatic stations in the six papers to be presented at one session of the Annual Convention in Chicago, by C. W. Place, H. L. Wallau, C. A. Butcher, Herman Bany, F. D. Wyatt and R. J. Wensley. The work of the next year has been very definitely laid out and the numerous subdivisions of this subject will be studied in considerable detail for a more comprehensive report next year. It is definitely planned to investigate the possiblity of applying automatic devices to perform all of the functions ordinarily included in the operators' duties even as far as such matters as the leakage of oil from transformer or switch tanks.

Subcommittee on Current-Limiting Reactors

N. L. POLLARD, *Chairman*

From the results of this year's study it appears that the reactors have filled the requirements more completely during the past year and reactor failures have been few. The manufacturers of this piece of equipment have studied the special requirements of the tremendous forces and potential strains and have produced a reactor which apparently meets the requirements in every respect.

In order that the special requirements of reactors may be brought before the industry, the committee has prepared a specification for current-limiting reactors which was published in the June issue of the A. I. E. E. JOURNAL. The disputed question of the desirability of using resistors with reactors is apparently no nearer solution than it has been for the past few years.

One of the large manufacturers recommends the use and two do not. There has been no operating experience which shows clearly that either the resistances are a hazard or that they are a necessity. The present status of the manufacture has been brought out in the three papers to be presented at the Annual Convention by H. O. Stephens and F. H. Kiersteadt, W. M. Dann, and S. I. Oesterreicher.

Subcommittee on Grounding of Systems

E. R. STAUFFACHER, *Chairman*

Last year's committee covered the Eastern operating views on grounding of systems and this year's committee has studied the same problem from the angle on the Pacific Coast.

There is still considerable discussion as to the amount of resistance which should be inserted in the neutral of a system which varies from several hundred ohms down to a solid ground. The very high-voltage systems have in general adopted this solidly grounded neutral and considerable apparatus is specified on that basis. Some of the more moderate transmission systems having 22,000 volts have adopted the solidly grounded neutral last year and there has been considerable extension of the solidly grounded 3-phase, 4-wire distribution system.

HARRY R. WOODROW, *Chairman.*

ELECTRICAL MACHINERY COMMITTEE

To the Board of Directors:

DURING the administrative year 1923-24 the Electrical Machinery Committee has conducted the following activities:

1. *Papers*—Under the direction of the Meetings and Papers Committee, thirty (30) papers have been secured by the Committee for Institute meetings, including the Annual Meeting of this year. These may be grouped as follows:

a.	Factors which influence design of electrical machinery	9 papers
b.	Generator design and construction	9 papers
c.	Motor design and construction	5 papers
d.	Frequency-Converter design and construction	1 paper
e.	Transformer design and construction	5 papers
f.	Static-Condenser design and construction	1 paper
	Total	30 papers

Opinions have been expressed to the effect that the presentation of so large a number of papers is not accompanied by sufficient advantages to justify the heavy expenses associated with their publication. It has to be admitted that any one paper is rarely even read by or could be useful to more than from 20 to 200 people and the publication of 20,000 copies in order that 200 copies or less shall reach the people who will profit by them seems at first thought very wasteful. But any other known method is liable to fail to place copies in the hands of the particular individuals who will make to the community the best return from the knowledge or inspiration received from them. The expenses are greatly reduced by the Institute's present practise of publishing in the JOURNAL merely an abstract of not over four papers (and in some instances merely a statement of the title) accompanied by the statement that a copy of the complete paper will be sent to any member applying for it.

The presentation of these papers and their discussion affords the opportunity for the specialists in the design, construction and operation of electrical machinery to interchange experiences and thereby advance in knowledge and ability.

Several of the papers, as examples of which may be mentioned:

Eddy Current Losses in Armature Conductors
Tooth Pulsations in Rotating Machinery
Harmonics Due to Slot Openings
Shaft Currents in Electric Machines

are of the nature of researches leading to information of which general use is made by all designers until such time as still better and more complete results are made available. In other words, while the discussions bring out valuable criticisms with respect to the assumptions made, the methods of investigation employed and the conclusions drawn, there is general satisfaction at the increase in the store of available knowledge represented by the papers.

A second group of papers (really a subdivision of the first group) describes researches into such characteristics of electrical machinery as require to be analyzed before Standards can be established. We may give the following examples of this group:

Effects of Expansion and Contraction on Insulation of Long Armature Coils.

Effects of Time and Frequency on Insulation Tests of Transformers.

Effect of Altitude on Temperature Rise of Electrical Apparatus.

Temperature Rise of Stationary Electrical Apparatus as Influenced by Radiation, Convection and Altitude.

As examples of a third group of papers may be mentioned:

The Inertaire Transformer.

Recent Advances in the Manufacture and Testing of Static Condensers in Power Sizes.

A New Type of Single-Phase Motor.

A New Synchronous Induction Motor.

In papers of the class of which these are examples, radically novel features of design and operation and novel methods of construction are described. The propositions put forward by the authors of papers in this class generally embody radical alternatives to usual types of machines and in the ensuing discussions the propositions are subjected to careful analysis by specialists in the respective fields.

As a fourth kind may be cited those papers consisting in clear and timely descriptions of especially important installations of machinery. We may take as examples:

65,000-kv-a. Generators at Niagara Falls.

The 35,000-kv-a. Frequency Converter for Hell-Gate Station.

While these descriptions are primarily valuable for record and for reference, the discussions often include valuable opinions with respect to characteristics and features of the designs described and of alternatives preferred or at any rate described by those contributing to the discussion.

Committee Deliberations on Matters Referred to It

Various matters are referred to the Committee for opinions or action. Recently the Board's Committee to Review the Technical Activities of the Institute referred its Tentative Report to the members of all technical committees. At a meeting of the Electrical Machinery Committee, the Chairman of the Board's Committee, Mr. Berresford, accepted the Electrical Machinery Committee's invitation to attend and assist the Committee in its consideration of the matter. The parts of the report specifically dealing with the Electrical Machinery Committee are reproduced in the following extracts:

EXTRACTS FROM TENTATIVE REPORT OF COMMITTEE TO REVIEW TECHNICAL ACTIVITIES OF INSTITUTE

1. Committee on Electrical Machinery

Field: Cognizance of all matters in which the dominant factors are the design and construction of devices and machinery for the generation, transformation and translation of electrical energy and the requirements determining design and construction, except where such requirements are specifically otherwise assigned.

Note: The expectable functioning of this committee should be initiatory and determinative in the matters within its province. Subject to the approval of the Board it should have power in all matters arising therein, except such formulation of standards as is the function of the Standards Committee, including those of contact with other bodies and of arrangement for joint action where such is indicated.

Standardization:

In your Committee's opinion, a degree of standardization work by technical committees is not only permissible, but desirable. Composed, as it is, of individuals active and experienced in a given field and associated for the purpose of contact with the operations and possibilities of that field, the need for and the possibilities of standardization therein should first present themselves to the Technical Committee.

There are two steps in the making of a standard—

a. The perception of the possibilities, the evaluation of the desirability and the determination of the degree to which standardization may be practicable, including preliminary formulation.

b. The actual and final formulation of the standard.

Your Committee believes that "a" will best be accomplished by the Technical Committee and "b" under the auspices of the Standards Committee, the working committees of which, under these conditions, would instinctively be composed in large parts of the men responsible for "a".

The Electrical Machinery Committee expressed its agreement with these sections of the Tentative Report of Mr. Berresford's Committee.

Committee Consideration of Standardization Matters in Their Initial Stages

In the tentative report of the Board's Committee it is stated that prior to the "actual and final formulation of standards" relating to electrical machinery, there is occasion for the Electrical Machinery Committee to make valuable contributions in "perceiving possibilities," "evaluating the desirability" and "determining the degree to which standardization may be practicable" and also in the "preliminary formulation."

At two meetings of the Electrical Machinery Committee held respectively on the 21st of April and the 5th of June, careful consideration has been given to some matters of considerable importance relating to the basic principles underlying the standardization of electrical machinery. These have included propositions drawn up to more clearly distinguish between "rating" and "service conditions." The whole subject is of such immediate interest as to justify including a review in this Report.

Review. Some ten years ago a general plan of Standardization which had particular reference to Electrical Machinery was adopted by the A. I. E. E. This plan was reasonably in agreement with the I. E. C. proposition and has since been very widely used in America and abroad. With respect to temperature recommendations certain limitations were established. These limitations varied with the class of insulation employed, the type of enclosure of the machine, the nature of the cooling medium and the method specified for the measurement of the temperature. But in a general sense or at any rate as an example, it may be stated that for open-type machines built with Class A insulation and cooled by air, the limiting temperature rise as determined by thermometers applied to prescribed accessible parts was established as 50 degrees. This limiting rise was permitted for places where, and at times when the temperature of the surrounding air did not exceed 40 degrees, with the further limitation that the recommendation only applied to machinery operating in places whose altitude was not more than 1000 meters (3300 feet) above sea level. While this general plan was adopted after much thorough discussion in this country and abroad in which many experienced people participated, the original impetus in America came chiefly from Dr. C. P. Steinmetz, Mr. B. G. Lamme, and Prof. A. E. Kennelly, who at that time applied a great deal of study to the subject of *Standards for Electrical Machinery*. It was not the intention either of those in Europe who contributed to this plan, nor of Steinmetz, Lamme, Kennelly and their associates to advocate these values as anything more than *limits*. They fully realized that in the ordinary course of events a very few machines might occasionally come to be subjected to these limiting conditions simultaneously. They recognized that such simultaneous occurrence of these limiting conditions frequently or for long periods would not be desirable but there appeared no sufficiently simple way of specifically discountenancing such operation at these limits without reducing the limits for *all* machines. This would have resulted in the use of

uneconomically large machines for almost all cases in order to avoid rather severe conditions in an almost negligible number of instances. Furthermore in this practically negligible number of instances it was known that any disadvantageous consequence would be simply a reduction in the life expectancy of the machine and would not consist in its failure. Naturally approved construction in all respects and the use of approved materials are assumed in these statements.

This general standardization proposition has gradually come into very wide use not only in America but abroad. In recent years, however, due partly, it is believed, to gradually losing sight of or mistaking the underlying ideas, a great deal of study has been directed to the development of proposals for utilizing machines frequently and for long periods under conditions which may occasion sustained temperature rises equalling and even exceeding the *fifty degree limit.*

Thus, if a consumer's motor was located where the surrounding air never or rarely exceeded 30 degrees, it seemed to him, (and the suggestion was sometimes made to him), that if there were no other limitation, such as stalling load or commutation or mechanical strength, he could advisedly place on the motor any load not occasioning more than 60 degrees rise.

Also if he had knowledge that a certain motor with a 50-degree rating actually on test showed a margin of, say, 7 degrees, the rise at rated load being only 43 degrees instead of the limiting value of 50 degrees, then even if the surrounding air had a temperature of 40 degrees he considered that he could place on the motor a greater load up to the point where he had used up this 7 degrees margin; and if the surrounding air had a temperature of only 30 degrees, he considered that he had a margin of 17 degrees extra rise which he could properly utilize. It should be needless to state that no such interpretations or consequences were contemplated when the system of limits was established. Had it been supposed that such interpretations were liable to become general, it would have been necessary to establish correspondingly lower limits. Indeed it was expressly stated in the Standards that the fact of a surrounding air temperature lower than the limiting temperature of 40 degrees was not to be taken as justification for loads occasioning a temperature rise in excess of the 50 degree limiting rise.

Also with respect to altitude, the original purpose in broadly endorsing the use of machines rated on these principles at any place whose altitude does not exceed 1000 meters (3300 ft.) for carrying the same loads as at sea level, was dictated by the desirability of having a simple basis of rating and it was believed that the few degrees greater temperature rise sustained by a machine carrying a given load at the upper limiting altitude as compared with the sea level rise, would at the most only slightly decrease the life expectancy, especially since it was realized that the coincidence of the occurrence of the conditions of the limiting altitude of 1000 meters and the limiting cooling air temperature of 40 degrees would be extraordinarily rare and it was believed that it would not justify the introduction of correction complications.

But the more general knowledge of the influence of altitude on temperature rise is leading people to observe that their machine is described as adequate to carry its rated load at the limiting altitude of 1000 meters. They add this to their knowledge that at 1000 meters altitude the machine has, at its rated load, a temperature rise greater by, say, 5 degrees, than at sea level. They note that on the occasion of its test at sea level it was only required to come within the limit of 50 degrees rise. They consequently consider that the machine must be regarded by its makers to be adequate to carry loads occasioning 55 degrees rise if the temperature of the surrounding air is not over 40 degrees. They may even go further and conclude that if the temperature of the surrounding air is only 30 degrees there is also available a 10 degree higher rise for that reason, giving them license to impose any load which will not occasion over 65 degrees rise. If, furthermore, instead of having, on test, the limiting rise of 50 degrees the rise was only, say, 43 degrees, they can equally reasonably add this further 7 degrees and conclude that the correspondingly increased load is in accordance with the proposition.

Meanwhile, although not as yet recognized in any way in the Institute Standards, manufacturers have established the practise of entering into undertakings applying to the operation of motors with *off normal circuit conditions.* The following is an example:

> Motors shall operate successfully at rated load and frequency, with voltage not more than 10 per cent above or below the name plate rating, but not necessarily in accordance with the standards established for operation at normal rating.

The user presumably reasons that he wants his motor to operate *successfully.* It is of less importance to him if it is "*not necessarily* in accordance with the standards established for operation at normal rating." Let us take the case of a consumer whose circuit voltage is 220 and who has available a 240 volt motor. If he operates it at its rated load on the 220 volt circuit, (on the security of the above quoted clause), the current will be increased about 9 per cent and the copper loss about 18 per cent. The core loss will be somewhat decreased, so the thermometric temperature rise may be only increased by (let us say) some 5 degrees. But if we add this 5 degrees to the 5 degrees relating to altitude which we have already discussed, then, with a cooling air temperature of only 30 degrees the user will be concluding that he will not be impairing the life expectancy by having his motor carry such loads as will occasion a temperature rise of 70 degrees.

But the average user cannot reasonably be expected to know that the 50 degrees limiting rise by surface thermometers is usually associated with a further rise

of some 15 degrees in the insulation in contact with the copper and that this further 15 degrees becomes

$$\frac{70}{50} \times 15 = 21 \text{ degrees}$$

additional when the surface temperature rise is 70 degrees. This 6 degrees further rise together with the 5 degrees further rise for altitude and the 5 degrees further rise assumed to correspond to the *successful* use on a circuit with a voltage 9 per cent lower than that on the name-plate aggregate 16 degrees addition to the "hottest-spot" temperature of $40 + 50 + 15 = 105$ degrees which is taken as the *Limiting Hottest Spot Temperature* for Class A Insulation. The hottest-spot temperature corresponding to this *successful* operation thus becomes $105 + 16 = 121$ deg.

The well-meant and entirely reasonable and practical standardizing proposition built up by Steinmetz, Lamme, Kennelly and their associates and based on suitable *limits* is thus seen to have become a web of inconsistencies and absurdities when interpreted and amended in ways which could never have been reasonably anticipated.

During the few months immediately preceding his death, Dr. Steinmetz was again directing his close attention to this subject and was suggesting a revision of the general proposition to cope with the new circumstances. It was the privilege of some of us to be working with him in this matter.

One of the tentative propositions to which this has led consists in having two entirely distinct statements relating respectively to Service Conditions and to Rating. The statement relating to Service Conditions aims to present a carefully considered recommendation as to when and where a machine may carry its rated load, (or more than its rated load), and when and where the load should be restricted to values less than the rating.

The plan proceeds from definitions of (1) *usual service conditions*, and (2) *unusual service conditions*. For the former the machinery should be adequate to carry its rated load, but for the latter it *may* sometimes be desirable to restrict the load to values less than the rating. These are *application recommendations*, and are distinct from the *rating*, which is a simple value corresponding to defined test conditions.

If this plan should be employed in a standardizing proposition, it is probable that the text would have to be somewhat different for different kinds of machines. The following text entitled SERVICE CONDITIONS has been suggested as suitable for use in *Standards for Transformers* and is being considered as an alternative to a more usual test.

SERVICE CONDITIONS

Usual Service Conditions: Usual service conditions are those in which none of the limits listed below are exceeded, nor two or more of these limits simultaneously closely approached.

Limits:

1. The temperature of the cooling medium should not exceed 40 deg. cent. for air or 25 deg. cent. for water.
2. The altitude should not exceed 1000 m. (3300 ft.)
3. The voltage should not be more than a specified limiting per cent above or below that set forth on the rating plate.
4. The frequency should not be more than a specified limiting per cent above or below that set forth on the rating plate.
5. The power factor should not differ more than a specified limiting per cent from that guaranteed.
6. The maximum load should not exceed the rated load, in combination with a 24 hour load factor approaching 100 per cent.

Unusual Service Conditions: All other service conditions should be designated as "unusual service conditions." Such would be

(a) If one of the above listed limits is exceeded.

(b) If two or more of those limits are simultaneously closely approached.

APPLICATION RECOMMENDATIONS

Under *Usual Service Conditions*, the apparatus should be expected to carry its rated output.

Where either of the two previously stated classes of *Unusual Service Conditions* occurs, it *may* sometimes be desirable to restrict the output to values less than the rating.

For example, a machine may be required for operation where:

a. The cooling medium frequently and for considerable periods approaches the limiting value and

b. The altitude approaches 1000 meters and

c. The machine is required to operate continuously at rated load for periods approaching 24 hours per day and every day and

d. The voltage differs from the rating plate voltage frequently and for considerable periods by amounts approaching the specified limiting per cent deviation and

e. The frequency differs from the rated value often and for considerable periods by amounts approaching the specified limiting percentage deviation.

The need for special consideration in these matters is apparent when it is pointed out that if the prevailing value of (a), the temperature of the cooling medium is sufficiently low, then other limits may be approached without concern; or as another instance, if (c) the load is very fluctuating, the average load being sufficiently low, then other limits may be reached without concern, etc.

In cases where transformers are operated under technical supervision it will be permissible to make

use of special loading instructions furnished by the manufacturer.

For example, the instructions may be in the form of maximum available capacity for different ambient temperatures or for different water temperatures and different rates of water flow for water-cooled types, without the maximum temperature exceeding approved values for continuous operation.

Or, where the nature of the load is fluctuating, these instructions may permit loads in excess of those approved for continuous operation but of such a magnitude that the deterioration of the insulating materials is no greater than that resulting from rated load in average ambient temperatures.

H. M. HOBART, *Chairman.*

EDUCATIONAL COMMITTEE

To the Board of Directors:

The outstanding event in the field of engineering education during the past year has been the inauguration by the Society for the Promotion of Engineering Education of a comprehensive project of investigation and development with provision for the active cooperation of the faculties of the engineering colleges, the professional societies, the employing industries, federal and state bureaus of education and other agencies.

It will be recalled that in 1907 the Institute joined with its sister professional societies and the Society for the Promotion of Engineering Education in undertaking a detailed study of engineering education. Finding the task to be beyond their financial resources, this group of societies proposed to the Carnegie Foundation for the Advancement of Teaching that it take over the problem. After due examination of the project, the Foundation generously acceded to the request and finally selected Dr. Charles R. Mann to make an extended investigation and report.

The report appeared just as the nation was developing its maximum war effort. The resulting disturbances in the work of the colleges assisted educational progress in details but retarded fundamental changes. As normal conditions returned it was apparent that the broader problems remained as before, plus the added complications arising from the war. It seemed necessary to supplement Dr. Mann's report by gathering additional evidence in order to deal intelligently with both the old and new problems confronting the colleges.

Through the generosity of the Carnegie Corporation, the Society for the Promotion of Engineering Education has been enabled to undertake (1) a project for the cooperative gathering of evidence from the past experience of the engineering colleges; (2) a survey of the occupational demands confronting the schools, to be carried out in cooperation with the organized industries and professional societies; (3) a study of the ways and means by which the engineering schools may be effectively related to the organized life of the engineering profession; (4) a study of recent advances in the principles and practises of education and psychology which are adaptable to the work of engineering schools; and (5) a study of corresponding problems and activities in Europe.

An important part in this project is being taken by the national engineering societies. At its 1923 convention the Society for the Promotion of Engineering Education voted to invite the four founder societies to appoint advisory councillors on education who should confer with the Board of Investigation and Coordination having the oversight of the general project. All four societies accepted the suggestion. The Institute appointed Messrs. Gano Dunn and F. B. Jewett to serve as councillors and the other societies named men of equal distinction and ability. The Board of Investigation and Coordination held a conference with the councillors, to which the secretaries of the four societies were also invited, on May 15, 1924.

The conference group recognized that its function is purely advisory and formulated agenda of studies to be pursued rather than action to be accomplished. The present circumstances seem particularly favorable to an inquiry into the professional status of engineering and the implications which arise from it with regard to engineering education. In recent years there has been a strong trend toward standardization in professional education for medicine, dentistry and law. In each case the respective groups of schools and related national professional associations have set up joint agencies of educational standardization. This movement has been closely related to the comprehensive investigations conducted by the Carnegie Foundation for the Advancement of Teaching and has been productive of important gains in the standards of educational preparation for these professions. On the other hand, there have been some results at least temporarily less beneficial.

With a comprehensive study of engineering education now in progress, it is fitting that these movements in other professions should be studied under the joint auspices of the schools and the professional bodies with an entirely open mind. It seems evident that engineering occupies a professional status dissimilar in important respects to the older, highly individualized professions of divinity, medicine and law, and that the formal relations between education and professional life which have been built up in these professional fields, do not necessarily constitute precedents of compelling logic. It is equally true that the national engineering societies might lend a far greater body of support to the engineering colleges without any trespass on their independence or autonomy.

As a step toward the clearer understanding of these problems, the conference group has agreed to sponsor and direct studies of the following subjects, to be carried out by the staff of the Director of Investigations of the

Society for the Promotion of Engineering Education:

1. The criteria of professional status, with a view to defining more accurately the status of the professional engineer.

2. The present status of relations between other professional bodies, particularly those concerned with medicine, dentistry, law and architecture, and the corresponding groups of professional schools, including the background of the present schemes of standardization and rating of schools by professional bodies, the evidences of detrimental as well as beneficial results from such standardization, and the present state of relations between engineering schools and engineering societies abroad, particularly in Great Britain and Germany.

3. Minimum standards which may properly be established for the recognition of any institution as an engineering school or any course of study as an engineering course.

4. Standards of educational attainment, in other than technological fields, which should underlie the professional training of engineering students. This would include languages, history, literature, economics and psychological and sociological sciences.

5. Standards of educational attainment in the common group of mathematical and physical sciences and of technological studies which should underlie the professional training of engineering students.

6. Sanctions concerning the normal length and the degree of specialization of engineering curricula to which the societies represented may be willing to give support.

7. Sanctions concerning the desirable qualifications of teachers who deal with professional engineering subjects, their professional and economic status and the appropriate scale of compensation for engineering teachers, to which the societies represented may be willing to give support.

8. The determination of aptitudes as a basis for admission to engineering colleges.

9. The extent to which the relations of the professional engineering societies to affiliated student groups may advantageously be unified or coordinated.

10. The contributions which the profession-at-large and the business and industrial organizations closely allied to it may make to the fund of vocational information relating to engineering and the means which may be employed to bring such information to the attention of parents, teachers and students at the time of selection of a college or university and of a course of general or professional college study.

11. The recognition to be given to graduation from an engineering college in the requirements for admission to professional engineering societies.

12. A survey of the occupational demand for engineering graduates in the more distinctly professional fields, as a complement to the surveys of demand in industrial fields now being undertaken.

W. E. WICKENDEN, *Chairman*,

ELECTROPHYSICS COMMITTEE

To the Board of Directors:

ADVANCES IN ELECTROPHYSICS 1923-1924

No attempt will be made to point out outstanding advances for the past year. Progress, in general, is continuous and not in marked steps. For this reason, it has been the policy of this committee to keep the membership informed by means of lectures by noted physicists and research workers rather than by an annual catalog of steps in progress. Such lectures have taken place during the year on general and specialized subjects. It has also been our policy to arrange popular lectures or reviews on the latest status of electrophysics. These lectures have probably always been better attended than those on any other subject. In passing, it may not be out of place to mention that wonderful advance has been made in the past few years in the knowledge of the interior of the atom and the radiations or energy changes that occur from its very heart. It is suggested that the committee next year arrange a popular lecture covering the latest knowledge of the atom.

LECTURES AND PAPERS

During the past year the Electrophysics Committee has had technical sessions at the Pacific Coast, the Midwinter, the Annual and the Regional Conventions. All of these sessions have been very well attended and the discussions have been at least as extensive as those at any other technical sessions.

The papers have been on a large variety of subjects such as insulation, transmission, ionization, magnetics, heat convection, transients and oscillations, vacuum tubes and detectors, radio and mathematics.

The committee expects an especially interesting session at the coming Pacific Coast Convention.

It is hoped that our Institute will continue to encourage this work.

F. W. PEEK, JR., *Chairman*.

TELEGRAPHY AND TELEPHONY COMMITTEE

To the Board of Directors:

In this report we are giving a brief summary of the advances which have been made or which have come into prominence in the communication art during the past year. The papers which have been presented under the auspices of this committee have, in general, been a record of such advances, and they are mentioned under the appropriate headings in the report.

TELEPHONE EQUIPMENT

Transformers perform so many and such valuable functions in telephone circuits that the paper on "Telephone Transformers," read at the February Convention, covers a field of the very highest importance. Some interesting special requirements in tele-

phone transformers have been introduced by the comparatively high impedance of many vacuum tube circuits.

One phase of the very important subject of machine switching was presented to the Institute during the year in a paper on "The Economic Development of a Step-by-Step Automatic Telephone Equipment."

Telephone Transmission

A "telephone transmission unit," differing from the commonly used "mile of standard cable," has been adopted for general use by the companies of the Bell System. A paper entitled "The Transmission Unit and Telephone Transmission Reference Systems," to be presented at the June Convention of the Institute describes the unit and the reasons for adopting it.

As telephone circuits, particularly long distance circuits, are necessarily elaborate and complicated, it is very important that convenient and rapid methods be available for checking their transmission efficiency at frequent intervals. A February Convention paper on "Measuring Methods for Maintaining the Transmission Efficiency of Telephone Circuits" discusses this important problem.

In all engineering of communication circuits and apparatus it is important to know accurately the characteristics of the currents and voltages which are being carried by the circuits, whether these be the signaling currents themselves, or interfering currents. A very convenient tool for analyzing currents into their component frequencies was described in a February Convention paper on "An Electrical Frequency Analyzer."

Two papers giving interesting and important discussions of long distance telephone transmission were given at the Pacific Coast Convention under the titles "Telephone Transmission over Long Distances" and "Applications of Long Distance Telephony on the Pacific Coast."

Outside Plant Practises

The Western Union Telegraph Company are employing, after an investigation of about three years, a method of treating existing pole line timber for the purpose of prolonging its life. They consider this method so promising that the apparatus for its application has been well standardized, and the practise of treating poles in this manner extensively adopted during the past year.

In this treatment the earth is first excavated from around the pole to a depth of about 18 in., decayed matter thoroughly cleaned off, and where practicable the pole allowed to air-dry for a few days. The section to be treated is then heavily charred by means of a portable kerosene burner, and while the pole is still hot, creosote that has been previously heated to a temperature between 180 deg. to 212 deg. fahr., applied by means of a high-pressure spray until the temperature of the pole has been lowered to the temperature of the oil, and all vaporization ceased.

The heat of the charring flame thoroughly sterilizes the timber and destroys any existing decay fungi, bacteria or borers; dries the wood and drives out all moisture; opens up checks and cracks to at least as great an extent as will probably occur in ultimate seasoning; heats the wood to a temperature higher than that of the oil so its subsequent cooling during the spraying process will actually contract the air in the cells and draw in the oil; and changes the thin, hard, outer layer of wood into a porous sponge of charcoal which acts as a reservoir to store up a considerable quantity of free oil that will afterwards gradually soak into the underlying layers of wood.

Telegraphy

The development of long telephone cables of 19 and 16 gage, capable of operating for distances of 1000 mi. and upward, has also led to the development of telegraph systems capable of operating through these cables. Two telegraph systems especially designed for the purpose are in commercial operation over such cables. It is expected that papers describing these systems will be presented to the Institute during the coming year.

In telegraphy there are certain definite relationships between the possible speed of operation over a circuit, the frequency range available for the circuit, the alphabet used, and other factors. Some of the fundamentals of these relations were brought out in a paper read at the February Convention, entitled "Certain Factors Affecting Telegraph Speed."

Submarine Telegraphy

The Western Union Telegraph Company expects to complete the laying during 1924 of a radically new type of ocean cable developed by the Western Electric Company. The cable to be laid will extend from New York to the Azores, there to connect to points on continental Europe. It is being manufactured by the Telegraph Construction and Maintenance Co. of London, England. The manufacture of this cable involves the use of a new material and new processes. In order to have a practical confirmation of the results which laboratory tests and theory indicated should be obtained, the engineers of the two companies made the unprecedented experiment of laying a temporary trial length of 120 miles of this cable in a loop from the island of Bermuda, and carried out comprehensive tests over it.

The essential difference between this cable and cables previously laid lies in the provision of a thin layer of "permalloy" placed in the cable between the copper conductor and the gutta percha insulation. "Permalloy" is a recent development in magnetic materials made by the Western Electric Company, consisting of a nickel-iron alloy with about 80 per cent nickel. At small field strengths its permeability is many times greater than that of any material hitherto known.

The layer of permalloy is obtained by putting the alloy in tape form and wrapping it around the con-

ductor. This increases the self-inductance of the conductor per mile—that is, the cable is "loaded." This reduces the attenuation and distortion of telegraphic signals and permits transmission at higher speeds over the cable. The new cable is no heavier in weight or larger in outside diameter than any of the cables recently laid by the Western Union Company, yet its message capacity, as shown by the recent tests, is expected to be fully three times as high as cable of the old type of similar weight and length.

With cable of this efficiency it may become practicable and economical to make considerable increases in the lengths of sections between terminals, thereby cutting down the number of stations where meassges are repeated with obvious operating advantages.

Radio

The great public interest in radio telephone broadcasting has continued to grow during the year, and such broadcasting is already established as a very important facility in our modern civilization. Much remains to be done, however, in improving the quality of the transmission received, and in overcoming interference. Two papers of interest, particularly in connection with these matters, were presented at the February Convention, one on "High Quality Transmission and Reproduction of Speech and Music," and the other on "The Function and Design of Horns for Loud Speakers."

The rapid development of radio broadcasting left the part of the National Electric Code covering the installation of radio sets and antennas in an unsatisfactory form. This has now been taken care of in the new code adopted at a convention of the National Fire Prevention Association in Atlantic City, and going into effect from December, 1923. Since the total of radio installations is now in the millions, the importance of this work is evidently very great.

In last year's report there were recorded tests of radio telephone transmission from America to England carried out in cooperation by the American Telephone and Telegraph Company and the Radio Corporation of America. Following this work, the British Post Office appointed a committee to consider transoceanic telephony, and this committee has now recommended that the British Post Office install at its new Rubgy radio station a 200-kw. transmitter of a type similar to that which was used by the American engineers in their transmission to Europe. If the committee's recommendations are followed, it will result in a station in England which can talk back to America, thus permitting two-way tests between the two countries.

Tests of transmission from America to Europe have been carried out at practically weekly intervals throughout the year, and this data, together with the data which will be made possible by two-way tests, will determine the practicability of a United States to London transoceanic telephone service. Under favorable weather conditions in winter, it is the expectation that telephone subscribers in the United States and in London can be connected so they can talk together as over ordinary telephone circuits. The difficulty of giving a continuous service, however, can be appreciated from the fact that in spite of the long wave lengths used, the amount of power necessary to give satisfactory speech in London at one time may be as much as 10,000 times as great as that required a few hours earlier.

An outstanding development in radio has been the use of short wave lengths of 100 meters and less for transmitting material for rebroadcasting and for other purposes. Under some conditions these shorter wave lengths appear to travel with less loss and less interference than do the wave lengths ordinarily used in radio broadcasting. Under some conditions, however, the short waves appear to involve rapid fluctuations which are not yet completely analyzed and understood. There is not yet sufficient data available to determine just how great the practical value of these short waves may become.

A paper on "Radio Telephone Signaling—Low Frequency System" read at the February Convention describes important developments which have been made in radio calling systems to permit any one of a considerable number of radio stations to be "rung up" without interference with each other, and with a high degree of reliability.

Many forms of selective circuits are in use, or have been proposed for reducing the effects on radio transmission of static interference. A theoretical discussion of the possibilities and limitations of such circuits will be given at the June Convention in a paper entitled "Selective Circuits and Static Interference."

Telephone, Telegrpah and Radio Terminology

The Bureau of Standards has been carrying on active work on the question of telephone, telegraph and radio terminology, which they believe will lead to much more satisfactory definitions of the terms used in the communication art. One feature of this work is that key terms are first defined, such as "telephone," "telephone station," "telephone line," "central office," etc., and then related and associated terms are defined on the basis of their relationship to the key turns. Illustrative examples of definitions made up along these lines have been prepared, and it is expected that a paper on this whole subject will be available for submission to the Institute during the coming year.

Military Signaling

The potential value of radio signals as an aid to the navigation of aircraft at night and in fogs has long been recognized, but the application has been delayed largely because special receiving equipment of considerable bulk and weight seemed to be necessary in the air where both space and lifting power are limited. The Signal Corps of the Army has sought a solution of the problem which might keep all the special equipment on the ground and has during the past year built an

experimental station which has given most satisfactory results. The system in brief, consists of a radio transmitter at a ground station which is coupled to two crossed loop antennas alternately in such a way that double dashes sent by an automatic transmitter are received with equal strength in one vertical plane only through the station. This plane may be given any direction by adjustment of the special coupling device, or it may be made to rotate continuously at the rate of one complete revolution per minute. The former is desirable for aircraft flying over fixed routes. In this case the pilot simply steers a course which keeps the two received signals of equal intensity. The rotating equi-signal plane is better adopted for military operations of aircraft from their base. In this case, a special timing signal is automatically sent out from a non-directional antenna at the instant the equi-signal plane extends due north, and the double dashes follow that timing signal at 10-sec. intervals. A pilot hearing the timing signal, simply counts the signal pairs heard until he hears a pair of equal intensity. If that equality comes in the seventh pair following the timing signal it is evidence that the line joining his position and the transmitting station makes an angle of 7 × 10 deg. = 70 deg. with the North-South line through that station. The direction of rotation of the equi-signal plane is determined by the direction of rotation of the coupling device and is necessarily made known to pilots in advance. No special equipment of any kind is used in the air, the ordinary radio receiving equipment serving for both communication and position finding.

During the past year, the Army has put into service two radio stations, using water-cooled vacuum tubes of 5 and 10-kw. rating, and delivering 10-kw. to the antenna. The transmitters are remotely controlled from receiving stations where both automatic transmission and recorded reception are employed at speeds up to 75 words per minute. These two stations, as well as several others of lower output, are daily handling practically the whole of the War Department telegraph traffic, as well as traffic for several other government departments.

The Signal Corps of the Army reports that it is also actively developing an a-c. system for submarine cable telegraphy, and a uniform code for all forms of transmission, *i. e.* wire, cable and radio. Certain of these developments will be tried out shortly on the Alaskan cable system, and it is hoped that a paper on these results will be made available for the A. I. E. E.

Carrier Telephone Operation over Power Lines

A number of different systems has been developed for permitting the superposition of a telephone channel on an operating power line by employing carrier current methods. Four papers have been presented to the Institute on this subject during the year, three at the California Convention, entitled "Recent Developments in Carrier-Current Communication," "Carrier-Current Telephony on the High Voltage Transmission Lines of the Great Western Power Company" and "Some Experiences with a 202-Mile Carrier-Current Telephone," and one at the Birmingham Convention entitled "Carrier Telephony on Power Lines."

Supervisory Signaling Systems for Power Circuits

Several supervisory signaling systems for the control and indication of remote power equipment in power distribution systems have appeared during the year. With these systems an operator at a central point may know continuously the condition of operating units at one or more distant stations which may be unattended and may control these units as he may desire.

Audiometers

Instruments for measuring the acuity and quality of hearing have been developed. In these instruments a thermionic tube oscillator is arranged to produce pure tones which may be varied in pitch and intensity throughout the range of auditory sensation. The determination of the amount of tone required for hearing as the pitch is varied over the range, gives data of great importance in studying the condition of the hearing of those who are partially deaf.

Transmission of Pictures over Telephone Lines

A demonstration was recently given to the press of the capabilities of a new system for electrically transmitting pictures over long distance telephone lines developed by the engineers of the Bell Telephone System. The sending apparatus was located in Cleveland, Ohio, and the receiving apparatus in New York City, a long distance telephone line connecting these points.

In this system a photoelectric cell, responding to variations in intensity of a beam of light shining in turn through successive elements of the picture to be transmitted, is employed to modulate an alternating current. This modulated alternating current transmits the picture over the telephone line. At the receiving end this alternating current controls a beam of light by means of a device called a "light valve" so that successive elements of a sensitized film are exposed in accordance with the lights and shades in the original picture. The picture to be transmitted and the sensitized film at the receiving end are mounted upon cylinders, these being rotated in synchronism by means of a low-frequency alternating current which passes over the same telephone circuit which transmits the picture current.

The system was shown to be adaptable to the rendering of commercial service. It is possible to transmit not only photographs suitable for reproduction in a newspaper, but also line drawings, printing, and handwriting.

It is stated that the extent to which the system will be used in conjunction with long distance telephone lines will depend upon the demand which arises for this type of service. The system is also applicable to radio

transmission of pictures when atmospheric conditions are such that steadiness of transmission and freedom from interference can be assured.

The Committee is especially indebted to its following members for their activities in obtaining material for this report: E. H. Colpitts, H. W. Drake, R. D. Parker, F. A. Raymond, Edgar Russel, F. A. Wolff.

O. B. BLACKWELL, *Chairman.*

RESEARCH COMMITTEE

To the Board of Directors:

PART I

Activity in the field of electrical research has been very pronounced and has covered a very wide range during the past year. A number of results of outstanding importance may be recorded, although it does not appear possible to single out any one of them as being preeminent over the others.

In the field of molecular physics and the constitution of matter notable progress has been made, resulting in greater certainty as to the nature of the structure of the atom, particularly with reference to the relations of electron orbits, the quantum theory or radiation, and the functions of the electron structure as determining chemical affinities and reactions. Also from the physical laboratories, we have important new data on gaseous conduction at low pressures, and on the production and behavior of electronic emission in high vacuua. The application of these new data has led to great improvements in the construction of vacuum tubes, particularly in the directions of higher power and greater efficiency.

Special mention should be made of the intensive studies which have been devoted to the field of magnetism. Noteworthy papers have been printed on the relation of the magnetic and mechanical properties of steel. Increased knowledge is available as to alloys having high permeability at low flux densities. An especially noteworthy contribution has been made on the importance of carbon, even in the smallest quantities, on the magnetic properties of the iron-silicon alloys and the exact nature of its influence.

There has been unusual activity in the study of the properties of high-voltage insulation. These studies have taken the form of a continuation of tests under the conditions of practise, as for example, in the study of high-voltage cables, and also of laboratory investigation aiming at a better understanding of the underlying processes. Studies in this field, either completed or under way, cover the following variety of topics: The insulating properties of glass as affected by moisture, the pyro-electric theory of breakdown with special reference to paper insulation, internal ionization and its influence on the life of insulation, dielectric absorption in built-up insulation, the importance and exclusion of moisture in built-up insulation, the transmission and dissipation of heat in insulation and reviews of theories of insulation.

In the high-voltage field a number of observations on 220-kv. lines has resulted in further knowledge of the conditions to be met in this important new field. Unusually high values in voltage in both laboratories and on power lines have been the means for further study with particular reference to the question of line insulation. These studies are resulting in a steady extension of our knowledge and in the improvement in the methods for handling higher values of voltage for transmission.

Numerous other problems have been attacked, among which may be mentioned the study of net works of conductors for transmission and distribution, the performance of storage batteries with special reference to impurities in electrolytes, the standardization and accurate measurement of radio frequencies, and the properties of electrolytic rectifiers.

PART II

The committee has had before it as its principal object a thorough review and digest of the literature under the eight headings of the Problem of Insulation, as published in the JOURNAL of the Institute for June, 1923, and which was a joint report of the Committee on Research of the A. I. E. E., and the Committee on Electrical Insulation of the Division of Engineering, National Research Council. The committee has addressed itself first to the securing of volunteers for carrying out this examination of the literature, and to this end has published appeals at various times in several journals, and has addressed letters to a large number of authorities and workers in the field of insulation, always requesting cooperation and assistance.

While the number of volunteers for the work of the examination of the literature has been disappointingly small, a beginning has nevertheless been made in connection with the principle sections of our report. A chairman of a subcommittee has been appointed in connection with each of the sections, and the assignments are as given in the following list:

I Reviews and Compendia of Work Already Done Subdivided among the following sections:

II Nature of Dielectric Absorption
J. B. Whitehead, Chairman, C. A. Adams, Michel G. Malti, H. H. Race

III Phase Difference in Dielectrics
Delafield DuBois, Chairman, LeRoy Clark

IV Electric Strength
W. A. Del Mar, Chairman, F. W. Peek, Jr., G. B. Shanklin

V Dielectric Constant
T. S. Taylor, Chairman

VI Restivity
H. L. Curtis, Chairman

VII Flashover Voltage
F. W. Peek, Jr., Chairman, R. H. Marvin

VIII Theories
V. Karapetoff, Chairman
B. Whitehead

A standard form for recording the results of the examination of a single paper has been prepared and forwarded to all workers. The use of this form should not only facilitate collection of data and the preparation of individual reports, but it is hoped that it will also assist greatly in the collection and coordination of all the investigations on particular topics.

Reports from the several subchairmen indicate that substantial progress has been made, particularly under headings, II, IV, VI and VII. So far as the actual examination of the literature is concerned, the particular value of this work, will be found in the summaries and conclusions under the special headings, which the committee hopes will include statements as to the present problem under these headings with suggestions for the most profitable line of experimental attack.

The committee held a meeting at the recent Philadelphia Convention of the A. I. E. E. at which nine members were present, and at which the various topics in connection with the program were discussed. Of particular interest was the report of Professor Karapetoff of Cornell University of a grant of money from the Heckscher Foundation for experimental work in the field of insulation, and that this committee had rendered him material assistance in the securing of this grant. The committee endorsed the general outline of the work proposed by Professor Karapetoff.

While it cannot be said that the work of the committee is progressing rapidly, it must be remembered that the character of the work now before it is of such a nature as to require time and sustained effort. Surveys in the field of insulation can only be made by experienced and competent men, and under our present plan we are relying entirely on the voluntary efforts of a comparatively small number. All of them are busy men, and with them the work of the committee must necessarily take a subordinate place. The committee is endeavoring to point out that the examination of this literature is a research work of first importance, and that in each case it will constitute a valuable publication. Nevertheless the present method of procedure undoubtedly means that the progress made will be very slow. Apparently it can only be greatly accelerated by the securing of the full time or perhaps the half time of two or three competent men. Obviously, for this purpose financial support is necessary. The work which the committee has outlined cannot properly be done by graduate students or inexperienced men. The committee, therefore, recommends that the Institute consider the advisability of the raising of a small fund for the purpose mentioned, or possibly in some other way secure the more extended services of men competent in this advanced field.

J. B. WHITEHEAD, *Chairman.*

INSTRUMENTS AND MEASUREMENTS COMMITTEE

To the Board of Directors:

The Instruments and Measurements Committee submits the following report, giving briefly a summary of its activities during the past year:

At the Mid-Winter Convention held at Philadelphia, February 4th to 8th, one session was assigned to the committee. The following papers were presented:

1. *Method of Testing Current Transformers*, by F. B. Silsbee. This paper described eleven methods which might be used and gives the advantages and disadvantages of each, together with results which might be expected.

2. *Recent Developments in Kilovolt-Ampere Metering*, by B. H. Smith and A. R. Rutter.

This paper described two suggested types of commercial kilovolt-ampere meters.

3. *Automatic Transmission of Power Readings*, by B. H. Smith and R. T. Pierce.

This paper described seven methods by which meter and instrument readings may be transmitted to distant points and results which might be expected from each.

4. *Quadrant Electrometer for Measurement of Dielectric Loss*, by D. M. Simons and W. S. Brown.

This paper described a new zero method of using an electrometer for testing cables.

This group of papers was well received and an interesting discussion followed.

Standardization of Electrical Measuring Instruments, by H. B. Brooks.

At the annual convention in June, 1923, as mentioned in our previous report, the first draft of specifications for standardization of instruments was presented. The committee has done nothing since that time, preferring to wait for the results and comments covering this first section before going ahead with additional sections. It is expected, however, that in the near future this committee will again actively take up this work with a view of ultimately developing a complete set of specifications on instruments.

Developments. The principal development during the year is probably the announcement of a commercial type of kilovolt-ampere-hour meter. The Westinghouse Company announces that it will have a commercial type meter available during the Summer of 1924. The Committee also understands that the General Electric Company and the Sangamo Company will have models available in the near future.

The tendency of the art toward the use of small indicating instruments as mentioned in last year's report seems to be continuing and we would expect larger demands for the smaller instruments in the future.

A number of operating companies have installed systems of remote metering and totalizing of power readings. The benefits derived by having at one

central point the readings of all power stations is greatly appreciated by system operators and executives. It is anticipated that considerable progress along these lines will be seen in the immediate future.

Bottom-connected meters in polyphase and direct current types of meters are appearing on the market and finding considerable favor. The General Electric Company has announced a new bottom connected d-c. meter and the Sangamo Company a bottom-connected polyphase meter.

The report of I. B. Smith, summarizing the activities abroad in the instrument field is attached. This gives in a very complete and convenient form the summary of the work being carried on in foreign fields and is presented for the convenience of our members and for the sake of its historical value.

G. A. SAWIN, *Chairman.*

Measuring Instruments and Methods 1923

ABSTRACTS OF FOREIGN ACTIVITIES IN THIS FIELD

Ampere-Hour Meter

Ampere-Hour Meters for Alternating Current: Designed to give a linear relation between current and torque over about 90 per cent of the working range of the meter. Accomplished, by adjusting the length of the iron path, constricting it at various places, by adjusting the difference of phase between the fields and, by taking into account the stray field. Meter begins to register at 2½ per cent of full load.
J. Busch, (*Elekt. Zeits.*, Sept. 7, 1922).

Breakdown Voltage

A "Dielectrimeter" for testing the breakdown voltage of insulating oils. It is described as portable and inexpensive.
Empsom Electrical Engineering Co., Ltd., *Journal of the Institution of Electrical Engineers*, June, 1923.

CO_2 Meter

The Econometer CO_2 Tester: This apparatus is suitable for taking snap tests of flue gases. It consists of a cylinder and graduated piston, the gas is drawn into the cylinder and then passed into the absorbent, and the piston is pushed down until the final pressure is the same as the initial. The percentage of CO_2 is read from the graduated rod.
Engineering, April 27, 1923.

Ranarex CO_2 Recorder: An attempt is made to get over the defects of many of the existing CO_2 recorders, *viz.*, the delicacy of their construction, amount of attention required, and length of time for test. The essential parts of the present device are two small fans, run by a motor, and each run at the same speed. In the chamber adjacent to each fan is a disk with vanes so mounted that it tends to rotate owing to the friction of the air or gas set in motion by the vanes of the driven fan. Its tendency to rotate is proportional to the density of the gas in the chamber, and this fact is taken advantage of to determine the percentage of CO_2. The instrument is adapted for testing motor engine exhaust gases, and it is claimed that it has an accuracy of 1 per cent.
Engineering, April 6, 1923.

Electrical CO_2 Recorder: The general principle of the method, which was developed by G. A. Shakespear, of Birmingham University, is that two identical spirals of platinum wire are enclosed in two separate cells, in a metal block, and that each of the spirals is connected to one arm of a Wheatstone bridge, the other two arms being of manganin. Current flowing through the bridge heats the spirals, and causes them to lose heat to the walls of the cells. If the two cells contain gases of different thermal conductivities, the spirals will cool at different rates, and the difference in temperature will cause a deflection of the galvanometer, the extent of which will depend on the difference in the conductivity of the two gases. The construction is such that equal changes in the temperatures of the two gases affect both sides of the bridge equally, so that if one of the cells contains a pure gas and the other the same gas mixed with some other constituent, the deflection will be a measure of the amount of the second gas present, and the galvanometer can be calibrated to show directly the percentage composition of the mixture. In practise one cell is filled with air saturated with moisture, and the other is exposed to the gas under test. The difference in conductivity in the gases in the two cells therefore depends solely on the percentage of carbon dioxide present.
Electrician, Nov. 10, 1922.

Current and Voltage Transformer

Transformers for Measuring Apparatus: The pressure and current transformers for voltmeters, ammeters, relays, etc., are generally a weak point of a plant, as their degree of security against excess pressures and currents is inferior to that of the generators and power transformers, owing to lack of space. The author points out some remedies for this state of things, which can be summarized as follows: (1) Limitation of the number of such apparatus, (2) Increase of their power, (3) Insertion of ohmic resistances in parallel with current transformers and in series with pressure transformers, (4) Loading the secondary of the pressure transformers, (5) Grouping of several transformers in series, (6) Establishment of different series of transformers in relation to the importance of the plant, and (7) Reducing as much as possible the number of the terminals.
G. Campos, *Elettrotecnica*, May 15, 1923.

Compounded Current Transformers: In an ordinary current transformer, the ratio and the angle of displacement vary with the load on account of the varying permeability. In this article the values of the errors involved are fully discussed mathematically. The compounding effect is obtained by providing an exciting winding, having no mutual inductive action on the main windings in order to bring the iron to a condition corresponding to the maximum permeability for the materials, so that the permeability remains practically constant at all loads.

Two methods employed by the Compagnie pour la Fabrication des Compteurs are described. In the first, there are two closed magnetic circuits side by side. The primary and secondary coils are wound over the two adjacent limbs together, while the exciting winding, consists of two equal coils, one on each of the outer limbs, connected so that the flux due to the exciting winding opposes the main flux in one limb and assists in the other. In this arrangement, the exciting coils must be wound by hand, and in order to keep the number of turns low, it is advisable to use a small auxiliary transformer. To obviate this, the method shown in the Figure is used, in which the exciting winding is wound directly on a separate portion of the iron circuit.
Iliovici, *Elect. Soc. Franc. Bull.*, Feb., 1923.

Current Transformers: A new tube type current transformer is advertised for use with instruments and meters.
Chamberlain & Hookham Co., Ltd., *Electrician*, Oct. 26, 1923.

Current Transformer: Designed to give a large number of ranges with precision accuracy in one piece of apparatus. The instrument has five self-contained primary ranges, and is arranged so that by "looping through" the primary winding, ten additional ranges, from 150 to 1800 amperes, may be obtained. This instrument should be exceptionally valuable as a standard for use with current transformer testing sets. It apparently is somewhat in advance of any American instruments in which three self-contained ranges is the maximum number that has been combined with "loop-through" construction.
Elliott Brothers, London, *Electrician*, Jan. 18, 1924.

Calorimeter

A recording and Integrating Gas Calorimeter: The article is a brief description, with illustrations, of C. V. Boys' calorimeter, described by him at the annual meeting of the Institution of Gas Engineers on June 22. The calorimeter is of the water-flow type, the same water being circulated continuously through the apparatus. The fundamental features of the instrument are: water and gas are doled out positively at the correct respective rates, and the correction for gas volume as affected by temperature, pressure, and humidity, are likewise effected by a positive operation. A number of extremely ingenious features are embodied in the design.

J. S. G. Thomas, *Nature*, Aug. 19, 1922.

Capacity and Phase Angle Measurement

Measurement of Small Capacities by the Resonance-Suspension Method: The possibility by means of cathode tubes of producing oscillations of the greatest stability has enabled processes to be devised for the measurement of very small capacities and changes of capacity. Reference is made to the publications of Pungs and Preuner, Herweg, and Hammer on such processes. Each of the latter, as well as the one now described, depends on the principle that a particular oscillation frequency in an electrical system alters with capacity changes, so that the latter may be determined by means of the former. Section 1 deals with procedure; Section 2 discusses mathematically the measurement of capacities by an increase of normal capacity, and derives a formula thereto; Section 3 gives details for the measurement of small self-inductions by the resonance-suspension method.

W. Glitsch, *Phys. Zeits.*, Dec. 15, 1922.

Condenser Leakage

Measurements of Leakage Conductance: A bridge method for testing imperfect condensers which will be useful in technical practise rather than in the high precision work of the laboratory. After describing briefly the usual method of comparing the capacitance and leakage conductance of a condenser with a standard condenser, the author suggests as preferable the use of the Maxwell bridge. In this the imperfect condenser in one arm is compared with an adjustable inductance and resistance in the opposite arm. The two remaining arms contain fixed non-inductive resistances. The standard condenser with its accompanying troubles is therefore eliminated. The resistance of the variable inductance is compensated by a resistance connected in parallel with the test condenser; balance is obtained by adjustment of the inductance and the variable resistance in series with it. Expressions are deduced for the capacitance, leakage conductance, and loss-angle of the condenser, full account being taken of residual errors. Earth capacity troubles are removed by use of the Wagner earthing device. A discussion of the conditions for sensitive working is given, together with a complete diagram of connections of the network. The paper concludes with a description of several bridge arrangements for the direct measurement of the working capacitance of a cable, and also shows how to adopt the Maxwell bridge to enable the working leakage conductance to be determined.

U. Meyer, *Elekt. Zeits.*, Aug. 16, 1923.

Capacity

Capacity of Fine Wire Coils: For purposes of measuring the resistances of coils possessing great self-induction, the usual processes involving bridge arrangements are inapplicable, and an oscillation method has to be adopted. This not only demands special precautions, but is dependent on the availability of the Thomson formula $t = 2\pi\sqrt{LG}$. The method now described gets over both types of complication, and very full apparatus details with illustrative diagrams are included. The principles of the arrangements employed are as follows: (1) A primary coil is coupled so loose with that to be measured that the oscillation frequency of the latter is not appreciably influenced. (2) By change of frequency of the current, the tension in the primary coil is kept constant and the maximum tension in the other coil evaluated. (3) Different supplementary capacities are employed in conjunction with the unknown. (4) The tension measurement at the primary and secondary coils is found by means of a high ohm valve-voltmeter arrangement using a highly sensitive mirror galvanometer. The frequency measurement is made acoustically. Tables of data are given.

E. Marx and A. Karolus, *Phys. Zeits.*, Feb. 1, 1923.

A Simple Compensation Method for Measuring the Capacity and Leakage of Telephone Cables: Capacity and leakage measurements on telephone cables are generally made by Wien's bridge method with Wagner's auxiliary connection, three measurements being required to make possible the calculation of the working value. The method here described gives the working values by a single measurement. It is a compensation method and offers advantages compared with the bridge methods previously proposed for the same purpose, particularly in point of simplicity and accuracy in the hands of relatively unskilled observers. It is shown analytically and by numerical examples that the present compensation method is not appreciably affected by asymmetry in the supply circuit, hence there is no need to take precautions such as are required by bridge methods, to avoid asymmetry. By a method of screening described in the admittance of the leads can be eliminated from the observed result.

J. Kuhle, *Elekt. Zeits.*, Sept. 28, 1922.

Condenser Loss: A small condenser without losses can be measured with considerable accuracy by the method of oscillations. Another equally accurate method applicable only to perfect condensers has been given by Falckenberg, and it is the object of the author to give a modification of the method to enable imperfect condensers to be measured. In principle two resonance circuits are equally coupled to a source of oscillations, the natural frequency and damping of one circuit being capable of adjustment so that the resonance curves of the two circuits for variations of the source frequency can be made to coincide. The condenser to be measured is then introduced into the adjustable circuit and the natural frequency and damping restored to the previous values by changes in the circuit adjustments. From these changes the capacitance and loss resistance of the condenser can be deduced. The paper concludes with a brief discussion of the means of increasing the sensitivity of the method and claims an accuracy of the order of 10^{-5}.

S. Benner, *Zeits, f. Physik.*, 100-102, 1923.

Cable Capacity and Leakage: In a two-core cable with earthed lead sheath, if c_1, c_2 and c_{12} are respectively the earth capacities of the two cores and the Intercapacity between them, the working capacity between the cores is given by $c = c_{12} + (c_1 c_2)/(c_1 + c_2)$, a similar relation holding between the corresponding leakage conductances. The author points out that c cannot be measured in a simple Wein bridge without considerable error, unless the sheath can be maintained at earth potential. Wagner has ensured this by the application of his well-known earth connection to the detector branch-points; three measurements and a calculation then serve to determine c. To reduce the work several ways have been suggested to enable c to be found by a single measurement. By a consideration of the pressure drops in the arms of a Wein bridge, the author devises a new test connection, consisting of a double bridge arrangement, which enables the sheath to be held at zero potential, whether the earth capacities of the two cores be equal or not. Tabulated results of measurements made by various methods are given for purposes of comparison.

E. Wellmann, *Elekt. Zeits.*, May 17, 1923.

Cable Capacity and Leakage: A simple compensation method is described for measuring the capacity and phase angle of condensers and cables. A comprehensive description requires

diagrams. The method has been tested out and is stated to give accurate results.
W. Geyger, *Archiv. f. Elektrot.*, June 30, 1923.

Condensers

New Electric Condenser: The new condenser consists of plates or ribbons of a special quality of celluloid, called cellon, upon both sides of which silver armatures are deposited by a chemical process. The cellon employed can stand 40,000 volts per mm. and has a specific inductive capacity of 4. The dielectric losses are very low, of the order of 1 per cent at 50 cycles. The losses at the edges are reduced to a very low value by surrounding the armature edges by an extremely thin, high resistant, border of silver. In the case of a battery for power-factor improvement, the edge losses are reduced to 0.1 or 0.2 per cent of the apparent power.

The condenser takes the form of a porcelain cylinder closed by metallic caps, so that a number of cylinders can be connected in series by simply superimposing them. Applications of the new condenser are considered. The claim is made that when it is used as a "passing-through" insulator for high pressures, it allows a very efficient and reliable apparatus to be obtained. It is also remarked that, owing to the perfect adherence of the armatures to the dielectric, very silent working is obtained by the use of this condenser in radiotelephony.
E. Pfiffner, *Eletrot.*, Oct. 15, 1922.

Dielectric Loss

Losses in Insulating Materials: A Wattmeter method of measuring dielectric loss at high voltage in which errors due to brush discharge, phase displacement in the wattmeter, etc., can be easily corrected.

The current coils of the wattmeter are earthed and carry the test current. The voltage coils are connected to the low tension side of the transformer in series with a high resistance and an inductance also one winding of a variometer. A specially designed adjustable air condenser of 4×10^2 microfarads capacity is included in the circuit. The phase error of the transformer is compensated when the wattmeter reads zero by adjusting the inductance.

The variometer compensates for the change of mutual inductance in the wattmeter. The special iron core wattmeter has exceptionally high sensitivity.

The paper concludes with an interesting series of characteristic curves for micarta and other insulating tubes showing the losses as related to temperature, time and voltage.
S. Rump, *Brown Boveri Rev.*, Aug., 1923.

Electrometer

String Electrometer: A platinum string of 2 μ thickness is used under variable tension. The electrodes are movable and with different tensions on the string, the range of the instrument is 0.001—1000 volts. There is a nearly linear relation between the voltage and displacement of the string.
C. W. Lutz, *Physik. Zeits.*, April 15, 1923.

Fluid Velocity

Stream Velocity: The relatively low velocities of the cooling media in electrical machines and apparatus may be measured conveniently by a method based on variations in the coefficient of cooling devices exposed to the stream in question. The heat W lost from any body to a stream flowing with velocity v increases rapidly with v, when the latter is small. The value of $d\,W/d\,v$ decreases as v increases, because the particles of the cooling medium have less time in which to pick up heat by conduction. It is most important to know the exact velocity of cooling medium when this velocity is low, and its value is best determined by a method subject to the same laws as the cooling of the machine. The actual temperature of the cooling medium being T_o, the time taken for a thermometer bulb to cool from T_1 to T_2 (both higher than T_o) is a measure of the stream velocity, and the latter can be read directly from an empirical calibration curve. In air at 5 m./sec. a certain thermometer bulb cooled from 80 deg. excess temperature ($T_1 - T_o$) to 30 deg. excess temperature in 25 sec. and this, or a lower velocity could be determined with a high degree of accuracy. In liquids, the rate of cooling is more rapid, but good results can be obtained within the excess temperature range 15 to 5 deg. by enclosing the thermometer in a copper shell with a rubber sheath, to increase its heat capacity and retard the cooling. An electrical method uses a spherical coil of insulated copper wire which is maintained at a constant temperature, say 116 deg. cent., by varying the current through it until balance is obtained in a bridge circuit, the other three resistances of which are constant. The watts required to maintain the coil at constant temperature can be plotted against the velocity of flow of the cooling medium. Typical calibration curves for both the mercury therometer and the electrical methods of measurement are given in the original.
F. Müllner, *Elek. u. Maschinenbau*, April 8, 1923.

Velocity of Flow in Pipes: An electrical effect which can be utilized is the sudden change which occurs in the electrical properties of a fluid when a charge of salt is inserted. A method of measuring consists of noting the time required for such a charge to pass through a measured length of pipe, and determining the time of its arrival at the discharge end or some other point by the jump of the needle of a sensitive voltmeter connected to two electrodes placed in the discharge. Thin sheets of zinc and copper about 6 in. long, about ¼ in. apart, insulated from each other and from the pipe end, were used for poles, and connected to the terminals of a sensitive voltmeter. During ordinary discharge the needle indicated a difference of potential between the poles of about 0.2 volt, but when the salt solution arrived it jumped to about 0.5 volts, dropping again to 0.2 volt as the salt passed. The accuracy of this method was found by comparison to check very closely with the potassium permanganate measurements which were carried on simultaneously.
I. E. Houk, *Engineering*, May 25, 1923.

Fluid Velocity Meter

Velocity of Water: This paper describes experiments made to test the usefulness of a method of measuring water currents at low velocities based on the fact that the resistance to the passage of an electric current between two electrodes immersed in water depends on the velocity of motion of the water. The experiments were made with tubular electrodes and with rods of brass, copper and iron arranged 2 to 10 ft. apart in pipes from 4 in. to 10 in. in diameter. Tests on the various pairs of electrodes showed that the resistance, when measured by an alternating current was independent of the motion of the water in the pipe. It therefore appeared that the changes observed when a direct current is used must be done to the removal or liberation of the products of electrolysis by the moving water. With a voltage below 1.5 volts the instability of the conditions was such that no reproducible results could be obtained. A battery of 4 or 5 cells giving an e. m. f. of 3 or 3.75 volts across the electrodes was therefore used, but even then it was exceedingly difficult to obtain a repetition of any measurement. It is suggested that the phenomena must be of an electrolytic nature depending on the effects of over-voltage and transfer-resistance at the electrode surface. Curves are given showing the results obtained by Cleverdon and by the author.
M. A. Hogan, *Engineering*, Jan. 19, 1923.

Galvanometers

Instability of Differential Galvanometer: In the course of certain experiments in which a differential galvanometer was employed, the author remarked that when the current in the coils exceeded a certain value the equilibrium of the needle became unstable. As a matter of fact if the currents in the two coils were established when the needle was slightly deflected towards the right, the needle was further deflected towards the right; and if it was slightly deflected towards the left, it went

further towards the left. The author studies this phenomenon analytically and compares it to that shown by a balance which, when the load exceeds a certain value, becomes unstable, because its center of gravity is higher than the center of oscillation. In any case, the phenomenon is rendered possible by the coils not being perfectly coaxial.
A. Sellerio, *Elettrotecnica*, Dec. 5, 1922.

Galvanometer for Zero Reading: The telephone is generally more convenient than contrivances giving visible readings; but with thermionic valves to rectify the alternating currents the sensibility and the precision may be made much greater than with the telephone, while the rapidity of measurement is at least equal. This is due to the amplifying effect of the thermionic valve. But a thermionic valve has a high resistance, and requires a high-resistance galvanometer. Much smaller resistances may be used if the thermionic valve be replaced by a crystal-detector, as used in radio-telegraphy; the best is a crystal of argentiferous galena, against which a copper point is pressed by an adjustable spring.
L. Mazza, *Accad. Lincei*, Atti, Dec. 5—Dec. 17, 1922.

Ballistic Galvanometer: Conditions for sensibility of ballistic galvanometers in closed circuits with damping.
A. J. Staring, *Arch. des. Sciences*, Sept.-Oct., 1922.

Einthoven String Galvanometer: The discussion of the theory of the string galvanometer has been in general of too mathematical a character and has not considered many of the cases commonly occurring in practise. The author in this paper gives a short and simple presentation of the theory, taking account of some practical cases which are specially important.
A. Pochettino, *Accad. Sci. Torino*, Atti, 1921-1922.

A New Galvanometer: This galvanometer has resulted from the demand for a very sensitive instrument occasioned by a previous discovery of a new type of thermo-element specially suitable for ultra-red radiation. The principle involved is the pendulum-like oscillation of a thin metallic frame in a magnetic field. The metal is almost non-magnetic and the magnetic field is produced by weak permanent magnets capable of such arrangements as are convenient for producing the required sensitiveness. The paper gives a very complete description of the instrument with five illustrative figures. All galvanometer requirements are claimed to be fulfilled by this instrument.
R. Mechau, *Physik. Zeits.*, June 1, 1923.

Improved Mirror Galvanometer: For bringing about a refinement of the mirror reading, a Fresnel double mirror is used instead of the ordinary galvanometer mirror and the interference fringes read by means of a micrometer. The utility of the instrument is thereby improved enormously. The paper contains a detailed description of the modified instrument and its working.
W. Mobius, *Phys. Zeits.*, May 15, 1923.

Ballistic Galvanometer Sensitivity: In connection with certain magnetic researches the author has been led to investigate the means available for increasing to the optimum the sensitivity of a moving coil ballistic galvanometer working on closed circuit. Diesselhorst has studied the performance of the instrument, assuming all its dimensions to be given, and has worked out the field strength which must be provided by its magnet to give the greatest sensitiveness. The author in the present article investigates, by a slightly simplified analytical solution of the differential equation, the independent effects of the various quantities (dimensions of moving coil, control torque, field strength, constants of the closed circuit, etc.) entering into the equations upon the optimum sensitivity. Details of design procedure to provide optimum sensitivity under stated experimental conditions are given. The paper concludes with the description of an instrument in which the moving coil system can be easily replaced by one suitable for the work in hand. Since the optimum sensitivity depends on the nature of the closed circuit, some means of adjusting the sensitiveness of the galvanometer to suit a circuit of given resistance must be provided. In the author's instrument an electro-magnet is used for this purpose. In common with the observations of other workers it was found that, with the strong fields provided by the electromagnet (1200 gauss), the paramagnetic impurities in the moving coil produced a marked increase in control and a loss of sensitiveness; this effect was overcome by the addition of small pieces of diamagnetic bismuth to the moving system.
A. J. Staring, *Arch. des. Sciences*, Mar.-April, 1923.

Moving Coil Galvanometer: This is a description of a moving-coil instrument with pointer made by the Siegfr. Guggenheimer A.-G. The field is variable by means of a magnetic shunt. Aluminum wire is used for the coil, of which the weight is 0.48 grams. The instrument is for use as a thermoelectric pyrometer with thermocouples.
Gorgas., *Zeits. Elektrochem.*, Sept. 1, 1922.

Loop Galvanometer: It is called a "loop galvanometer" because it has a single loop of wire which hangs in the magnetic field and acts as the moving part. It is air damped and nearly dead beat. The motion of the loop is observed through a microscope, which makes a very compact and portable outfit. The sensitivity is between 3×10^{-7} and 7.5×10^{-9} amp. according to the magnification used in the microscope. It has a resistance of 6-10 ohms.
Robert Mechan, *Physik. Zeits.*, 24-1923.

New Galvanometer: A very interesting instrument, using the thermal-conductivity method devised by Dr. Shakespeare. This instrument is called an "Electrical Micrometer," and is designed to magnify very small deflections of indicating instruments. The magnification is produced by causing the pointer of the instrument which gives but a small deflection to stretch one heated spiral and at the same time to compress another heated spiral in the opposite arm of the Wheatstone bridge. Apparently the elongation and contraction of the heated spirals causes a difference in the thermal emission, and thereby changes the temperature of the spirals. This unbalances the Wheatstone bridge to an extent enabling the detector in the bridge circuit to magnify the initial motion by a factor of approximately 1000.
Cambridge & Paul Company, *Electrician*, Jan. 11, 1924.

Gap Voltmeter

Sphere-Gap Voltmeter: A simple form of sphere-gap voltmeter is described equipped with screw adjustment and vernier. The screw adjustment can be thrown out of action so that the platform carrying one of the spheres can be moved back quickly, leaving the vernier to be read at leisure. The spheres are 3 inches in diameter and a table of voltages for various spark-gaps is given for this particular size of sphere.
E. A. Owen, *Rontgen Soc. J.*, Oct., 1922.

Instrument Design

The Mechanical Design of Scientific Instruments: The scientific instruments here considered are mechanical. The author deals successively with the questions of definite position, turning pair, frictional aberration, the screw pair, backlash friction and variance, accuracy and sensitivity.
A. F. C. Pollard, *Roy. Soc. Arts J.*, Sept. 29, Oct. 6, 13, 1922.
Also *Engineering*, June 9, 16, 23 and 30, 1922.

Magnets

Magnet Steel: This article gives further particulars about the new type of steel, which has been found by the Reichsanstalt to give better results when used for magnets. Weiss and Preuss discovered that an improvement was made by adding cobalt to alloys of iron and manganese: the author shows that an improvement results from a further addition of chromium. The article contains the results of tests on various alloys, hardened at different temperatures.
E. Gumlich, *Zeits. f. Physik.*, 241-252, 1923.

Friction of Pivotal Movements: A description of researches

made with very small pivots (0.9 mm. diameter) working between jewels, such as used in watch-making. Taking the case where the spindle is horizontal, it was found, after studying the influence of speed of rotation, that the results presented the same general character as those of Stribeck (working on spindles several cm. in diameter), who interprets the hydrodynamic theory of Sommerfeld. The coefficient of friction diminishes rapidly at first as the speed increases, passes a known minimum, then immediately increases indefinitely. The viscosity of the lubricant plays a most important part. The results are represented empirically by the equation:

$$f = f_o\ e^{-\lambda\omega} + A\ \omega$$

where f is the coefficient of friction, ω the angular velocity, and f_o, λ, and A constants depending on the bodies in contact.

A. Jaquerod, L. Defossez and H. Mugeli. *Arch des. Sciences*, July-Aug., 1923.

Totalizing Meters

Wattmeter: It is often necessary to sum up in a central position the energy or the currents supplied to, or received from, different parts of a main. This problem presents itself, for instance, if the energy is furnished to an electric railway at different points from the same power station. The author has solved this problem by suppressing the spring of, say, the different wattmeters installed at the feeding-points and mechanically connecting their moving coils with the moving coils of suitable ammeters. For each value of the energy indicated by each wattmeter a given current will be required in the ammeter coil to hold the apparatus in equilibrium. An arm connected to each apparatus can establish a current through a small electric motor, in one sense or the other, so as to increase or diminish the value of a variable resistance and, consequently, the current through the ammeter, and to bring again the apparatus into equilibrium. The currents from the different wattmeters are sent in parallel to the central position through the general ammeter, which can indicate total watts, or through a meter, etc.

Two wires, or a single wire and earth return, are required for connections; these wires can be of small section and even of iron. The same system can be used for the summation of intensity, etc.

G. Campos, *Elettrotecnica*, Oct. 5, 1922.

Megger

Constant Pressure Meg: The "Meg" is a small size megger, and apparently the addition of the constant pressure feature is something new.

Evershed & Vignoles Ltd., *J. Inst. of Elec. Eng.*, Jan., 1924.

Ohmmeter: An insulation testing ohmmeter, similar to the megger type of instrument and somewhat reduced in size.

Record Electrical Co., *Electrician*, Jan. 18, 1924.

Magnetic Measurements

Magnetomotive Force Meter: This instrument, devised by Rogowski and Steinhaus, 1912, consists of a thin, flat, flexible strip of wood fiber or celluloid wound, with the utmost attainable uniformity, with fine insulated wire. The author shows how it may be employed in determining with great accuracy the number of windings in a coil, and if this be known, the number of short-circuited windings, if any. He also shows how its use may sometimes simplify phase-angle measurements.

V. Engelhardt, *Archiv. f. Elektrot.*, Aug. 20, 1922.

Magnetic Flux: It is known that if an electric current flows through a fluid, which is at the same time in a magnetic field perpendicular to the current, the liquid is subjected to a force at right angles both to the current and to the field. The author has imagined a permeameter and a fluxmeter based upon this phenomenon. Both apparatus are essentially formed of a German silver cylindrical helix comprised between two coaxial cylinders of insulating material, the helicoidal space between the turns being filled with mercury. Two metallic disks form the basis of the cylinders, which are disposed horizontally. Two vertical glass tubes filled with colored alcohol form the natural continuation of the mercury helix. The current flows parallel to the axis of the cylinders, alternatively through the German silver and the mercury. The magnet, the flux of which should be measured, is introduced inside the cylinders. The force acting on the mercury produces a difference in the levels of the two alcohol columns. The sensitiveness obtained was 20 Maxwells per mm. of level difference of the alcohol columns, when the apparatus carried a current of 10 amps. per sq. cm.

Hysteresis Measurement

Magnetic Hysteresis: Many investigations have been carried out on rotary magnetic hysteresis, yet the recent results show great discrepancies. This inconsistency is thought to be due chiefly to the systematic errors of various methods of measurement. Taking the irregularity of the electromagnetic field brought into existence by the unsymmetrical forms of test pieces and Joule's effect as the chief disturbing factors, the author describes a comparatively accurate method of measuring the torque of a solid spherical test piece in a rotary magnetic field and the correction of Joule's effect.

T. Miyazaki, *Inst. El. Eng.*, Japan, Nov., 1922.

A Simple Method for Determining Hysteresis Loss; with Notes on Relations between Magnetic Constants: The author has investigated and improved upon a formula originated by Anderson and Lance for the calculation of hysteresis loss from the maximum induction and the corresponding coercive force. As given by Anderson and Lance, the formula is: $W_h = a\,B_m\,H_c$; where W_h = hysteresis loss in ergs/cm.^{3}; B_m = maximum induction; H_c = coercive force; and $a = 0.2133 + 0.01082 \times 10^{-3}\,B_m$. In this form, the expression for W_h is not applicable to high values of induction because when saturation is approached W_h and H_c become constant, but B_m and a continue to increase. Also, due to differences between materials, the hysteresis loop broadens to a greater or less extent in the neighborhood of the knee and the value of W_h may vary widely though H_c and B_m be the same.

The author's tests on dynamo core plates show that a does not vary linearly with B_m, but rather according to the equation: $a = 0.225 + 0.000889 \times 10^{-3}\,B_m + 0.000861 \times 10^{-6}.\ B_m^2$. Values for the coefficient a up to $B_m = 18{,}000$ are given in the original. The improved formula is sufficiently accurate for purposes of approximate estimates. No single formula can be applicable to both hard and soft material.

The following relations, determined experimentally, are used in the Reichsanstalt. For normal magnetization curves of uniform material, the remanence of which lies between 5000 and 12,000: μ max. $= k\,B_r/H_c$ very nearly; where μ max. = maximum permeability; B_r = remanence corresponding to a high magnetization; H_c = corresponding coercive force; and $k = 0.476 + 0.00568\,H_c$. For the smaller values of H_c, it is permissible to take $K = 0.5$. The field strength corresponding to maximum permeability is approximately 1.3 H_c. From these expressions it follows that the induction $B\ \mu_{max}$. corresponding to maximum permeability is given by: $B\ \mu_{max} = 1.3\ (0.476 + 0.0057\ H_c)\ B_r$; and can be determined without plotting the actual permeability curve. For soft materials it may be taken that $B\ \mu_{max} = 0.62\ B_r$ but for cast iron and hard steel, the complete formula must be used. Comparisons between calculated and observed values for $B\ \mu_{max}$ show that the formula gives results accurate within $\pm$ 5 per cent (often considerably closer).

E. Gumlich, *Elekt. Zeits.*, Jan. 25, 1923.

Meter Testing

Portable Testing Equipment: A full description is given of the construction and use of a portable testing equipment used by the Lech Electricity Works, Augsburg, for calibrating high-tension meters. The equipment includes a standard three-phase meter for unbalanced loads, a precision, dynamometer-type, three-phase wattmeter, a voltmeter, ammeter and rotary field indicator, and

sets of precision current and pressure transformers. By alternately short-circuiting the coils of the three-phase watt-meter, two readings are obtained from which the power factor of the load can be calculated, provided that the load is nearly balanced. The connections of the test circuits are shown in the original and data are given from a typical test.
D. Freyer, *Elekt. Zeits.*, Feb. 8, 1923.

Oscillograph

Braun Tube: This paper gives details of a graphical method of obtaining Cartesian curves from the figures obtained with a Braun tube whose field plates are shunted across an inductance and resistance in series in an alternating-current circuit, the magnetic field coils being in series with the inductance and resistance. A numerical example is given for the case of a 500-cycle alternator.
G. Joos and E. Mauz, *Jahrb. d. drahtl. Tele.*, April, 1922.

Braun Tube: A description is given of a high-voltage cathode-ray oscillograph which is employed in the study of a-c. wave-forms of all frequencies up to 10^7 cycles per sec. The oscillograph is essentially a development of the Braun tube, but is adapted for photographic recordings as well as for visual observation. Methods of generating a true axis on the records are described. In the case of very low frequencies a mechanical method of translating the film is sufficient, but at higher frequencies the inertia factor becomes too serious, and it becomes necessary to resort to electrostatic and electromagnetic means of deflecting the pencil of cathode rays rapidly across the film. Excellent reproductions of records are made at all frequencies up to 220,000,000 per second. The oscillograph has obvious applications to high-frequency research as in wireless telegraphy, where the ordinary forms of oscillograph are quite useless.
A. Dufour, *Onde Elec.*, Nov., Dec., 1922 and Jan., 1923.

The Cathode Ray Oscillograph: The paper deals with a new form of cathode-ray oscillograph adapted for commercial production and laboratory use. The instrument described is of the low-voltage type, in which a hot cathode is employed as a source of the electron current. This low-voltage type of oscillograph is much more sensitive than the high-voltage cold cathode type designed by M. Dufour. Various methods are described for focusing the cathode-ray stream, and a proposal has been made for an oscillograph with external (*i. e.*, outside the vacuum) photgraphic film. Experiments have been made to determine the most suitable photographic film or plate. Ordinary gelatine coated roll films or plates are unsuitable, owing to the marked absorption of the cathode-rays by the gelatine. The best results have been obtained with Schumann plates containing a proportion of calcium tungstate. This material phosphoresence with a light rich in ultra-violet, and consequently the secondary luminous effect on the Schumann plate is very great.

Mechanical, electrostatic and electromagnetic methods are described for generating a time-axis on the records. For certain purposes this time-axis is sinusoidal, whilst for others it is linear. Numerous records of high-frequency A. C. wave forms and of impulsive electrical phenomena have been obtained, and a few of these are reproduced in the Paper. Brief reference is made in conclusion to the applications of the oscillograph to research and electrical engineering problems, where other well-known forms of oscillographs (Duddell, Einthoven, etc., types) cannot be employed on account of the inertia of the moving element.
A. B. Wood, *Physical Soc. of London*, Feb. 15, 1923.

Oscilloscope

Oscilloscope: This instrument, called an "Ondoscope" by the author, is an oscilloscope so mounted that it can be rotated about an axis parallel to the tube and thus used for obtaining the "current-time" curve of a high-tension discharge apparatus; and, if the applied voltage exceeds the ionizing voltage of the oscilloscope tube, is suitable for any alternating or fluctuating current. It can be used on circuits from 200 volts up to 250,000 volts or more, and will give the current wave-form when the current has a maximum value between 2 milliamperes and 50 or more.
F. L. Hopwood, *Rontgen Soc. J.*, Jan., 1923.

Peak Voltmeter

Peak Voltmeter: The method described consists essentially of introducing a fraction of the high potential to be measured into the anode circuit of a triod valve and varying the grid potential till the anode current vanishes. A known anode potential serves to calibrate the arrangement. The fraction of the high potential is obtained from a static potentiometer consisting of four equal and parallel plates arranged with their centres in line. The high potential is applied to the two outer plates and the fractional potential obtained from the two inner ones.
A. Hund, *Jahrb. d. drahtl. Tele.*, May, 1923.

Potentiometer

A-C. Potentiometer: This paper describes an a-c. potentiometer which measures two rectangular components of the voltage under test. The instrument contains two elements; one, called the "in-phase" potentiometer, is supplied with alternating current through a sensitive reflecting dynamometer, the readings of which can be standardized by means of direct-current and a standard cell. The second, or "quadrature" potentiometer is supplied with current in quadrature with the preceding; this element contains the primary of a mutual inductance, the secondary of which can be connected to the potential tappings of the first potentiometer through a vibration galvanometer. The mutual inductance is of such a value that, with the "in phase" potentiometer tappings at a chosen reading, balance can be secured by adjustment of the rheostat in the circuit of the "quadrature" potentiometer; the latter is thus indirectly checked against the dynamometer. With both elements standardized in this way a given voltage can be measured by connecting it to the instrument through a vibration galvanometer, the potential tappings of the two elements being joined in series therewith. By operation of the two elements and of phase-reversing switches, if necessary, balance can be secured between the unknown voltage and the sum of its two quadrature components tapped off the instrument.
D. C. Gall, *Electrician*, April 6, 1923.

Thermocouple Potentiometer: A thermocouple potentiometer expecially designed for measuring the electromotive force of thermocouples.
Siemens Brothers & Elliott Ltd., *J. Inst. Elec. Eng.*, Aug., 1923.

Precision Potentiometer: Five dials with a total resistance of 11,000 ohms are employed. Using a current of 0.1 milliampere, the range is 1.1 volts which can be read to 10^{-5} volt, with a current of 1 milliampere the range is 11 volts which can be read to 10^{-4} volt. Using a voltage divider or multiplier, the measuring range can be raised to 110 or 1100 volts when using a current of 0.1 milliampere in the potentiometer. With the corresponding shunt resistance the range can be decreased to 0.11 or 0.11 volts. Three of the dials have double brushes which make contact so that the two resistance coils between every second block of the dial are in parallel with the entire resistance in the next lower dial. In this way each position on the lower dial represents 1/10 the voltage of that obtained on the higher dial.
Zeit. f. Instrument, 43, 288, 1923.

Power Factor

Electrometer Method: The paper proposes null methods of using a quadrant electrometer to enable measurements of power factor and effective resistance in a-c. circuits to be made. Such measurements have hitherto been almost exclusively made by deflectional use of the electrometer; it is then necessary to calibrate the instrument and to take account of the influence of electric control on the needle. If the voltages on needle and quadrants are arranged so that the deflection is reduced to zero, the instrument need not be calibrated, and the electric control has no effect. Such a null use of the electrometer possesses marked advantages due to simplification of theory, to the fact that steadi-

ness of voltage is not so essential as in deflectional use, and to the usual general merits of null methods.

Two methods of connection of the instrument to attain the desired object are described. The theory is worked out and practical tests are recorded. It is also shown how the methods can be adapted for use at high voltages. The theory of the electrometer is worked out with a view to investigations of the effect of electric control and to emphasize the advantages of the null use of the instrument. In the discussion, various speakers brought out practical points arising in the use of the methods. E. H. Rayner drew attention to important details in the design of electrometers. A. Rosen pointed out the need for great constancy of frequency in tests of condenser power factor.

D. Owen, *Phys. Soc. Proc.*, April, 1923.

Phase Meter: The purpose of this paper is to describe the action of several instruments made by Hartmann & Braun for power factor and allied measurements. The well-known phase meter for use in a single-phase circuit is first described, in which a uniform rotating field is produced by stationary coils displaced by 90 deg. in space and carrying currents in quadrature. Freely pivoted in this field is a coil supplied with current from a current transformer connected in one of the lines, this moving coil setting itself in such a direction that its angular displacement from an initial line is equal to the phase-angle of the circuit. In the form described in the paper the rotary field is produced by an ironclad stator producing two component fields displaced 120 deg. in space and 60 deg. in time, the windings being excited from the mains, one having a resistance and the other a choker in series. The moving coil is fed from the secondary of a current transformer. The influence of the distortion of the rotary field, arising from changes in the angle of phase displacement between the component fields and from the effects of the iron magnetic circuit, upon the scale of such instruments is discussed. By provision of a suitable elliptic field a scale about 65 deg. long covering a range of power factor from 0.4 — 1 — 0.4 can be produced, a recording phase meter embodying this feature is described.

A phase meter for polyphase networks is described in which current is led into the moving coil from a special transformer, the secondary of which is pivoted coaxially with and rotates together with the moving coil, thus eliminating any need for leading in ligaments to the moving system; a scale covering 360 deg. is thus secured, since the coil can make a complete revolution, and thereby indicate a change of phase rotation or a phase reversal. The application of the principles embodied in these instruments to power-factor meters for unbalanced loads, is given. Instruments for the measurement of idle power ($E\,I \sin \phi$), wattless current ($I \sin \phi$), and for the indication of phase equality in the paralleling of alternators are described.

F. Voller, *Elekt. Zeits.*, April 5, 1923.

Pyrometer

Optical Pyrometer: Employing an incandescent lamp the filament of which is placed in front of an opening in the furnace, is described, with the methods of obtaining a balance in the portions of the field of view illuminated by the lamp and by the furnace. Experiments to determine the effect of the distance between the pyrometer and the furnace are described, and it is shown that this distance can be increased to 2 or even 3 meters without loss of accuracy. The effect of dust and smoke in the air between the furnace and the pyrometer is considered, and experiments described on the effects produced by water-vapor and CO_2 in this space. There is very little physiological effect as between different observers.

U. Retzow, *Zeits. Vereines deutsch. Ing.*, Feb. 24, 1923.

Resistance Measurements

Contact Plugs: When using the Thomson bridge to measure small resistances in machines, cables, or other cumbersome equipment, the source of current and the bridge with comparison resistance and galvanometer are mounted on the test bench, and four leads are run to the unknown resistance, two for the main circuit and two for the bridge. If circumstances do not permit these leads to be connected in a permanent manner, the connections may be broken; or made in incorrect sequence, so that the galvanometer is subjected to a dangerously heavy current. This risk is eliminated by the special keys described. A copper pin 2 mm. in diameter is surrounded by, but insulated from, a brass tube of 4 mm. internal diameter and 1 mm. thickness. A spiral spring presses the tube forwards so that it makes contact first when the plug is applied to the terminal of the unknown resistance. As the plug is pressed down, the brass tube recedes and thus allows the terminal to come into contact with the end of the internal pin. In one of the plugs, the internal pin is itself spring-supported and provided with an insulated head which, when the plug is pressed to its full extent, closes a key in the galvanometer circuit. The connections are such that when the first plug is applied the main circuit (connected to the pin) cannot be closed until the bridge lead (connected to the outer tube) has been connected. The second plug makes the bridge circuit, main circuit, and galvanometer connections in the order stated. Disconnections are automatically made in the reverse sequence. The voltage drop at the main circuit connections does not enter into the measurement when these keys are used. The resistance of the plugs and their bridge leads is generally negligible. It has been found that, however carelessly the plugs are used and whatever the form of the surface to which they are applied, the connections are made and broken in the correct sequence.

H. Schering, *Elekt. Zeits.*, Jan. 4, 1923.

Non-Inductive Resistance Coils: The authors consider the theory and design of a double-wound non-reactive resistance coil, and give an example of a 100,000-ohm coil, having a phase angle less than 5 deg. at a frequency of 5000.

H. Nukiyama and Y. Shoji, *Inst. El. Eng.* Japan, J., Aug., 1922.

Manganin: The resistivity and temperature coefficient of copper-manganese alloys, and the effects of other elements, such as nickel, iron, aluminum, and silicon, are investigated. The authors find that a straight copper-manganese alloy gives the best manganin, and that there is no need to add other elements to improve the resistivity and temperature coefficient. The alloy containing 13 per cent manganese has a specific resistance of 45 michrons per centimeter cube, the temperature coefficient at 22.5 deg. cent. being 0.00000348.

S. Kimura and K. Sakamaki, *Elekt. Lab.*, Tokyo, Sept., 1922.

Effective Resistance: The Wien bridge method of measuring the effective resistance of an inductance coil requires a knowledge of the losses in the condenser. The author describes a method which allows the losses of the inductance coil and condenser to be separated by making use of two different forms of bridge. The inductance and capacity are first joined in series in one arm of a bridge, the other three arms of which are non-reactive resistances, one of the adjacent arms being adjustable. Either the capacity or frequency must be finely adjustable. A balance having been obtained on this bridge, another bridge is formed in which the inductance coil and condenser, unchanged in values, become the opposite arms, the other two arms being non-reactive resistances, of which one must be adjustable. The results are obtained in the form $R_L = 1/2\,(R' + R'')$ and $R_c = \frac{1}{2}\,(R' - R'')$, in which R_L is the effective resistance of the inductance, R_c is the effective resistance of the condenser, R' is the apparent resistance of the inductance in the first bridge, and R'' that in the second bridge.

H. V. Higgitt, *Electrician*, Feb. 2, 1923.

Recording Instruments

"C. G. S." Relay Graphers: This paper describes recording instruments working on the relay principle which embody some original features. The instruments are made by the officine Mechanische Italiane. They employ a relay motor, controlled by the movement of the measuring system, to operate the record-

ing gear and at the same time to restore the moving system to its equilibrium position. In the "C. G. S." recording wattmeter the moving system consists of two coils, one mounted on each of two arms projecting from a pivoted spindle; each moving coil lies within a fixed current coil. The two current coils and two potential coils are connected to a three-phase circuit according to the well-known two-wattmeter method of measuring power. Electrodynamic action between the fixed and the moving coils deflects the latter through a small angle and causes an arm carried by the spindle to make contact with one or other of two pins, thereby making the circuit of a small relay motor. The spindle carries at its lower end a flat spiral spring, the relay motor being geared thereto in such a way that a torque is put on the spindle to oppose the deflecting torque and thereby to restore the moving system to its mid-position. At the same time the motor traverses a recording pen over the chart mounted on a clock-driven drum.

This principle is also applied to a recording phase-meter, this instrument being a recording wattmeter with the restoring spring removed. The moving system is now energized from the rotor of a phase-shifter geared to the relay motor, the stator of the phase-shifter being fed from the three-phase supply. The fixed coils are connected one in each line. The apparatus is arranged so that the relay motor turns the rotor of the phase-shifter until the voltage impressed on the moving coils is in quadrature with the current in the fixed coils; there is then no torque on the moving system, which will stand in its mid-position. If the power-factor varies, one or other of the relay contacts will be closed and the motor will operate the rotor of the phase-shifter so as to restore the moving system to zero; at the same time a recording pen is traversed over a chart calibrated in power-factor.

By combination of a phase meter with a recording voltammeter a record of power-factor and reactive voltamperes can be secured on an unbalanced three-phase system. To meter the kv-a. and the maximum demand a phase-meter can be used in combination with a watt-hour meter and a maximum demand indicator. The instruments have a high torque, are free from friction error, and have very great sensitiveness.

Electrician, Nov. 3, 1922.

Remote Indicator: This is an instrument designed in accordance with the Fawssett patent. This instrument is designed to indicate or record at a central station, the voltage, current, power or power-factor at a remote station, which may be many miles away.

Cambridge & Paul Instrument Co., Ltd., *Electrician*, Dec. 28, 1923.

Machine Timing: A special type of recording instrument which comprises a recording ammeter together with an operation recorder. The object of the arrangement is to provide a record of the timing of one or more operations of a machine or group of machines simultaneously with a record of current or power consumption.

Evershed and Vignoles, *Electrician*, Jan. 18, 1924.

Ionization Recorder: The photographic registering drum is mounted on the same shaft as the switch, which regulates the voltage between the incandescent cathode and the grid, accelerates the electrons, and produces the velocity which ionizes or excites the molecules of the gas under investigation. Light from the mirror of the galvanometer, which measures the ionization current, or other current produced in the tube, falls on the photographic film, the deflections being along the length of the drum, or at right angles to the displacements due to the voltage changes. A device is employed in which a small additional lamp is lighted at regular intervals, and prints a series of lines on the film, parallel to the axis of rotation, corresponding to equal increments of voltage. This enables the curves taken to be measured with accuracy. The galvanometer lamp can be automatically switched on and off in a regular manner during a run; so that the line recorded is dotted in a distinguishing manner, and a number of curves may be taken on the same film, and easily identified. It is possible to shift the apparatus parallel to the axis, so that the different curves taken are separated from one another. The shaft can be driven at constant speed, which can be varied within large limits, by means of a special motor, and special switching arrangements were made so that measurements could be carried out in the darkened room, which could only be lighted by means of a red lamp, which did not affect the photographic film. The following investigations have been carried out with this apparatus; ionization and excitation of light in helium and in hydrogen (not as yet completed); ionization of the halogen compounds of hydrogen, and of complicated compounds such as acetic acid; these last have as yet given no definite values, but show the enormous influence of small quantities of water-vapor; ionization of water-vapor (incomplete); exit work of the electrons from different incandescent wires.

P. Knipping, *Zeits. f. Instrumenten.*, Aug., 1923.

Stress and Strain

Electric Telemeter: The authors describe a form of instrument used for measuring rapidly varying pressures, stresses, and strains, and recording these at a distance. The principle is that of the variation with pressure of the resistance of a stack of carbon plates. A method has been devised for mounting these in such a way that the resistance is stable and free from hysteresis. By using two stacks in a Wheatstone bridge arrangement it has been found possible to give the instrument a linear characteristic. The carbon plates are mounted in a steel frame cut from a solid piece of metal, and they are mounted under a certain definite pressure to ensure stability of resistance. In the actual instrument described annular rings are used instead of plates, about 50 being generally employed. The change of resistance found is of the order of 46 per cent for a change of length of the stack of 0.00217 in. The two stacks mounted in the Wheatstone bridge are so arranged that the resistance of one is decreased and the other increased by the force or displacement in measurement. In use, the bridge is first balanced. Then as change takes place in the resistance of the carbon stacks the balance is upset and the bridging instrument deflected. As long as the current taken by the bridging instrument is small in comparison with the total current in the bridge circuit, these deflections will be proportional to the total change of resistance of the stacks, and the latter being proportional to the force or displacement under test, the ultimate result is a uniform scale reading of the bridging instrument. This enables calibration directly in thousandths of an inch in the case of strain gages, or total load or pounds per square inch in the case of stress or pressure gages. The leads from the carbon stacks to the other portion of the bridge circuit may be of almost any length, some of No. 16 copper wire, 100 ft. long, having been used successfully. This enables simultaneous readings or records to be obtained at a number of widely separated points by a single operator, the fixed resistances and bridging instruments being combined in one suitable panel. The instrument has found a number of different applications. In addition to measuring deformations it may be used as a strain indicator for rigid members, and the necessary modifications for this purpose are described in the paper. An example is given of the results obtained by two separate instruments for measuring the longitudinal compression and the transverse tension of a member at various loads.

O. S. Peters & R. S. Johnston, *Engineering*, 116 pp. 253-254, Aug. 24, 1923.

Inductance

The Thomson Bridge with Alternating Current: This article deals especially with the use of the Thomson bridge for measuring the small inductances of non-inductive shunts. The method can be also used for determining the transformation ratio and the phase-angle between the primary and secondary currents in current transformers. The theory of the method and the results obtained for some shunts are given.

E. Biffi, *Elettrotecnica*, Aug. 5, 1923.

Steam Flow Meter

The Metering of Steam: An account is given of the meters developed by the author and his firm, George Kent, Ltd. These depend upon the pressure difference set up when steam flows through an orifice in a pipe. The theory underlying the instruments is given, and the paper is accompanied by numerous diagrams.
J. L. Hodgson, *Inst. Naval Architects Trans.*, 195-202, 1922.

Synchronizers

Synchronizing Voltmeters: Some recent improvements in the devices for synchronizing alternators are described in this article. After recalling the study of Styff and some devices of Siemens, the author briefly describes a device imagined by him and used in Italy during the war, when, owing to coal shortage, it became necessary to connect power stations in parallel so as to relieve one another. This device is characterized by its simplicity and low price. It consists essentially of a two-coil voltmeter, each coil being fed by a phase of the three-phase system, the connections being taken to opposite sides of the paralleling switch. The coil connected to the leading phase is in series with a choke producing a lag of 60 deg., while the other coil is in phase with a suitable ohmic resistance. The paralleling switch can be closed when the voltmeter passes through zero.
B. Usigli, *Elettrotecnica*, Sept. 5, 1922.

Tachometer

Measurement of Speed of Rotation by a Stroboscopic Method: A beam of light passes through a hole in a disk attached to a string and illuminates a white disk with a radial black line, on the end of the rotating shaft. When the string vibrates the first disk moves to and fro in its own plane, and the second disk is only illuminated when the hole passes its position of rest. The tension of the string, and its vibration frequency, can be regulated by turning a graduated drum, until the black mark on the second disk appears to be at rest, owing to persistance of vision; and the graduations can be arranged so as to give the speed of rotation.
A. Guillet, *Comptes Rendus*, May 22, 1923.

Temperature

Relative Effects of Radiation and Convection: The rates of cooling of two large alcohol thermometers, one of which has its bulb silvered and polished, are observed under the conditions to be tested. Combining these with the rates of cooling of the unsilvered thermometer when enclosed in a high vacuum and in still air surrounded by an enclosure at the given temperature, the relative effects of radiation and convection are determined.
L. H. Nichols, Roy. Soc. Canada, *Trans.*, 333, 1922.

Thermometer

Bolometer: The conditions for realizing industrial electric thermometers of the bolometer type are theoretically studied, and two types of such apparatus as constructed by the firm of Allocchio, Bacchini & Co., are described and illustrated. The first type requires adjustment of the arms of the Wheatstone Bridge: the second type is of the direct-reading type. A special three-wire connection is required between the variable resistance and the system of the bridge resistances, battery and ammeter in order that the resistance of the connecting wires may be neglected. The constancy of the e. m. f. of the battery can be verified from time to time by inserting a given resistance in place of the variable one. This is made of nickel wire and, like the other resistance of the bridge, is of the order of 100 ohms. The scale of the direct-reading ammeter is practically uniform and is marked in degrees. These thermometers are employed for determining at a distance the temperature of transformer oil, dynamo bearings, etc.
C. Bacchini, *Elettrotecnica*, Oct. 5, 1922.

Temperature Bridge: The bridge is a temperature difference instrument designed for use with resistance thermometers. It apparently employs a shunted-decade arrangement, similar to that used in the Mueller bridge.
Dr. F. E. Smith, *Electrician*, Jan. 11, 1924.

Recording Pyrometer: A multiple-point temperature recorder, operating on the millivoltmeter principle, and using several colored inks for identifying the various records.
Siemens Brothers & Co., *Electrician*, Jan. 18, 1924.

Ammeters and Voltmeters

Voltmeter: A direct-reading Thermionic Voltmeter. The feature of this voltmeter is that it is arranged for measuring very low values, such as one or two volts without absorbing any appreciable power from the circuit of which the voltage is being measured. The instrument is apparently in commercial form, and appears to be of the type manufactured by Cambridge and Paul. The instrument utilizes a uni-pivot direct-current galvanometer, in conjunction with a vacuum tube rectifier.
E. B. Moullin, *J. Inst. Elec. Eng.*, Feb., 1923.

Avometer: A portable electrical measuring instrument designed to measure current from .001 to 12 amperes, voltage from 0.1 to 600 volts (or higher if required) and resistance from zero to 5000 ohms. It is claimed that this instrument is direct reading, no calculations being necessary, but no explanation is given as to just how direct readings of resistance are obtained.
Automatic Coil Winder and Electrical Equipment Co.,
J. Inst. Elec. Eng., Jan. 19, 1924.

Switchboard Meters: A series of instruments for mounting on industrial switchboards. The instruments are of the moving iron type, and the feature of the instrument seems to be that while front connections are used, these connections are completely enclosed in a separate chamber.
Electrical Apparatus Co., Ltd., *J. Inst. Elec. Eng.*, Jan., 1924.

"Cirscale" Meters: A series of circular-scale indicating instruments under the name "Cirscale." These are apparently direct-current instruments having a scale almost 300 deg. in length.
Record Electrical Co., Ltd., *J. Inst. Elec. Eng.*, Feb. 19, 1924.

"Oval" Meters: Permanent magnet moving coil instruments for switchboard mounting. This apparently has been designed to fit in with a similar line of "Oval" instruments which has been in use for many years on a-c. circuits. The instrument probably finds its greatest demand for switchboard mounting where space is limited.
General Electric Co., Ltd., *Electrician*, Feb. 1, 1924.

Ammeters and Voltmeters: Measuring instruments with their accompanying resistances arranged in a side compartment so as to be self-cooling, the air being drawn in downwards around the periphery and rejected upwards through the central part.
Nalder Bros. & Thompson, *Electrician*, Jan. 18, 1924.

Small Current Meter: A device is described for use in connection with the compensation method of measuring currents of 10^{-9} ampere or less. It consists essentially of a current divider, which divides a variable current in a ratio very large compared with unity. The small current is used for compensating the unknown current; the large current is read in a relatively insensitive instrument. The device consists of a thermionic cathode and an anode pierced by a small hole. The large current is that received by the anode; the small current is the fraction passed through the small hole in the anode. The currents are varied by changing the temperature of the thermionic cathode.
General Electric Co., Ltd., *J. Scientific Instruments*, Nov., 1923.

Volt-Ampere Meter: A knowledge of the consumed volt-ampere hours is required in devising an accurate method of charging for the energy supplied to an a-c. circuit. The paper gives a simple two-wattmeter method of measuring the volt-amperes consumed in a three-wire, three-phase circuit with balanced load. The current coils of the two instruments are connected in lines 1 and 2 respectively. The voltage circuit of the first wattmeter is joined across lines 2 and 3, and has a total

resistance of r_1 ohms. The voltage circuit of the second instrument is connected between lines 1 and 2; its total resistance can be varied by means of a sliding contact on the voltage coil series resistance to a value $r_1 - x$. The total power indicated by the two instruments is

$$W = 3\,E\,I\left\{\frac{\sin\phi}{\sqrt{3}} + \frac{1}{\sqrt{3}}\,\frac{r_1}{(r_1 - x)}\cos(30 - \phi)\right\}$$

By adjustment of x the bracketed factor can be made equal to unity for a given value of ϕ, and the sum of the readings of the two wattmeters will be the total volt-amperes. The variation of x with $\cos\phi$ and $\sin\phi$ is traced. It is shown that x is zero when $\phi = 60$ deg., and that its variation with $\sin\phi$ can be taken to be nearly linear reckoned from that point. Some form of ϕ or $\sin\phi$ indicator can be utilized to actuate the sliding contact and to give automatically the correct value of x for various power factors. Assuming the linear variation, the instruments give substantially correct readings of volt-amperes for values of $\cos\phi$ exceeding 0.2, the maximum error being 2.4 per cent.
C. Breitfeld, *Archiv. f. Elektrot.*, May 28, 1923.

Corona Voltmeter: Corona occurs at a lower voltage when the wire is negative than when it is positive. If F be the voltage gradient at the surface of a wire of radius a, then $F = A\,\theta\,(1 + B/\sqrt{\theta\,a})$, where A and B are constants and θ the density of the gas in which the discharge takes place. If the wire be surrounded by a coaxial cylinder of radius b, then the voltage gradient at a point distance r from the common axis is $E/(r \log_e b/a)$, so that corona will occur when

$$E = a \log_e b/a\left[A\,\theta\left(1 + \frac{B}{\sqrt{\theta\,a}}\right)\right] \quad .$$

By suitably choosing a and b, the discharge can be limited to corona, sparking being prevented. It is found that rods or tubes are preferable to wires, as the diameter may be considerable. Two methods can be employed for measuring corona voltage. The first, which is rather expensive, is to mount cylinder and rod in an air-tight case. The rod is connected to one terminal of a high-voltage generator, and the cylinder to the other, and the pressure (and so the density of the density of the air) is adjusted till corona just starts. The second method is to mount cylinder and rod in air, rods of varying radii being employed for the different voltages, the current being adjusted through the primary of the high-voltage generator, so that corona always just forms. The voltmeter connections are shown diagrammatically.
J. R. Clarke, *Rontgen Soc. J.*, Jan., 1923.

COMMITTEE ON MINES

To the Board of Directors:

The Committee on Mines has very little to report this year. There has been but one session held, at which papers pertaining to mine electrification were presented —namely, at the Birmingham Meeting. At this meeting a partial mining session was held, and three papers were presented on mining subjects. One of these was by L. C. Ilsley, Electrical Engineer of the Bureau of Mines, and was entitled, "Electrical Safety in Coal Mines." C. E. H. Von Sothen of the Industrial Engineering Department of the General Electric Company presented a paper on, "Automatic Sub-Stations for Mines;" and F. R. Grant and the writer presented a paper on "Tests on Mine Hoist Control," describing the operation of a large Ward Leonard hoisting equipment. Mr. Grant is also of the Industrial Engineering Department.

There has been no meeting of the committee this year, as the members are so widely scattered throughout the country and there have been no matters of sufficient importance to warrant calling them together.

No real constructive work has been undertaken by the committee, as there does not seem to be any field for such work at this time. The most urgent requirement in the mining field today, as far as electrification is concerned, seems to be the want and need of a satisfactory code for the safe installation of electrical apparatus underground, and this has been prepared by the American Mining Congress and the Bureau of Mines. This code is at present on the way to the Engineering Standards Committee for final approval. The majority of the members of your committee have been in touch with this work, and this field is very satisfactorily covered.

As to suggestions for future procedure, I feel the only way we can stimulate general interest in the work, of this committee, and possibly within the committee itself, will be by the holding of a joint session with some one of the important mining societies, and I would strongly recommend that such a joint session be considered. I believe that if this was put through it would be possible to secure quite a number of interesting papers on engineering subjects pertaining to electrification of mines; but electrical engineers intimately connected with mining work, I am afraid, do not feel that the A. I. E. E. is sufficiently interested in their work to warrant their presenting papers.

F. L. Stone, *Chairman.*

TRACTION AND TRANSPORTATION COMMITTEE

To the Board of Directors:

Just before the close of the last administrative year, a special committee was appointed to consider and report to the Board of Directors:

1. As to the desirability of continuing the Traction and Transportation Committee.

2. If the committee is to be continued, as to the character of the work which should be expected of it.

3. As to a specific program recommended for work of the committee for the ensuing year.

The committee reported on October 6 and recommended, in brief, substantially as follows:

1. That the Institute should have a technical committee to cover, broadly, the field of transportation.

2. That the most important function of such a technical committee would consist in guiding the activities of the Institute so that authoritative papers could be secured, bearing on the most important topics. Various subjects were suggested under this heading.

3. For the ensuing year, the committee recommended that the plan which the Meetings and Papers Committee had initiated for having a Railway Session at the Midwinter Convention in Philadelphia be carried

out; that this meeting be devoted exclusively to the production of papers by railway executives and operating men, if suitable papers could be secured.

The report was adopted by the Board and the present committee was appointed early in November with instructions to follow out the plans suggested. The recommendations of the committee concerning the Midwinter Convention were carried out. Two Transportation Sessions were held on February 5, one in the afternoon, the other in the evening. The latter was one of the largest ever staged by the Institute; it was held in the Metropolitan Opera House in Philadelphia and the proceedings were broadcast all over the country by radio. Five addresses by prominent railway and other executives were of a high grade and much appreciated. They were of a general character, of interest to everyone and as such they should be preserved.

The afternoon session was notable from the fact that the railway problem was discussed largely by railway operating men and brought out a good many interesting side-lights. The committee undertook to portray a vision of the future of rail transportation in this country and to gain a better understanding of the problems to be solved. Both were realized to a certain extent and it is the intention of the committee to continue the plan of getting the railway operating men to cooperate with us in this way.

The principal afternoon speaker was Mr. L. G. Coleman, Assistant General Manager of the Boston & Maine Railway, who gave an excellent paper in which he painted a graphic picture of the steam locomotive—its virtues and limitations. A number of other operating men joined in the discussion and contributed largely to the success of the meeting.

The past year has been distinctly one of progress in the field of the electric railway. No particularly spectacular events have been noted but the steady development going on in all lines promises to handle the transportation problem most satisfactorily when, finally presented.

Several new types of locomotives have been developed in the past year and improvements have been made in line construction, current collection, distribution systems, etc. Indications are that several large electrification projects will be started as soon as the financial situation will permit the railroads to undertake such improvements.

It is recommended for next year that:

1. Suitable papers be presented covering the points brought out in the Philadelphia meeting.
2. A suitable paper covering the subject of power supply for electric railways.
3. Papers covering the latest developments in electric locomotives.
4. Papers covering the development of the oil-electric or steam-electric locomotive.

N. W. Storer,
Chairman.

The Hysteresis Character of Corona Formation

BY HARRIS J. RYAN and HENRY H. HENLINE
Fellow, A. I. E. E. Associate, A. I. E. E.
Both of Leland Stanford, Jr. University

Review of the Subject.—To begin with the hysteresis character of 60-cycle corona formation was indicated by two factors: (1) the value of the crest voltage was of dominating importance in the corona loss-voltage relation and (2) the value of the power lost in corona from a high voltage transmission line approximated that given by the product of the voltage in excess of the critical voltage and the line charging current.

Diagrams of the cyclic instantaneous voltage-charge relation in corona formation were obtained and revealed the facts that in a given case the charge lags behind the corresponding voltage by an approximately **constant amount** *and that the energy dissipated per cycle is proportional to the product of the crest voltage and the difference between the crests of the voltage and the critical voltage. The corresponding equation for the full corona loss-voltage relation is*

$$P = 4 f C (E^2 - E E_0).$$

60-cycle brushes, coronas and streamers are due to the activities of ions carrying charges largely of the same sign as that of the conductors from which they emanate. The factors that control brush formation are considered. Local corona is due to an incomplete unstable brush pattern. Full corona is correspondingly due to a complete stable brush pattern. In relation hereto critical voltage, crest voltage and irregularity factor are defined. The difference in routing of linear 60-cycle and curvilinear radio frequency discharges is found to be due to the activity of ions carrying like charges in the former and a mixture of unlike charges in the latter.

* * * * *

YEARS ago in studying the nature of corona losses occurring from a small high-voltage laboratory line the cathode ray tube was used to observe the cyclic relation of corresponding instantaneous values of line voltage and charge.[1] It was found that the sides of the resulting diagrams were practically parallel, causing them to resemble hysteresis cards. The significance of this was not recognized at the time. More recently two items were encountered that have called for a critical study to be made of these same diagrams: (1) the value of the power lost through corona from a transmission line closely approximates that given by the product of the charging current and the voltage in excess of the critical voltage; (2) the dominating importance of the crest voltage in relation to corresponding corona loss. These items clearly indicated *the hysteresis character of corona formation.*

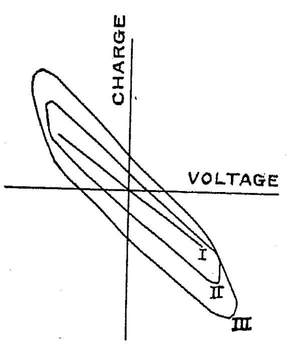

FIG. 1

Fig. 1 is a copy of Fig. 6 which appeared in the paper referred to above. The diagrams in this figure were obtained while using a pair of wires 0.085 inch in diameter spaced 12.5 inches apart. Card I was taken at 44,000, card II at 53,400 and card III at 64,000 root-mean-square approximate sine wave volts.

1. Numbers refer to the Bibliography.

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., Oct. 13-17, 1924.

The heavy line diagram in Fig. 2 represents the general form of card obtained in such cases. When the crest voltage is below the value E_0, the loss is zero, and the card is a straight line lying on the line X Y. At a crest voltage very slightly below E_0, the card is the line g h, and the maximum charge is Q_a. The charge varies directly with the voltage, and all the energy stored in the charge Q_a at the critical voltage, E_0, is

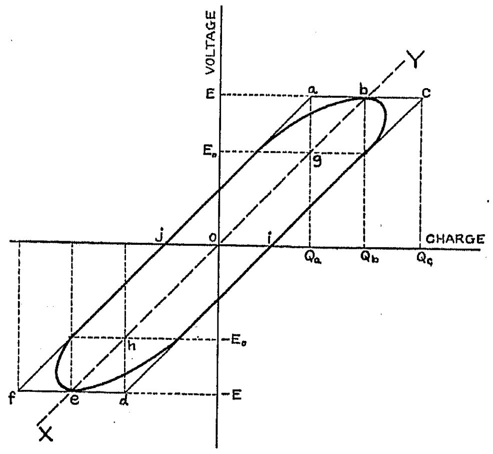

FIG. 2

returned to the source when the voltage is reduced to zero. As the voltage is increased beyond the critical value, E_0, to the value E and again reduced to E_0 the charge increases because of corona formation from the value Q_a to that of Q_b. The net result of this action is to increase the charge permanently through the succeeding half cycle by the amount $Q_b - Q_a$. Assuming that the cycle has now been formed up, the same thing occurs when $-E_0$ increases to $-E$, the isolated charge $Q_b - Q_a$ having a value of $o\,i$ is first discharged without return of energy and then built up to the same negative value, $o\,j$. Then as the cycle proceeds while $-E$ changes again to $+E$ the charge Q remains at all times reduced correspondingly by the same amount $Q_b - Q_a$. Thus a loss of energy per cycle is caused

through the corona formation determined substantially by the area of the card $a\,c\,d\,f\,a$.

From these boundaries the value of the power lost in corona may, therefore, be written as the product of the frequency and the $E - Q$ area determined by the corona cycle. Since the areas

$a\,c\,i\,j\,a = a\,c\,Q_c\,Q_a\,a$

$$P = 2\,f\,E\,(Q_c - Q_a) \text{ and} \tag{1}$$

because

$$Q_a = E_0\,C;\; Q_b = E\,C;\; Q_c - Q_a = 2\,(Q_b - Q_a)$$

it follows that:

$$P = 4\,f\,C\,(E^2 - E\,E_0) \tag{2}$$

wherein

P is the value of the corona loss in watts per conductor.

f is the value of the frequency.

E_0 is the crest value of the critical voltage to neutral.

E is the crest value of the line voltage to neutral.

C is the capacitance in farads of one conductor to neutral.

The reason for the close agreement of the values of corona losses and their corresponding products of line charging currents and line voltages in excess of critical voltage may now be made apparent, *i. e.*

$$P' = i_c\,(e - e_0) \text{ or}$$

$$P' = 2\,\pi\,f\,C\,e\,(e - e_0) \text{ or} \tag{3}$$

$$P' = \pi\,f\,C\,(E^2 - E\,E_0) \tag{4}$$

The value of P is only $4/\pi = 1.272$ greater than that of P' which accounts for the close proximity of *measured corona loss* P_0 and the corresponding value for the product of charging current and voltage in excess of critical voltage as in equation (**3**).

The form of these *voltage-charge* diagrams produced by corona is specific and may be clearly understood by a study of the ionization existing around a conductor subjected to high voltage. If the voltage does not at any time during the cycle exceed the value E_0 in Fig. 2, there is no corona loss and the cathode ray diagram is a straight line. If the voltage increases beyond E_0, the diagram opens out with sides virtually parallel, indicating that some change has occurred in the atmosphere adjacent to the conductor. The air, has, of course, been broken down or completely ionized about the conductor radially outward as far as the critical voltage gradient has been exceeded. Ions carrying charges of unlike sign to that of the conductor move in quickly to its surface and are discharged. Those carrying charges of like sign are repelled and move quickly to the boundary stated above, whereat the electric intensity has fallen to the critical ionizing voltage gradient. Thereafter their velocities are far lower, so much so that their positions remain in effect much the same until a reversal of the action occurs by a corresponding reversal of the voltage crest from E to $- E$.

Fig. 3 illustrates the state of things in the electric field about a conductor due to corona formation when the voltage has just passed through the crest value E, and is near the value of E_0, diminishing. The electric field attached to the conductor was set up by the critical value of voltage, E_0. The rest of the field due to the increase of E above E_0 was terminated upon the ions that were lodged just beyond the envelope of ionized atmosphere as specified. It follows that the electric intensity adjacent to a high-voltage conductor in the air cannot exceed critical value.

The value of the field thus detached from the conductor is $Q_c - Q_b$ in Fig. 2. Having been carried into place by ions it cannot be removed by the ordinary action of a displacement current through the charged dielectric to the electrode conductor. Such ion-attached field will persist until discharged by ions of unlike sign repelled from the conductor when the succeeding negative crest value of the voltage occurs. The energy in the ion-attached field cannot, therefore,

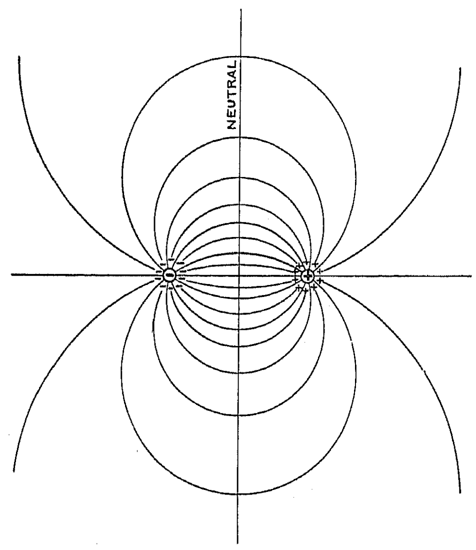

FIG. 3

be returned to source through the conductor. Such field can only be reduced to zero by degrading the energy stored in it to heat.

Fig. 4 illustrates the same corresponding state of things when the value of the voltage is near $- E_0$, increasing. The field attached to the ions now terminates on the conductor, and no longer on the neutral surface. Thus, it becomes understood that whereas the charge set up by the voltage, E_0, from conductor to neutral is Q_a without corona formation; with corona formation and E diminishing from E_0 it must have a value *larger* than Q_a by the amount of the field attached to the ions, *i. e.*,

$$Q_a = (E - E_0)\,C = Q_c - Q_b;$$

Likewise, with corona formation and E increasing toward E_0 it must have a value *smaller* than Q_a by this same amount of the field attached to the ions.

Thus it is that the chief factor in 60-cycle corona formation is the production of a hysteresis relation of volt-

age to charge. The charge lags behind the voltage a definite amount throughout the cycle. For any given value of the critical voltage, E_0, the energy thus lost in corona hysteresis per cycle is dependent only upon the crest value of the voltage, E. In the voltage-corona loss relation, therefore, the value of the crest voltage is of dominating importance. The root-mean-square value of the voltage, as such, has no relation to the magnitude of the energy lost in corona per cycle.

Critical and crest voltages to neutral, capacitance

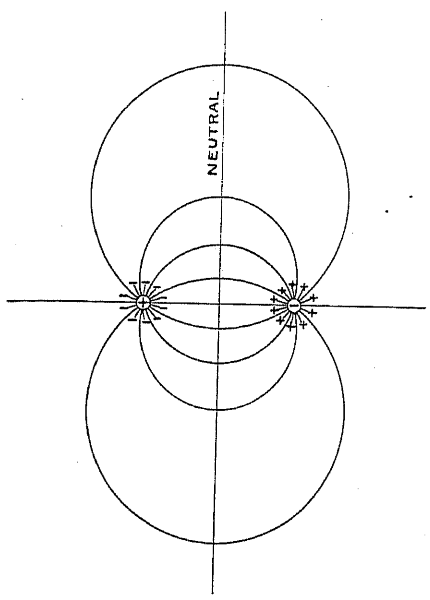

FIG. 4

to neutral and frequency have thus been found to be the primary controlling factors in corona formation. The value of the critical voltage, E_0, has long since been known to be dependent upon a number of secondary factors. Of these the *irregularity factor* is at once the most important and difficult to manage.[2]

Irregularity factor is the ratio of the average to the maximum intensity of the electric field adjacent to the high-voltage conductor. The value of this ratio is dependent upon other related factors such as the mechanical, physical and chemical irregularities of the conductor surface, the magnitude of the supply of free ions in the air about the high-voltage conductor and the manner and extent to which such free ions are associated with moisture, dust particles or with other finely divided matter.[3,4]

Critical voltage has a crest value that is just sufficient to produce break-down or ionization in the air adjacent to a high-voltage conductor. When the corresponding electric field is attached to the conductor with uniform density, the value of the critical voltage is maximum. When, from some cause, the density of the electric field is irregular, the corresponding value of the critical voltage is given by the product of the values of the maximum critical voltage and the irregularity factor.

These third-order factors may be absent to such an extent as to raise the irregularity factor to unity. In that event full corona will be found to occur near to and above the critical voltage. No isolated brushes will have been formed. Or these third-order factors may be present to such an extent that the resulting irregularity factor may have been forced to a very low value, 0.5, more or less.

At the corresponding critical voltage a few stray brushes are formed. As the voltage is raised, the number of brushes is increased. Through their mutual shielding effect the irregularity factor is also raised. This action continues with increase in voltage until a point is reached whereat no space is left in which to accommodate more brushes.[4] Thereafter the brush pattern is fixed and so are the irregularity factor and critical voltage constituting the condition of full corona formation.

From these considerations, it was evident further progress in the studies required that the voltage-charge relation should be understood for brushes occurring singly or in multiple, as well as for full corona formation.

To study the voltage-charge relation for single brush discharges the set-up diagrammed in Fig. 5 was used. Large metal screens were set in vertical planes about two feet apart and grounded. The cathode ray tube was placed between the screens. The 36-inch sphere was placed about three feet from the screen on one side, and the point which was the source of a brush discharge was placed about 30 inches from the other screen. It was connected to the wattmeter as shown. Its height above the concrete floor was about four feet. The potential reducing plate used on each side was insulated

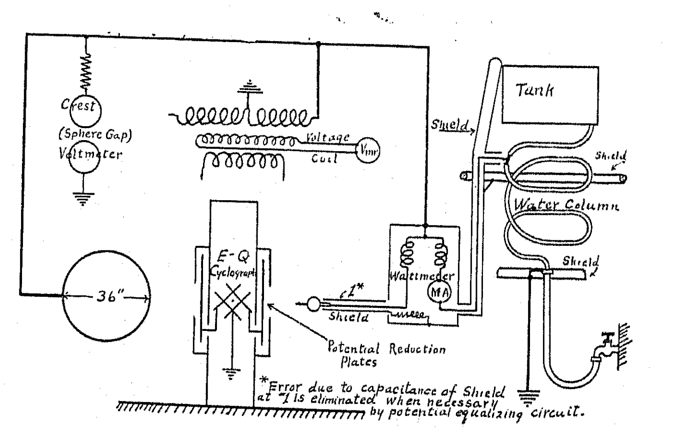

FIG. 5

from the large screen by a layer of beeswax. One deflector plate of each pair in the cathode ray tube was grounded, and the others were connected to the potential plates. Grounded shield plates partly covered the potential reducing plates for adjusting the amount of the deflection of the cathode ray beam along each axis so as to obtain a card of suitable dimensions.

The 36-inch sphere was used to produce the voltage deflection. Since there was no corona on it, the electric field set up was proportional to and in phase with the

voltage, and the potential reduction plate gave a certain percentage of the voltage between the sphere and ground. The point produced a good supply of ions on the other side even at relatively low voltages. Hence, the potential reduction plate on that side produced a deflection proportional only to the electric field or charge and not to the applied voltage. The appearance of the apparatus is shown in Figs. 6 and 7.

The point was connected to the source through the wattmeter[4] shown in the diagram whereby the powers consumed in the brush formed from the point at various

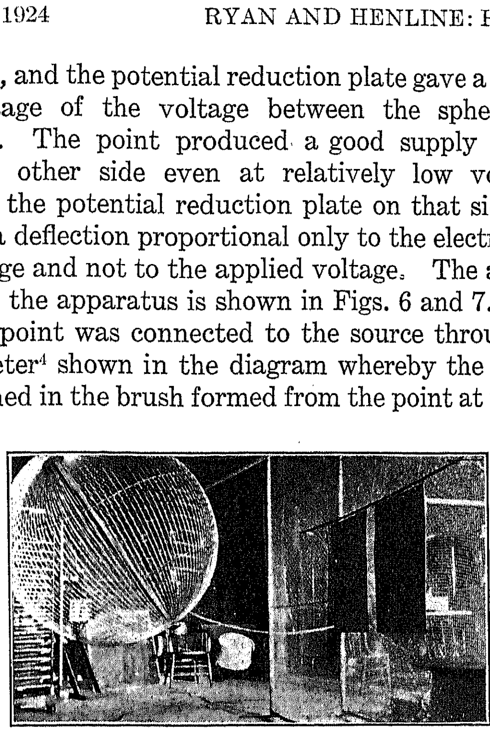

Fig. 6

voltages could be observed. The diagrams obtained at 20, 30, 50 and 80 kilovolts to ground are designated as A, B, C and D, respectively, in Fig. 8. The following table gives a summary of the results obtained.

Kilovolts to Ground	Watts by Wattmeter	Areas of Diagrams sq. in.	Ratios Watts/Areas
20	0.0	0.00	..
30	0.8	0.06	13.3
50	3.1	0.26	11.9
80	11.3	1.10	10.3

Because the deflections of the cathode ray were not exactly proportional to the actuating potentials, it

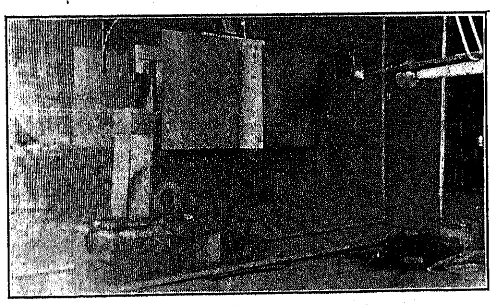

Fig. 7

follows that it was not proper to expect equality in the ratios of the areas and their corresponding powers observed by wattmeter. The fact, however, that the ratios did not differ greatly shows that the diagrams are good indications of the nature of the mechanism of the corona loss occurring in brush discharges.

Looking at the corona-brush diagrams critically one learns that their hysteresis character remains complete without mutilation until the value of the applied voltage is more than double the critical voltage at which the brush was started. Finally, as the voltage was raised the length of the brush became too great for all of the ions to reach their boundaries promptly. The space within the brush remained occupied to some extent with ions of both signs. Hereby gas conduction developed as it is ordinarily understood. A compound diagram resulted due to the combination of two, one because of hysteresis and the other resistance. The form of the one is obliquely rectangular and of the other eliptical.

For the study of corona brushes in multiple, brush patterns on cylindrical conductors were produced artificially by means of short tacks or water drops placed at regular intervals.[4]

The heads of the tacks were cemented to the surface of the conductors. The high-voltage wattmeter was used to determine the corona loss-voltage relations. The conductor length was 5 feet; diameter 0.532 inch; and the surface was studded with tacks ¼ inch long. The corresponding areas of conductor surface per tack, critical voltages, applied voltages, losses and values

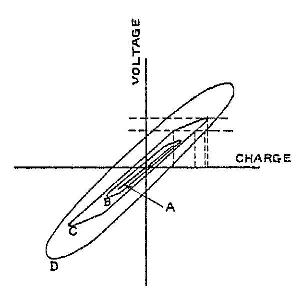

Fig. 8

of x in $P = k\,(e - e_0)^x$ at e are given in the following table:

Square Inches per Tack	e_0 Critical Voltage Kv.	e Applied Voltage Kv.	Loss Watts	x in $P = k$ $(e - e_0)^x$ at e
0.0625	40	90	50.5	1.56
0.25	40	90	50.5	1.56
1.00	40	90	50.5	1.56
1.64	43	93	44.5	1.64

From these results it is clear that the full corona loss-voltage relation remains unchanged over a wide variation of the brush pattern. It is also clear why Peek and his coworkers who first studied this relation found it to be unchanged by the degree of free ionization present in the air about the high-voltage corona-forming conductors.

As the value of the critical voltage rises from any or all of several causes specified above, local corona by brush formation diminishes and practically disappears when its maximum value has been attained. The corresponding loss-voltage curves obtained by measurement straighten out with rising critical voltage.

Thus, the difference between Peek's law of corona for a given frequency

$$P = k\,(e - e_0)^2 \text{ and}$$

equation (2)

$$P = 4\,f\,C\,(E^2 - E\,E_0) \text{ is}$$

of little importance. The essential difference is in the values of e_0 and $0.707\,E_0$. Each must be obtained by substituting the same observed values of P and applied voltages, e, and $0.707\,E$ in their respective equations. The cause of the difference will be apparent when the two methods of attack have been recalled and compared. E_0 can be observed by the voltage-charge indicator and by calculation, while e_0 can be obtained only by calculation from the full corona loss-voltage relation. In the case of Curve 3, Fig. 9, these calculated values were found to be for e_0, 116 kv. and for $0.707\,E_0$, 133 kv.

For comparison of the actual values occurring in the corona loss-voltage relation and the corresponding values calculated by equation (2) and Peek's equation No. 34 (High Voltage Engineering, 1920 Ed.) the authors are indebted to Messrs. J. C. Clark and Frank F. Evenson for the July and August, 1923 data by which the curves numbered 1, 2, 3 and 7 were located in rectangular coordinates in Fig. 9. The coronas were formed on cables made up of 49-strand copper, rope-laid. The conductor diameters, single-phase center to center horizontal separations and meterological conditions are specified in the figure. By means of an improved high-voltage wattmeter Curve 3 was relocated April 3 and again April 5, 1924 and the corresponding results were chartered also in Fig. 9. The curves thus located, but not drawn in, have been numbered 4 and 6. They were found to be in close agreement with Curve 3. Values corresponding to those in Curve 3 were calculated from Peek's law of corona and equation (2) and are given in the following table.

CORONA LOSS

*Local Corona Section.
†Full Corona Section.

As the voltage is lowered, if the full corona brush pattern breaks up and local corona is formed, full corona critical voltage cannot be determined by voltmeter. It can only be determined from the voltage-charge diagram. Without such diagram it must be obtained by calculation from the observed full corona loss-voltage relation. This relation within fair limits is never complex. The corresponding equation can be derived with no difficulty. It may then be used to calculate the value of the critical voltage. In curve 3, Fig. 9, the full corona part of the loss-voltage curve was found to be virtually a straight line. The value of the corresponding critical voltage was found, therefore, by extending such line to the point where it intersected the

voltage axis, viz. 134 kv. The capacitance to neutral per mile of conductor was 0.0145 μf. With these values by means of equation (2) Curve 5 was located in the same diagram, Fig. 9, and is in close agreement with curve 3.

The corona formed about large cables is virtually always pervaded by a brush pattern. Such pattern may be so complete as to occupy in corona formation substantially the whole of the electric field and, therefore, of the capacitance attached to the conductor; or the pattern may be less complete, occupying correspondingly less of the capacitance. When the pattern is nearly complete, as under the conditions for which the data locating curves 3, 4 and 6, Fig. 9, were obtained, the corona loss-voltage relation given by the equation

$$P = 4 f C (E^2 - E E_0) \qquad (2)$$

should be substantially correct. When the brush pattern is stable but less complete, not all of the electric field and, therefore, not all of the capacitance will be occupied in corona formation and the value of C in equation (2) will be correspondingly reduced. With this understanding of the values of capacitance, C, and the corresponding critical crest voltage, E_0, equation (2) should give the correct corona loss-voltage relation for every variety of 60-cycle corona formation with stable brush patterns. When the brush patterns are unstable the values of the capacitance, C, and the critical crest voltage, E_0, become unknown functions of the applied crest voltage, E, rendering the equation unavailable. This phase of the hysteresis character of corona formation is here presented more especially for the further understanding of the nature of corona than, as yet, to offer practical means for the economic study of conductor sizes in relation to corona losses. The economic forms of conductors are those which develop local corona only. In the present state of the science a large amount of experimental study remains to be done before the economic sizes can be predetermined with precision.

That the magnitude of the supply of free ions is a powerful factor in local corona formation may be understood through the results obtained in the following experiment: A bright, clean, 10-foot section of concentric strand aluminum-steel core cable, having a diameter of 0.952 inch, was mounted in the laboratory horizontally, 3 ft. 6.5 in. above the concrete floor neutral. It was connected through the wattmeter to the high-voltage source and properly shielded so that the only power values indicated by the wattmeter were those due to corona formation on the actual cable specimen. The corona loss-voltage values thus found were corrected to correspond to a distance to neutral of 8.5 ft. or 17 ft. between centers in a single-phase circuit. They were then used to locate Curve No. 8 in Fig. 9. The various active high-voltage leads and terminals present in the indoor laboratory drained the space of free ions to such an extent that the formation of an appreciable brush pattern was prevented, resulting in the absence of local corona formation. Full corona formed at an increment of voltage above the maximum critical voltage. Without correcting for the shielding effect due to the proximity of the high-voltage connecting leads the calculated value of the irregularity factor exceeded unity.

After aluminum cables of the sort just specified have been in service with corona formation, they will, in some circumstances, become coated with a definite layer of finely divided carbon, dust particles and cementing material causing the coating to adhere firmly. Through the understanding of corona formation herein presented it appeared reasonable to expect that the corona loss from the roughened carbon-coated specimen should be less at a given voltage than from the bright, smooth and clean specimen of what would otherwise be the same cable. The film of oxide covering the bright cable would thus inevitably interfere a little with the ready access of the incoming ions to the raw surface of the conductor. It would interfere to a degree with the uniformity of distribution of the ions moving toward and away from the conductor. On the other hand, the incoming ions for the carbon-coated cable would strike everywhere a conducting surface that should facilitate the development of full corona with a more nearly complete absence of brush formation with a corresponding increase of irregularity factor and of critical voltage. The test was, therefore, made for the black cable and the corresponding results were used to locate Curve 9 in Fig. 9. From these curves it was found that at 190 kv. the losses per conductor-mile for the bright and black cables were respectively 13.3 and 10.2 kilowatts. These bright and black cable specimens were very kindly furnished for the purpose by Mr. H. A. Barre, executive engineer, Southern California Edison Co.

For 10 years it has been known that 60-cycle discharges are routed substantially over the shortest paths between opposing high-voltage electrodes and that in contradistinction thereto radio frequency discharges occur over the routes of the tubes of force established by the impressed voltage.[5,6] The hysteresis character of 60-cycle brushes leads to an understanding of the cause of the difference in the routing of these two forms of discharge. At 60 cycles there is ample time for ions carrying charges unlike those attached to the high-voltage conductor to move up to it and be discharged; and for the ions of like charges to be repelled from the conductor and to reach their boundaries just beyond the ionized zone of air covering the conductor. Such surviving ions are drawn in a direct route to the opposing electrode by the tension of the electric fields attached from them to it. In the radio frequency discharges the state of things is quite different. The time between voltage crests is too short for the segregation of the ions to any considerable extent. The result is that the brushes which become discharges are occupied with ions of both signs. Their fields cancel

and they are propelled only in the direction of the original fields, due to the source voltage applied between the electrodes.

Conclusions

1. Sixty-cycle corona in all ordinary circumstances develops the character of a gas dielectric hysteresis.

2. The values of *crest voltages* are controlling in respect to losses by corona formation.

3. *Critical voltage* can have a definite value only when the brush discharge pattern in corona formation is stable. Its value should be understood to be given by the product of the maximum critical voltage and the irregularity factor.

4. *Irregularity factor* should be understood to be the ratio of the average to the maximum electric intensity of the field adjacent to the high-voltage conductor.

5. The rational corona loss-voltage relation is given correctly by equation (2) only within those limits of full corona formation wherein the capacitance value and brush pattern remain fixed.

6. Local corona loss varying from 0 to 8 kw. per mile depends upon too many variable factors to permit of calculation without the use of knowledge to be obtained only through a large amount of further study by measurements.

7. The strong ion-formed fields that are responsible for the corona hysteresis are the cause that routes a 60-cycle discharge by the shortest path between electrodes. Without such fields, as in radio frequency discharges, the discharge routes must be along the tubes of force of the original electric fields.

The High-Voltage Wattmeter

BY PHILIP C. CLARK and CHARLES E. MILLER
Associate A. I. E. E. Associate A. I. E. E.
Graduate students, Leland Stanford Jr. University.

Review of the Subject.—A complete laboratory set-up for measuring losses at low power factors from high-voltage circuits is assembled around a moving water column resistance multiplier which permits the direct use of standard low-voltage instruments. A shielding system is used to eliminate capacitance effects in the loading and voltage circuits. The paper contains structural details of the wattmeter aggregation and the loss loading equipment, and the operating procedure for conducting atmospheric and insulator loss measurements.

* * * * *

Introduction

The standard dynamometer-type low-voltage wattmeters may have their voltage ranges ordinarily extended to 1000 volts or thereabouts, by means of resistance multipliers. Higher voltage ranges are feasible only when the requisite multiplying resistances are constructed so as to be free from inductance and capacitance effects. Though expensive, this practise has been occasionally employed for voltages as high as 50,000.

The study of some of the problems encountered in 220,000-volt power transmission projects has required the use of voltage and power meters on extra high voltage circuits, accurate at low power factors. To provide satisfactory instruments for this class of research work, Professor Harris J. Ryan proposed to the authors to abandon the traditional use of "low loss" current control resistances in the voltage circuits and to substitute therefor moving water column resistances. The water columns are inexpensive, quickly erected, free of appreciable inductance and may conveniently be shielded from capacitance effects. When such resistances are designed to limit the currents in the voltage circuits of the instruments to 50 milliamperes at the highest voltages to be used in the studies, ordinary low-voltage standard makes of dynamometer-type voltage and power meters may be used. However, the experimental resources in these undertakings must include the requisite large amounts of power which must thus, necessarily, be consumed by such use of these measuring instruments on high voltage circuits. For example, the voltage circuit of a single instrument as herein presented will require 100 milliamperes, 50 for the instrument proper and 50 for the necessary shield to be considered later. The power thus consumed in a 350,000-volt circuit for the voltage circuit of a single instrument will amount to 35 kilowatts. In some of the application trials of the wattmeter reported upon herein, the low power-factor loading currents were less than 50 milliamperes. To increase the sensitiveness of the wattmeter, the loading current was passed through the moving coil and the voltage circuit current which was doubled (consuming 70 kilowatts) was passed through the field coil. Even so, such cost of power is small when compared with the total of the remaining costs involved in making studies of this character.

Plan

The wattmeter circuits are shielded in such a manner that all appreciable electric fields terminate upon the enveloping shields rather than upon the instruments and the connections. Fig. 1 is a schematic diagram of the shielded wattmeter. The power supply from the high-

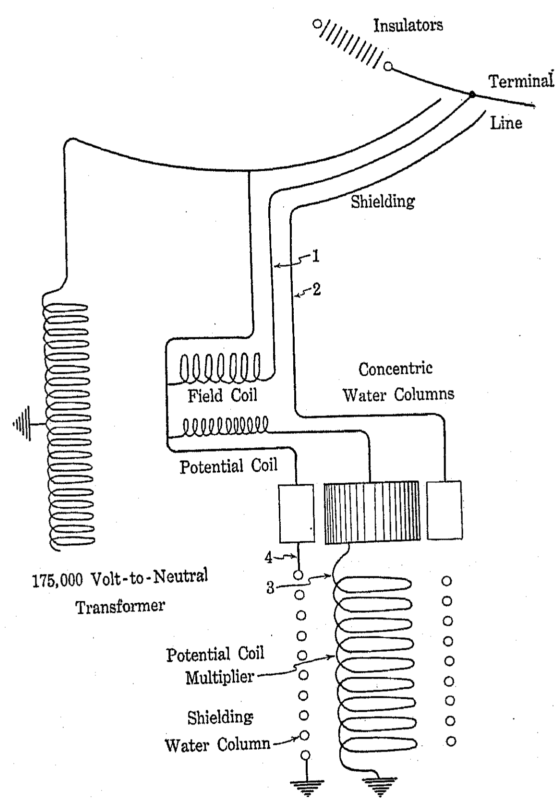

Fig. 1—Schematic Diagram

voltage source is divided into four circuits, (1) the power circuit which supplies power through the instruments to the line, (2) the main shielding circuit which surrounds the power circuit and supplies all losses and electric fields which would otherwise occur therefrom, (3) the potential circuit which contains the water resistance multiplier and (4) the multiplier shielding circuit.

Fig. 2 is a connection diagram of the assembly of

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

instruments and auxiliaries which constitutes the high-voltage wattmeter. The source of high voltage is a single-phase testing transformer which has the mid-point of the secondary grounded. A voltmeter, V_m, connected across the voltage winding of the transformer permits an accurate determination of the secondary r. m. s. voltage. A terminal which facilitates the connection of the wattmeter to different experimental lines permits a direct connection of the power circuit to the line and insulates the end of the shielding circuit

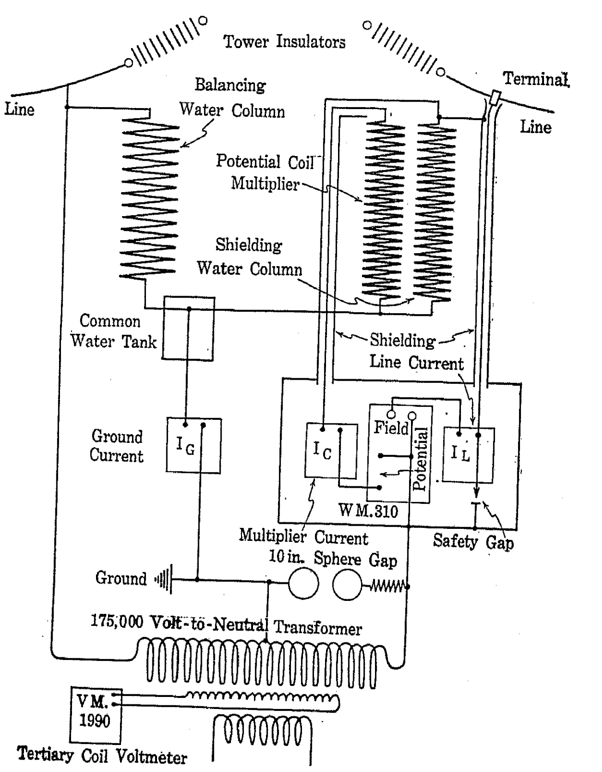

FIG. 2—CONNECTION DIAGRAM

from the line for a voltage that is equal to the resistance drop through the instruments.

The indicating instruments which must be used at high potential consist of a wattmeter, W_m, and two milliammeters located in the shielding cage which is insulated from the ground. One milliammeter, I_L, is connected in series with the field coil of the wattmeter and measures the current flowing through the power circuit to the line. The other milliammeter, I_C, is connected between the potential coil of the wattmeter and its multiplier and measures the current in the potential circuit. Because the resistance of the water column in the wattmeter voltage circuit changes with temperature, its value must be determined for each set of observations from the readings of instruments I_C and V_m. The multiplier is shielded by a concentric water column, the lower end of which is connected to the low-potential terminal of the multiplier. A balancing water column is necessary to load the other side of the transformer and avoid errors due to phase displacement. The low potential terminal of this balancing water column and the low potential terminal of the multiplier are joined and grounded through a milliammeter, I_G. A zero ground current indicates that the loads to neutral on the transformer are in balance. A sphere-gap voltmeter provides a means for determining the crest values of the voltages to neutral.

VOLTAGE CIRCUIT RESISTANCE MULTIPLIER

The multiplier is shown in the center of the illustration, Fig. 3. It is connected in series with the potential circuit of the wattmeter and consists of a water column contained in 71.5 ft. of ½-in. rubber hose. A cylindrical galvanized sheet iron tank, 20 in. deep and 19 in. in diameter, serves as a reservoir of sufficient capacity to supply the multiplier column with water continuously for half an hour. The water column which serves as a shield for the multiplier column is contained in 78.5 ft. of ½-in. hose. The reservoir which supplies water to this column is an annular galvanized sheet iron tank,

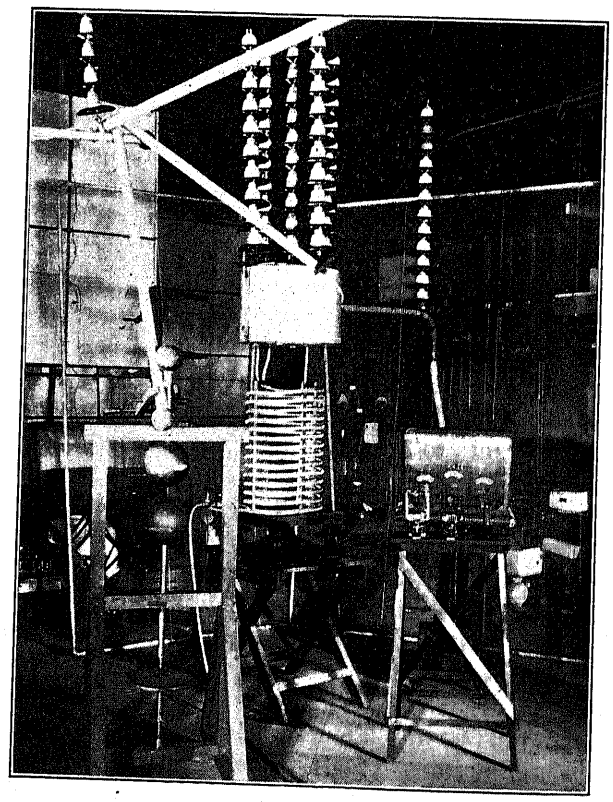

FIG. 3

19 in. deep, 21 in. inside diameter and 29.5 in. outside diameter. Four wood seperators maintain the tanks in their relative concentric positions. A glass gage on the side of the shielding tank indicates the level of the water supply.

For effectiveness in shielding and economy of space, the hose water columns are formed into two concentric coils with the shielding coil on the outside. The coils are 36 in. high and are mounted vertically on four 1-inch by 1-inch upright bakelite rods 39 in. long which

are placed at quadrant points on a 20-in. circular center line between the coils. Each coil forms a 14-turn helix with a 2½-in. pitch. The helices are fastened to the bakelite strips by small cotton cords which pass through holes in the bakelite. The maximum radial potential difference between corresponding points on the helices is that due to the drop of potential through the instruments. Since this drop is small, no special precaution is necessary in insulating the helices from each other. The axial potential difference between adjacent turns on the helices is 12,500 volts when the line voltage is 175,000 volts to ground. The voltage gradient is 6250 volts per inch, which gives a reasonable factor of safety, assuming the flash-over voltage of air to be 10,000 volts per inch.

Dowel pins are used in the construction of the multiplier frame in fastening wood spreaders to the upper ends of the bakelite rods as metallic pins would be possible sources of corona formation. The tops of the hose columns are connected to taps in the bottoms of their respective reservoirs by means of standard hose couplings. The lower ends of the water columns are joined so that they discharge through a common globe valve. The rods supporting the water columns are fastened to a wood base which rests upon four pin-type insulators. The annular reservoir is supported by four ten-unit insulator strings, while the inner reservoir is supported by a single ten-unit insulator string. Turnbuckles permit the proper distribution of the load between the insulator strings.

The resistance which provides the balancing load on the transformer is a water column contained in 75 ft. of ¾-in. rubber hose. This water column has approximately the same resistance as that of the multiplier and its shield in parallel. The column itself is connected to a 30-gallon galvanized iron tank which is suspended from a ten-unit insulator string. A glass gage on the side of the tank indicates the level of the water. The flow of water is controlled by a valve at the lower end of the column. A flexible 2-in. conductor connects the top of the column electrically to the transformer bus.

The water discharged from the columns flows into a common discharge tank insulated from the ground. Wire connections provide paths of low resistance from the low potential terminals of the water columns to the discharge tank.

The dimensions of the water columns are those which proved satisfactory for the tap water available at Stanford University. This water has an approximate resistivity of 1400 ohms per centimeter cube at 15 deg. cent.

Indicating Instruments

The instrument shield consists of a platform and a cage mounted on a 30-in. porcelain pedestal which provides sufficient insulation for a working voltage of 175,000 volts to ground. The platform is a 22-in. by 30-in. board clamped to the upper end of the pedestal. Wooden cylinders are grooved to fit flush with the top of the board so that the edges of the platform have a two-in. radius of curvature. The platform is covered with copper fly screen.

The cage consists of a wood frame 33 in. high, 30 in. long and 22 in. deep, covered with copper fly screen. The frame is doweled and glued together and the screen is fastened with brass tacks. All corners of the cage have a two in. radius of curvature to limit corona formation. The leads from the instruments pass through a brass plate screwed to the back of the cage. Brass hinges hold the cage to the platform and allow the cage to be raised in order that connections and adjustments may be made to the instruments.

A standard dynamometer-type low-voltage wattmeter, when used as the instrument in the high-voltage wattmeter, functions as a calibrated electro-power-dynamometer. A variable multiplying factor must be introduced to determine watts from the readings of the wattmeter aggregation. The power dynamometer used in the high-voltage wattmeter when employed for corona loss studies was designed to have a full scale deflection at 20 per cent power factor. The maximum voltage ranges were 75 and 150 volts. The maximum current ranges were (1), with the fields in series, 0.5 ampere, and (2), with the fields in parallel, 1. ampere. The scale had fifteen large divisions subdivided into tenths. This instrument was not sufficiently sensitive for accurate results when the power loss to be measured was less than 50 watts at 350,000 volts. In the present state of the art a more sensitive instrument may be had from the manufacturers for use when small power losses are under investigation.

The current, I_C, in the wattmeter potential circuit, and the line current, I_L, were measured by milliammeters which have full scale deflections of 75 milliamperes. The ground current, I_G, was measured by a milliammeter which had a full scale deflection of 15 milliamperes. The voltmeter, V_m, for measuring the voltage coil voltage had a maximum range of 450 volts. The instruments in the line circuit were protected from surges by a safety gap mounted within the instrument cage as shown in Fig. 2. A wire spring connected to the line conductor and a copper plate connected to the shield when separated by a sheet of tissue paper formed such gap. The breaking down of this tissue paper would short circuit the line current ammeter and the current coils of the wattmeter. Three telescopes, mounted on a suitable stand several feet in front of the instruments as shown in Fig. 3, were used in reading instruments I_C, I_L, and W_m. When the telescopes were focused on the meters within the cage, the screen did not interfere with the observer's vision, provided sufficient distance was allowed between the instruments and the screen.

The source of variable high voltages used for the corona loss integrity trials was a 150-kv-a. transformer with a maximum voltage rating of 350,000 volts. A voltage testing coil which gives a faithful 1/1000 reproduction of the secondary voltage is strategically located

in the windings of the transformer. The testing coil voltage in volts is equal to the secondary voltage in kilovolts. A 2300:230-volt multi-tap transformer serves as a primary supply for the high-voltage transformer. A hand-operated induction regulator provides uniform variation throughout the 23-volt interval from one tap to another of the multi-tap transformer.

The sphere-gap crest voltmeter as shown in the foreground of Fig. 3 was an essential unit in the assembly of the high-voltage wattmeter for the measurement of atmospheric losses. The 10-in. spheres were mounted according to the specification given by Farnsworth and Fortescue[1]. The calibration curve used for this sphere-gap was based on data given for 250 millimeter spheres with one sphere grounded in Table 204 of the A. I. E. E. Standards for 1922. A 300,000-ohm protective resistance was connected in series with the sphere-gap to limit the current at spark-over.

Structural Details of Atmospheric Loss Loading Equipment

Fig. 4 is an illustration of the general assembly of the

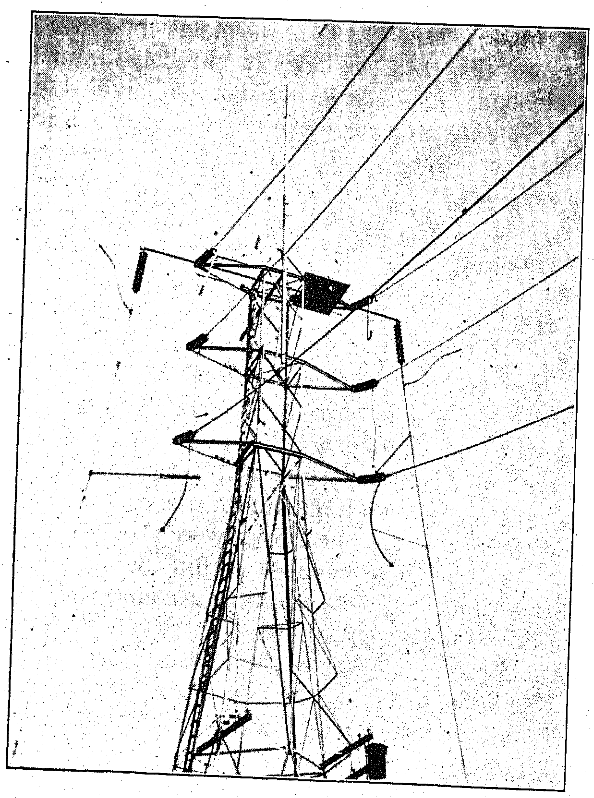

Fig. 4

switching equipment on the tower at the source end of the experimental line. Each length of cable is dead-ended to the tower cross-arms by a ten-unit string of 10-in. cap and pin-type suspension insulators. The vertical distributing busses which supply power to the transmission cables are insulated from the top of the source tower and from the ground by ten-unit insulator strings. These busses are equipped with projecting arms to facilitate the interchange of connections between the busses and the cables. Each bus is pivoted so that it may be rotated in either direction until the desired connection is made from the projecting arm to the corresponding conductor of the single-phase line under test.

1. Trans. A. I. E. E., Vol. XXXII, 1916, p. 733.

Fig. 5 illustrates the high-voltage terminal projecting from the vertical distributing bus. The line conductor is connected to this terminal by means of a 6-ft. hook-

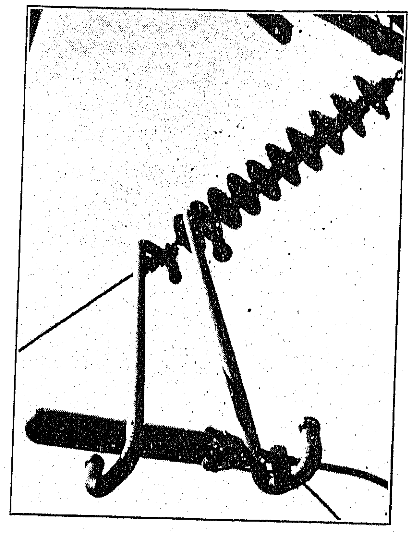

Fig. 5

link of 2½-in. galvanized sheet iron tubing. The main part of the terminal consists of a cylinder of galvanized sheet iron, length 30-in., diameter 5-in., one end terminating in a hemisphere of thin copper. The cylinder is mounted and insulated (1) from the hollow shaft of the terminal by two corrugated bakelite disks and (2) from the rain protecting funnel on the shaft by a small air gap. The conductor of the power circuit is a No. 14 insulated copper wire shielded by a flexible 5/8-in. armor. This cable is wound spirally about the vertical distributing bus and the end of the conductor is soldered to the galvanized cylinder of the terminal. The flexible armor is insulated from the cylinder and is fastened to the shaft of the terminal. To separate the insulator loss from the line loss, the loss over the insulators at the terminal end of the line may be eliminated by connecting the cap of the insulator next to the line to the shielding circuit as shown in Fig. 5. In this case the shielding circuit supplies the insulator losses. An extension of the shielding circuit to all of the insulators for the direct elimination of their losses from the power measuring circuit may be made when desired.

Operating Procedure for Atmospheric and Insulator Loss Measurements

The sphere-gap is set for the voltage at which observations are to be taken. The valves of the water columns are opened. Voltage is then applied and

gradually increased until the sphere-gap flashes over. The readings of the four meters, W_m, I_C, I_L and V_m just in advance of the flash-over are noted and recorded. The barometric pressure and temperatures by wet and dry bulb thermometers are recorded at the beginning and end of each test.

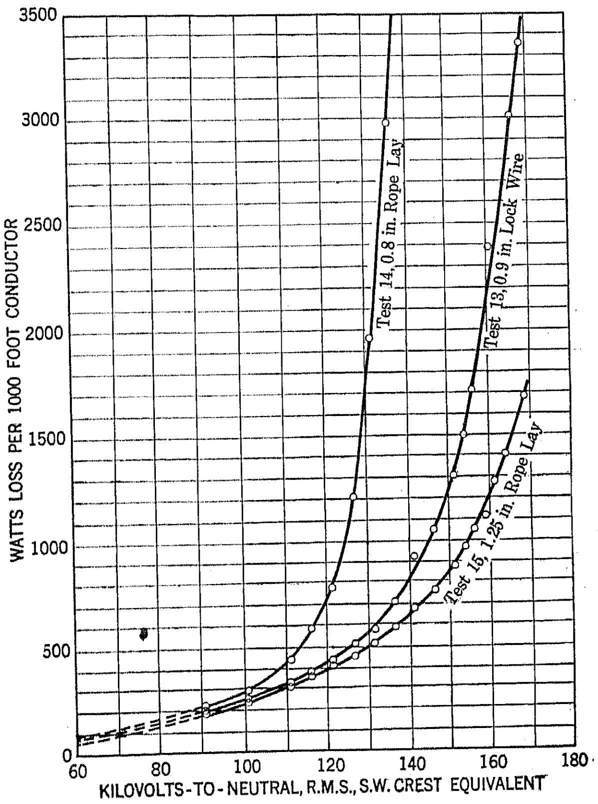

FIG. 6—TRANSMISSION LINE LOSSES MEASURED BY HIGH-VOLTAGE WATTMETER, STANFORD UNIVERSITY, CAL.

Fair weather, temperature 60 deg. fahr., humidity 58 per cent, barometer 30 in., frequency 60 cycles.

Test	13	14	15
Conductors.....	Smooth Lock Wire	375,000 Cm. Rope Lay	900,000 Cm. Rope Lay
Diameter.......	0.9 in.	0.8 in.	1.25 in.
Spacing........	17 ft.	17 ft.	18 ft.
Length.........	234 ft.	241 ft.	241 ft.

A typical test consisted of about 30 sets of readings with observations at 5-kilovolt intervals from 40 kilovolts to ground to 175 kilovolts to ground. Such a test under ordinary conditions required about 20 minutes and the services of at least five attendants.

Actual trials soon established the fact that the wattmeter could handle voltages up to the maximum operating limit of the transformer long enough to accomplish satisfactory observations. At 170,000 volts to neutral the total power loss for 234 ft. of 0.9-in. diameter single conductor amounted to about 900 watts in fair weather. This corresponded to a 1.5-watt deflection on the 15-watt scale of the low-voltage range indicating wattmeter. The minimum operating range of the high-voltage wattmeter aggregation was determined by the sensitivity of the indicating wattmeter. At 50,000 volts to neutral the total atmospheric power loss from the 0.9-in. conductor was less than 20 watts and no readable deflection of the indicating wattmeter, as used, could be observed.

During April, 1923, this wattmeter aggregation was used to determine the single-phase atmospheric power losses from three pairs of large conductors in lengths of 240 ft. approximately, each, as follows: lock-wire, smooth cable, 0.91-in. diameter and rope-laid cables 0.8- and 1.25-inch diameters. For illustration, the results of three of these tests are chartered by means of rectangular coordinates in Fig. 6.

The possibility of error, due to neglecting the loss over the insulators, was investigated by making two tests,—(1) with the insulators normally connected to the line, and (2) with the insulator loss supplied by the shielding circuit as shown in Fig. 5. The insulator loss was so small that the indicating wattmeter was not sensitive enough to give quantitative results in clear weather, although a slight loss was perceptible.

CONCLUSION

The high-voltage direct-measuring wattmeter as reported herein was in a pioneer state. The application trials showed that it is not only practicable but advisable to use a wattmeter directly on high-voltage circuits. The next advance in the development of the wattmeter was the evaluation and elimination of the error powers due to capacitance effects in the loading and voltage circuits. Such study was undertaken by Messrs. Carroll, Peterson and Stray in the Stanford high-voltage laboratory. Their results have been embodied in a paper entitled Power Measurements at High Voltages and Low Power Factors presented concurrently to the American Institute of Electrical Engineers.

Review of the Subject.—*A description is given of the apparatus for the measurement of power as low as a fraction of a watt at power factors approaching zero and voltages as high as 175 kv. to neutral. A standard make of portable wattmeter was used having maximum ranges of 1.5 watts, 37.5, 75 and 150 volts and 20 per cent power factor. To this wattmeter was adapted a three-megohm water column resistance multiplier.*

In the original form of the wattmeter the origins of certain errors, due to capacitances chiefly, were studied and methods for their elimination were subsequently determined. Integrity tests were developed by which the values of error powers were obtained and used as guides in making subsequent adjustments for the reduction of such errors to zero. These integrity tests were checked by using the wattmeter for the measurement of known amounts of power.

Reconnaissance studies were made of the voltage-corona power loss relations for rope laid copper, 0.91-in., lock wire smooth copper, 0.91-in. and concentric strand aluminum, 1.006-in. diameter transmission line conductors in rain and fair weather at differing degrees of humidity, temperatures, and barometric pressures, from "initial" to "full" corona formation. This class of studies was extended to corona loss values as offered by a wide variation of the "surface roughness" of conductors subjected to high voltages. The losses for a single brush were measured and the shielding effect of groups of brushes was studied. Losses to single strings of insulators under different conditions were determined.

THE sensitive, low-power factor, high-voltage wattmeter has been awaiting solution through twenty years or more. In the meantime, because of the lack of this wattmeter, satisfactory dimensional data over a wide range of important high-voltage actions have been difficult if not impossible to obtain. The promise for success of the high-voltage wattmeter using a water column resistance multiplier, leads to the conviction that it could be improved considerably, and that a series of high-voltage reconnaissance tests could be undertaken that would define lines along which further helpful studies could be made of the losses produced in brush discharges, local corona and insulators on high-voltage power transmission lines under conditions varying as to equipment forms, climate and altitude. The primary purpose of the present undertaking was, therefore, to make a series of reconnaissance tests of the above sort after improving the accuracy of the high-voltage wattmeter to the requisite degree.

The following study was made of the origin, nature and elimination of the errors occurring in the high-voltage wattmeter reported upon concurrently by Clark and Miller,[1] which will be referred to hereafter as the 1923 wattmeter.

At the outset of the work, when engaged upon laboratory transmission line corona loss measurements, certain peculiarities were observed in the indications of the wattmeter when the coil connections were changed. There were many possibilities as to the cause of the trouble. A systematic study of them was, therefore, made.

The usual low-voltage wattmeter errors such as self- and mutual-inductance of coils, electrostatic attraction, wave form, frequency, etc., were soon found to be negligible in the present case. The most serious of these, self-induction of the potential coil, produced, at the most, only 1 per cent error. The important source of error was found to be the capacitance in multiple with instrument coils. The schematic diagram of connections, Fig. 1, shows that the leads and their shields in the water column and line constitute condensers which shunt the wattmeter coils. These act to produce error by causing currents in the coils to differ from those in the water column and line, both in magnitude and

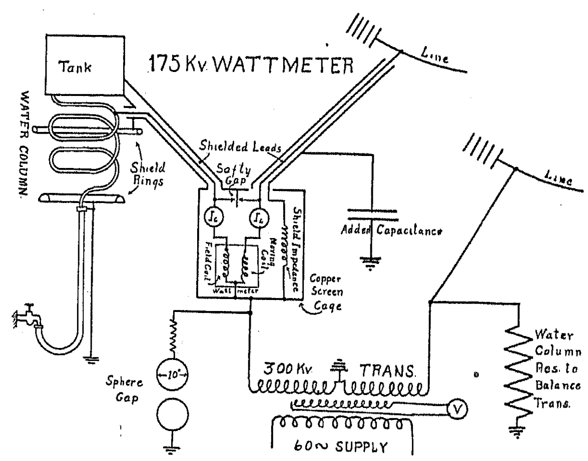

FIG. 1

phase position. Of these, the shift in phase is the only one of importance and is constant for fixed connections. The error reading, due to capacitance across the coil in series with the line, varies as I_L (current to line) and I_c (current to water column). That due to the other capacitance varies as $I_L\,I_c$. Since I_L and I_c are both very nearly proportional to voltage, E, the net error power varies as E^2.

The error due to the capacitance between the coil lead to the line and its shield was eliminated by equal-

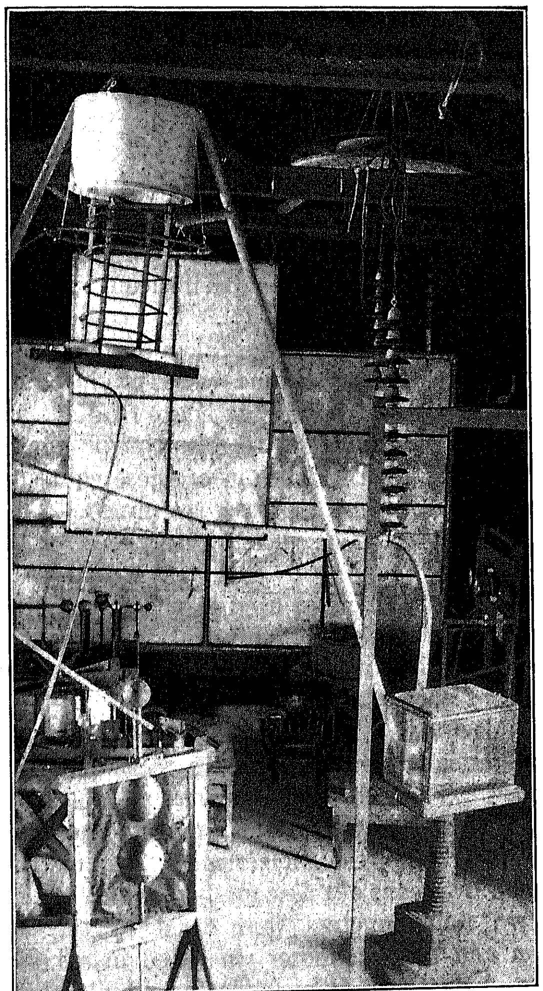
Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., Oct. 13-17, 1924.

izing their potentials. This was done by connecting the shield to the source through a suitable impedance mounted within the instrument shield cage as indicated in Fig. 1. The resistance-inductance ratio of this impedance was made the same as that of the coil and corresponding milliammeter connected to the line. The values of this impedance and the capacitance of lead-to-the-line shield to neutral were then adjusted so as to consume the same voltage as that consumed in the coil and milliammeter by the line charging current.

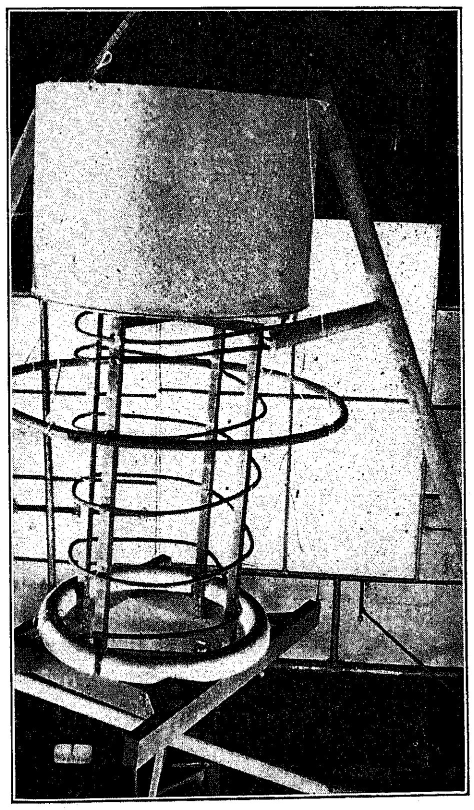


General View of High Voltage Wattmeter Showing Instruments in the Copper Screen Cage, the Water Column Multiplier and the Sphere Gap

The difference of potential then applied to the error-making capacitance was thus brought to zero and the error eliminated.

The companion error due to the capacitance between the voltage coil and milliammeter lead to the water column multiplier and its shield was reduced to a negligible value by a sufficient structural reduction of such capacitance. This was accomplished by making the lengths of the lead and shield a minimum and by using a relatively large diameter (2.5 in.) of shield and correspondingly small diameter of lead (No. 14 B. & S. gage) mounted axially within the shield. Thus arranged, the errors due to the capacitances shunting the wattmeter coils and milliammeters were eliminated.

Further studies of the 1923 wattmeter revealed another difficulty. It came up in the effort to repeat measurements of fixed corona losses. It was found that the values could not be repeated with sufficient agreement. The cause of the difficulty was finally traced to the highly undesirable manner in which the outer shielding water column functioned. The water multiplier and water shielding columns did not, in warming up, form exactly the same temperature patterns. The conductivity of ordinary potable water such as was used, changes rapidly with temperature. Varying potential differences were, therefore, caused between the multiplier and shielding water columns. Corresponding charging currents were, as a consequence, set up through the comparatively large capacitance that existed between the two columns giving rise to corresponding error-powers that would develop



Shielded Water Column Resistance Multiplier for Wattmeter

and vary as the temperature patterns changed. It was found impracticable to maintain equality of such temperature patterns. The shielding water column used in the 1923 wattmeter was, therefore, entirely abandoned.

Another form of water column multiplier was designed and constructed so as to reduce the errors due to capacitance substantially to zero. A quarter-inch air hose was used which allowed shortening the net length to 20 feet or one fourth the length of the hose in

the former column. It was wound on four bakelite strips and formed a helix eighteen inches in diameter and about three feet long. To insure a sufficient flow of water through such a small hose to keep it from overheating, the pressure of the tap water supply was used to force the water through it up into the tank above. In mounting it, the water column was placed as far above the ground as practical, which was about 12 ft. The capacitance of the tank was eliminated by connecting the wattmeter just one turn of hose below the tank, the latter being connected directly to the high-voltage supply. It is true that the water in this section of five feet of hose shunts the wattmeter coil; however, the resistance of this part of the water column was about half a megohm, whereas the total impedance of the wattmeter coil and milliammeter was only 1160 ohms,

so that the error introduced by the connection was negligible. With this arrangement the capacitance of the water column was very small. The tank itself served as a good shield, and only a little additional shielding was found to be necessary. This was accomplished by placing a ring, made out of one-inch metal tubing, around the water column. The ring was suspended from the tank to which it was connected and stood out concentrically from the water column about eight inches. The distribution of the shielding field was further improved by placing another ring at the bottom of the water column, connecting it to the ground wire at the end of the small hose.

When the true power was known to be small, it was found that the shields could be so placed that the wattmeter could be made to give a negative reading. The meaning of this was that the error power through adjustment of the shields could be reversed in sign. From this it followed that if the values of the error powers were known they would furnish a guide to find the positions of the shields whereat the magnitude of the error power would be reduced to zero.

A method was, therefore, developed to segregate the true and error power constituting the corresponding aggregate indicated by the wattmeter as follows: The real power due to a few watts (say 30 to 50) of line corona loss and the error due to the water column multiplier capacitance were held rigidly constant through fixed frequency and crest voltage. The latter was controlled by a sphere-gap By varying the flow of the water in the column, its temperature and thereby its resistance could be changed. In this way I_c (in phase with the voltage) could be varied by any fractional amount. Under these conditions the part of the wattmeter reading due to actual power increased by the same proportionate amount as I_c, while the residual part of the reading due to capacitance error remained constant (independent of I_c). Remembering these facts, with two sets of readings taken at different values of I_c, two simple equations were produced for the equalities of the wattmeter aggregate readings and the sums of the corresponding true and error power portions thereof. By the solution of these equations the value of the error reading was determined. Then, by trial, shielding could be varied until the error became zero.

The Weston wattmeter used in these measurements was a sensitive specially designed instrument. The full scale reading of 1.5 watts would be obtained at 20 per cent power factor with maximum rated current through each coil. The currents to the line and water column resistance multiplier were measured by milliammeters. These three meters were all inclosed in the copper screen cage which was connected to the high-voltage terminal of the transformer. The instruments were read by means of telescopes about six feet distant. The two milliammeters were used in the vertical position and the wattmeter was used in a horizontal position, being read from a platform built above the screen cage.

As a test of the ability of the wattmeter to measure actual power, a special test was devised. A 6000-ohm resistance consisting of two Thomson wattmeter multipliers was inclosed in a cylindrical metal shield with hemispherical ends, one end of the resistance being soldered to the shield and the other end brought out through an insulating bushing. A regular set of readings was taken at some definite sphere-gap setting then this resistance of 6000 ohms was inserted in the circuit at the point where the wattmeter lead connects on to the line and another set of readings taken at the same sphere-gap setting as before. Knowing the line current and this added resistance, the power absorbed by it could be computed and compared with the increase in

power as shown by the wattmeter. These results checked very well.

As a check on the reliability of the method of separating real and error power by changing the resistance of the water column by diminishing the flow of water, the following test was made: A set of readings was taken at a definite line voltage with the water flowing freely through the hose; the voltage was there held constant and the resistance of the water column decreased by restricting the flow of water. When the current through the water column had reached a predetermined value the meters were again read. The power was computed from the differences of the two wattmeter readings and the two currents through the water column. The resistance was then inserted in the line circuit and the procedure repeated at the same voltage as before. The difference in the power computed from these two tests should be the $I^2 R$ loss in the resistance. The following are the results of these tests at two different voltages:

Line Kv. V_H	I_L	I_C	W	Actual Power*	Mean Value
		No resistance in line			
240	31.9	38.6	0.062		
240	31.3	70.0	0.081	14.7

170	22.7	60.0	0.022	3.5	4.3 (d)

*Computed from the increase in wattmeter reading produced by the increase in I_C.

As can be seen from the data, the measured power increased when the resistance was inserted. The amount of power absorbed in the resistance is given by the difference of (a) and (c) for the one voltage and from (b) and (d) for the other voltage. These values are 8.0 watts and 4.1 watts and the loss computed from the resistance and the line current is correspondingly 6.0 watts and 3.1 watts. It was indeed gratifying to know that such small values of power could be measured with fair accuracy at such high voltages and low power factors. The accuracy here was not quite 100 per cent, however, considering the magnitude of the wattmeter reading, and also that the greater part of it was error power, the results are as close as would be expected. It was this test which showed that true power could be separated from error power by the method of changing the water column resistance.

The test was made before the water column had been sufficiently shielded to give correct power from a single set of readings. The shielding was then adjusted until the computed power was the same, irrespective of the resistance of the water column. The following are data of tests in which the power due to corona loss

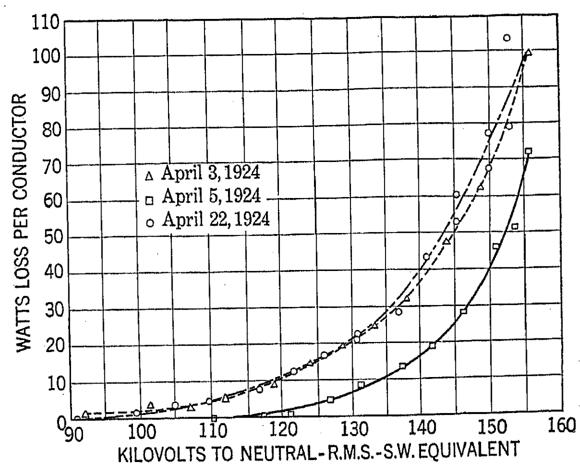

FIG. 3—CORONA LOSS. CONCENTRIC STRAND CABLE

on the line was measured with different currents through the water column:

V_H	I_L	I_C	W	Power: By Watt-meter	Power: Computed from $W_2 - W_1$ and $I_{C2} - I_{C1}$
		April 3, Aluminum Con. Cable in Light Rain (I_L held constant)			
190	..	43.5	0.018	8.0

210	..	44.3	0.050	24.0	
210	..	70.0	0.077	23.4	22.4 (Water up)
		April 4, Lock Cable. (Dry)			
210	27.6	49.5	0.0005	0.21	
210	27.6	70.0	0.0005	0.15	0 (Water down)
210	27.6	44.0	0.004	1.9	
210	27.6	70.0	0.006	1.8	1.6 (Water up)
		April 8, Lock Cable. (Dry)			
255	34.1	61.4	0.090	38.0	
244	34.2	70.0	0.103	38.1	39.6 (Water up)

The results were very satisfactory, showing not only that the water column capacitance error power had virtually been eliminated but also that the power loss below visual corona, if any, was extremely small.

THE CORONA LOSS—CREST VOLTAGE RELATION AT VOLTAGES UPWARD FROM CRITICAL VALUES

The value of the crest voltage in all corona and related actions is controlling.[2] The measured values

2. Harris J. Ryan and Henry H. Henline, The Hysteresis Character of Corona Formation. See Page 1118 of this Volume.

of power are believed to be as accurate as necessary as long as the sphere-gap must be used to determine crest voltage. It is only accurate to two per cent, but a two-per-cent change in crest voltage may cause a far greater change in corona loss because of the character of the corona loss-power relation.

The method of test was to set the sphere-gap and raise the voltage until the sphere-gap sparked-over. At that instant the voltmeter, wattmeter, and both milliammeters were read. This procedure was repeated at different sphere-gap settings until a sufficient number of values had been obtained. Power was

computed from the meter readings by the following formula:

$$P = \frac{W_m \dfrac{V_m \times 1000}{2}}{4931 \times 0.001\, I_c}$$

Where W_m is wattmeter reading, in watts, V_m is voltmeter reading in volts, I_c is current to the water column in milliamperes, 4931 is the wattmeter constant. P is the power in watts, and the other constants take care of voltage to neutral, and the proper units. I_L does not enter into the computation of power but was measured for other purposes.

The cables used in the tests were rope-lay, concentric strand and lock wire. The rope-lay and concentric strand cables are familiar to everyone. The lock wire cable is similar to that used on aerial tramways and has a smooth exterior.

The curves of corona loss in Fig. 4, show that the loss is less than that found by most previous investigators. Corona loss starts at approximately the visual corona voltage and the loss below this point, if any, is negligible. The rope-lay cable had a much rougher surface than the other cables and therefore might be expected to have a larger loss. At 130 kv. to neutral, the loss in fair weather was from 1.4 to 1.6 kw. per conductor per mile. At 120 kv. the loss was from 0.5 to 0.7 kw. per conductor per mile. In rain, the loss at 130 kv. is 9.5 kw. per conductor per mile. The loss at 120 kv. is 6.0 kw. per conductor per mile or twelve times the fair weather loss. The loss in rain starts at below 50 kv. to neutral while the loss in fair weather starts at from 70 to 90 kv. to neutral.

In fair weather the loss on the lock wire cable is very low. At 140 kv. to neutral the loss is from 0.35 to 0.9 kw. per conductor per mile while at 120 kv. the loss is only from 0.02 to 0.25 kw. per conductor per mile. In rain the loss is much greater. At 110 kv. to neutral the loss is 9.5 kw. per conductor per mile or nearly 200 times the fair weather loss for the same voltage.

The loss on the aluminum concentric strand cable is much less than would be accounted for by the fact that it is somewhat larger in diameter than the others. In dry weather at 140 kv. to neutral the loss is from 0.9 to 1.25 kw. per conductor per mile. At 120 kv. to neutral the loss is from 0.15 to 0.30 kw. per conductor per mile in fair weather. In rain the loss is about 4.5 kw. per conductor per mile at 140 kv. and about 1.2 kw. per conductor per mile at 120 kv. to neutral. This means that the wet weather loss is about four times the fair weather loss through a specified range of voltage.

From an inspection of the curves shown in Figs. 2 and 3, it is seen that the amount of moisture in the air has a great influence on corona losses of this order. Mershon[3] found that corona loss was a function of the vapor product. He defined vapor product as the product of the relative humidity in per cent and the vapor pressure in inches of mercury. Approximate equations of Mershon's corona loss vapor product curves were obtained and by them our results were reduced to the same vapor product. As can be seen by the comparison of Fig. 2 and Fig. 3, the curves of the concentric strand cable were somewhat closer together after correcting for vapor product. Although corona loss may vary as a function of the vapor product, the results of these tests do not follow Mershon's curves. Mershon found that the vapor product affected the "critical point" or point where the law of the curve changes. The critical point on his curves corresponds to the voltage

3. Mershon. High Voltage Test. TRANS. A. I. E. E., Vol. XXVII, p. 845, 1908.

where corona loss starts on our curves or approximately visual corona voltage.

The moisture in the atmosphere seems to affect the starting point of corona and the part corona loss, but it has little effect on the full corona loss. From the results of present tests it would seem that not only was the starting point of the curve shifted but the shape of the curve was changed by the amount of moisture in the air. When these values of loss are plotted on semi-logarithmic paper (Fig. 5) they seem to indicate the existence of three laws since three intersecting straight lines are formed. The slopes of the upper and lower straight lines are practically independent of the

humidity, but the slope of the middle line seems to depend on the amount of moisture in the air. It has been suggested that these three lines refer to brushes from clamps, part corona and full corona.

Insulator Losses

Insulator losses on a ten-unit string were measured in the laboratory building at 150 kv. to neutral. For cap and pin insulators with skirts the loss was about 7 watts dry and dusty, 5 watts dry and clean, 4¼ watts wet on top, 4¾ watts when sprayed from top; 9 watts when wet and dirty and 450 watts when wet all over. At 150 kv. the loss on a ten-unit string of core-and-tine insulators was found to be about 10.25 watts dry and clean; 10 watts when sprayed from top and 150 watts when wet all over.

Through corona loss tests on the laboratory yard tower line by difference between corona loss with one supporting insulator string excluded and again included in the wattmeter circuit, the loss on a 9-unit string

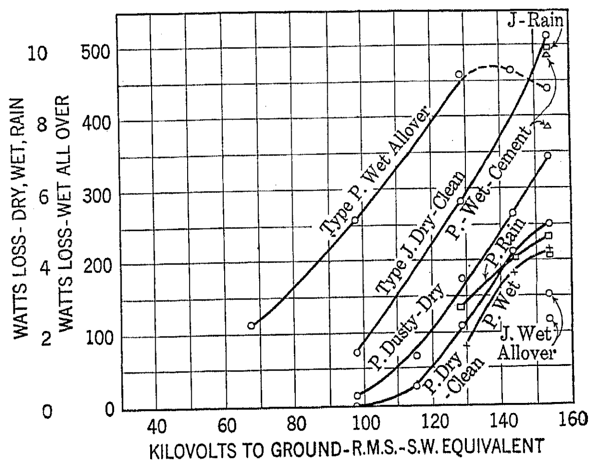

Fig. 6—Insulator Losses on 10-Unit String

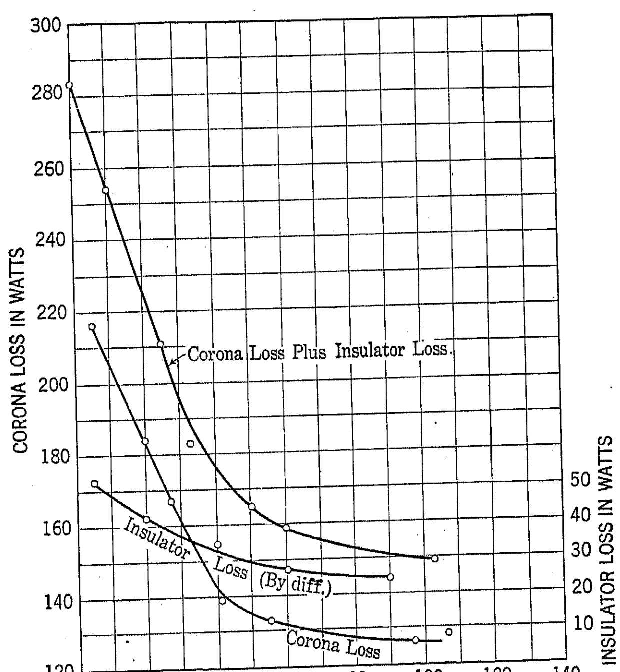

Fig. 7—Corona and Insulator Losses

Lock Wire Cable. Temp. 57 deg. to 62 deg. fahr. Barometer 29.94 in. Relative Humidity 77 to 67 per cent. Time 9:10 to 11 a. m., April 12, 1924. High Fog—to clear 151.3—150.0 kv.

of cap and pin-type insulators with skirts was found to be about 50 watts at 150 kv. when wet with dew. By the same method the loss on the same string of insulators was found to be 20 watts at 135 kv. in the rain.

From these results it is seen that insulator losses

in dry weather are negligible. In light rains the loss is still low but in heavy rains accompanied by wind the insulator losses may become very high. From the few observations made it seems that the loss when dew is on the insulators is greater than during light rains.

Brush Losses

Measurements were made of the power loss-voltage relation for a variety of corona brushes, singly or in multiples. When the number of brushes was small, 1 to 6, a wire was run out from the high-voltage source terminal through the wattmeter, a distance, generally, of about six feet. With its concentric shield, 2.5 inches in diameter, it was supported horizontally on insulators about four feet up from the concrete floor. The tubular shield was terminated with a three-inch sphere.

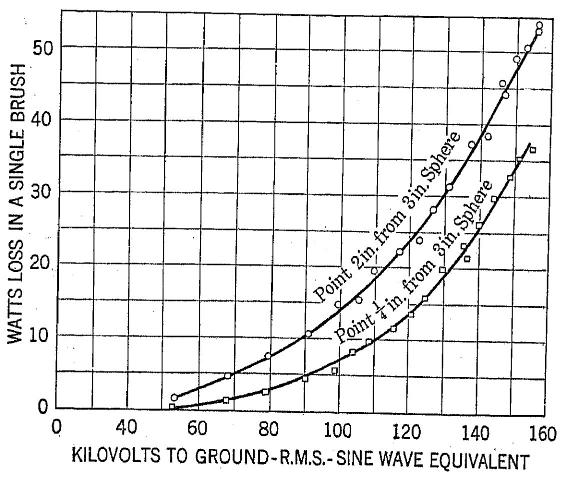

Fig. 8—Brush Losses

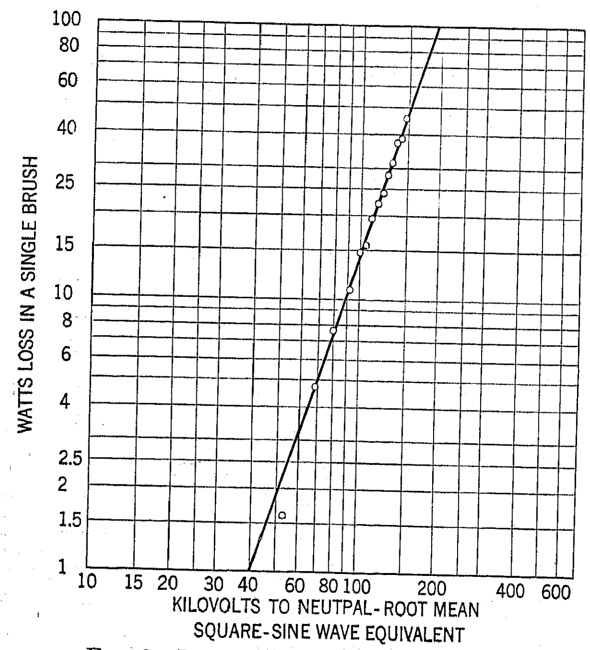

Fig. 9—Power Loss in a Single Brush

Barometer 29.89 in. Dry Bulb Temperature 51 deg. fahr. Wet Bulb Temperature 52 deg. fahr.

The lead wire was extended a convenient distance beyond the spherical end of the shield as specified later. From it from one to six points were mounted from which to set up brushes.

When the brushes to be formed were many (from a few to 500) the requisite points from which to form them were provided by cementing the heads of small (*one-quarter-inch*) tacks to the surfaces of metal tubes having diameters and lengths to be specified later. Both ends of the tubes were suitably shielded. Thus arranged, the wattmeter measured only the losses set up from the points as desired.

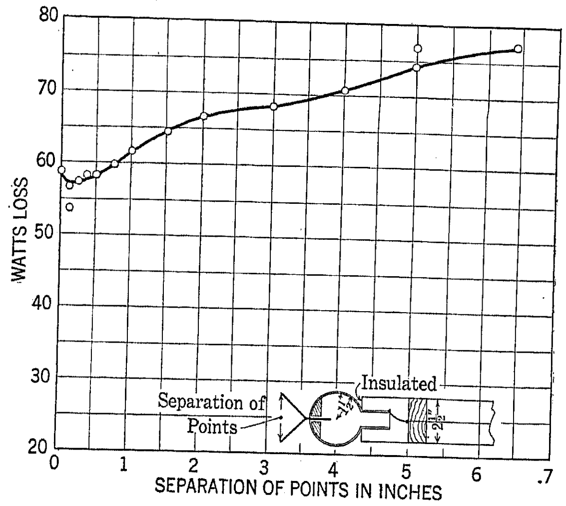

Fig. 10—Brush Loss

2 Points in a "V" Temp. 70 deg. fahr. Barometer 29.96 in. 154.0 kv. Relative Humidity 20 per cent. Points 3 in. from 3 in. Sphere.

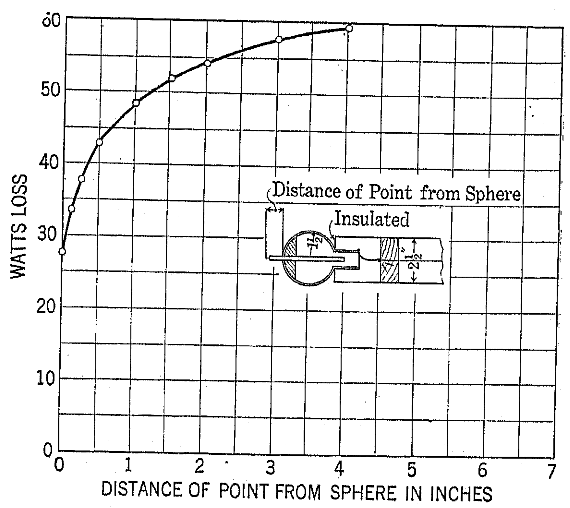

Fig. 11—Effect of Point Length on Brush Loss

Temp. 70 deg. fahr. Barometer 29.94 in. 154.3 kv. Relative Humidity 33 per cent.

The loss from a brush from the end of a wire or rod is much larger than the loss from a single brush on a line conductor cable. The brushes on a cable crowd each other. It is not surprising, therefore, that the loss per brush is less when there are more brushes.

The curve of a single brush located on logarithmic paper by losses and corresponding voltages (Fig. 9)

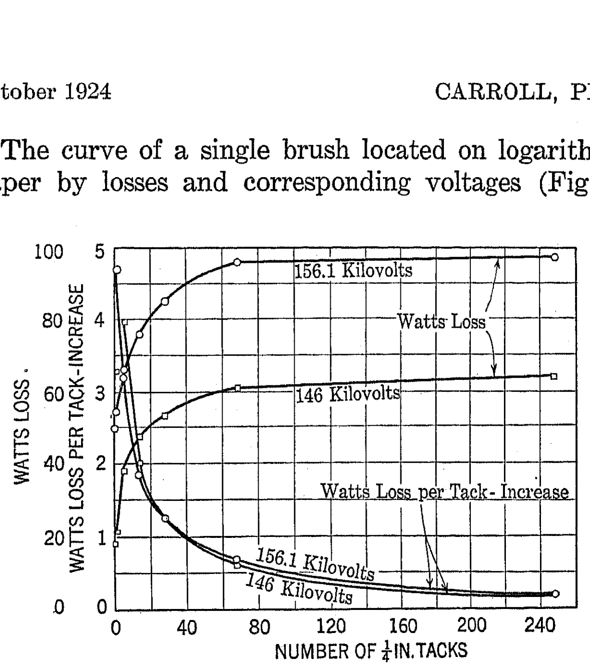

FIG. 12—EFFECT OF TACKS ON CORONA LOSS FROM CONDUCTORS
Length 2 ft. 3 in. Aluminum Tube Diameter 17/32 in.

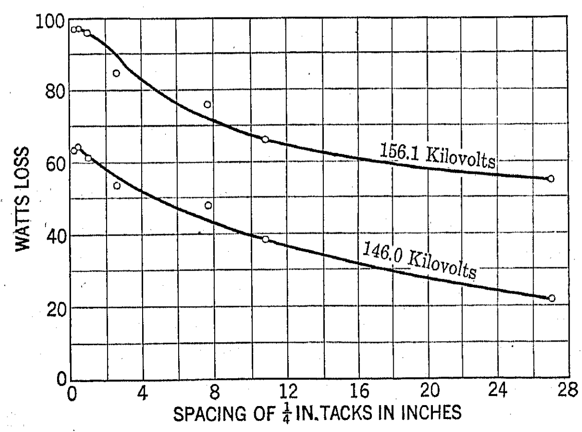

FIG. 13—EFFECT OF SHIELDING ON BRUSH LOSS FROM CONDUCTORS

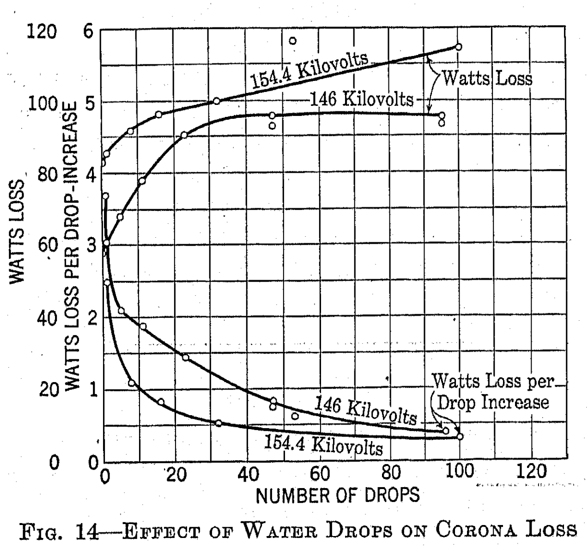

FIG. 14—EFFECT OF WATER DROPS ON CORONA LOSS FROM CONDUCTORS
Length 6 ft. Brass Tube Diameter ½ in.

indicates that the brush loss in the particular circumstances varies over a wide range with the cube of the voltage. For other brush losses the curve seems to be similar but the variation of loss is not as the cube but as some other power of the voltage.

The curve of Fig. 10 shows clearly the shielding effect of one point upon another. The curve of Fig. 11 likewise shows the shielding effect of the sphere from which the point projects.

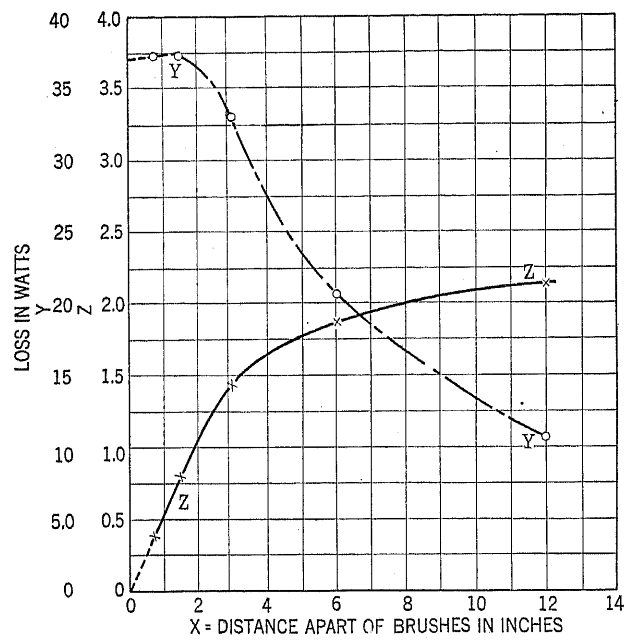

FIG. 15—CORONA LOSS TESTS

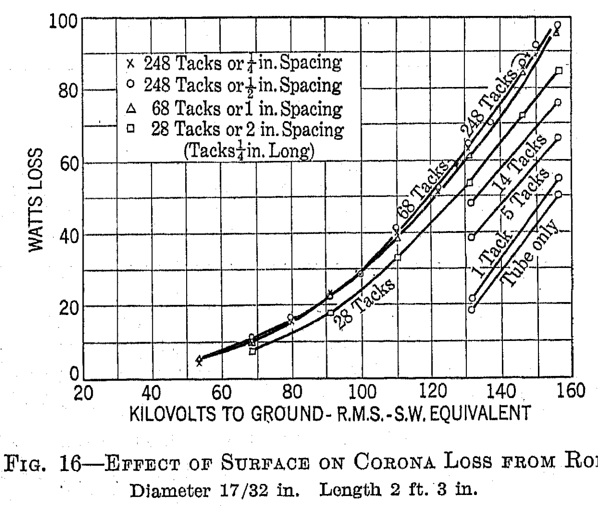

FIG. 16—EFFECT OF SURFACE ON CORONA LOSS FROM ROD
Diameter 17/32 in. Length 2 ft. 3 in.

Figs. 12 to 15 show the effect of surface irregularity and of water drops on corona loss as well as the shielding effect of the brushes from water drops and tacks. Figs. 16 and 17 show the effect of surface roughness on corona loss. Tacks were equally spaced on a rod and the corresponding curves were obtained as shown.

Loss from Conductors as Affected by the Surface

The curves of loss from a brass tube are especially interesting because they are virtually straight lines. The loss with a polished tube was considerably lower than it was when coated with soot from a candle flame. The loss from the tube when its surface carried its natural tarnish was still higher than when soot covered.

It is interesting to note that the loss from a section of the cable from the Big Creek Line covered with a natural deposit of carbon was three fourths that from a section of new cable under the same conditions.

From the curves of brush and corona losses as affected by surface conditions it would seem that the loss increases as the number of projections on the surfaces up to certain points and then remain practically constant or they may decrease slightly as the number of projections is greatly increased. This may be understood from the brush loss curves. The brushes stretch out quite a distance into the air around them and therefore are affected by what is taking place near them. When they are too close together the loss per brush will be decreased, but since there must be more brushes to accomplish this the total loss will be more. There is a final limit where the loss per brush decreases faster than the number of brushes increases and therefore the total loss becomes less. This explains the distribution of brushes on a conductor. Where opportunity for the formation of brushes is favorable they will form only so close together that their field will not decrease the total loss. When they are too close together their number is decreased and the total loss is again increased to the maximum. In other words, brush formation stabilizes toward the production of maximum loss.

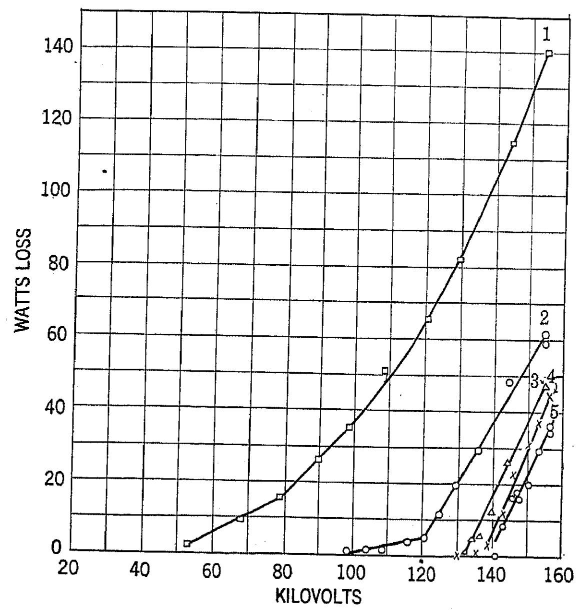

Fig. 17—Effect of Surface on Corona Loss

Conclusions

1. It has been found practicable to separate true and error power.
2. The power loss from transmission conductors below visual corona, if there is such a loss, is extremely small.
3. Humidity is a "part" or "local" corona loss factor.
4. Losses on dry insulators are small; when completely wet may be relatively high.
5. Rain increases corona losses considerably, the amount of such increase depending upon the type of conductor.
6. For a given length of conductor with points on it, the loss per brush decreases with the number of brushes and the total loss increases with the number of brushes up to a certain value and then remains constant or nearly so.

Acknowledgments

Though the names of the authors will usually be associated with the results of these studies, when credit is to be conferred, several others must be considered. Prof. Ryan, always inspiring, has been a very dependable source of ideas for the solution of problems. Prof. Henline has greatly assisted, not only in the operation of equipment but in many other ways such as pointing out errors in methods of measurement. It is with great pleasure that we acknowledge this and express our deep appreciation to them as well as to others who have been involved in the work.

Discussion

For discussion of this paper see page 1162.

Fair Weather Corona Losses at 60 Cycles
on Large Overhead Power Cables

BY J. C. CLARK

and

F. F. EVENSON
Associate, A. I. E. E.
Benson Lumber Co., San Diego, Cal.

Review of the Subject.—*After defining briefly the problem of the selection of a proper high-voltage transmission conductor, the authors discuss the difficulties that caused the failure of their earlier attempts to measure corona losses at the Stanford University laboratory.*

The equipment used for the present investigation, as well as the methods of test and the procedure followed in the reduction of test data, are described. The corona loss is taken as a function of the crest value of the voltage in accord with the theory of Professor Ryan. Insulator losses in fair weather are found negligible.

Errors existed in the authors' measurements of the losses, causing them to be high, but a correction is made by subtracting the "error power" from the gross power curves.

The cable samples are briefly described.

Complete tables of tabulated data are presented in Appendix A; and some idea of the consistency and reliability of the results may be obtained from these tables, and from the various curves.

INTRODUCTION

ATTENDANT upon the design of a large-power high-voltage overhead transmission comes the problem of the choice of a conductor having not only all the obviously essential mechanical properties, such as strength, flexibility, durability in abnormal as well as normal operation, but it must possess a desirable electrical character in addition to the requisite conductivity: namely, such a diameter and configuration of section that corona loss will not exceed an economic limit at the selected operating voltage and under the imposed conditions of weather and altitude for the proposed line. The urgent need of more data on the corona loss from medium and large-size cables in order to meet this problem has resulted in an attempt to obtain such data experimentally at the high-voltage laboratory of Stanford University.

EARLIER STANFORD EFFORTS—METHODS AND EQUIPMENT

Prior to the summer of 1923, efforts to measure corona

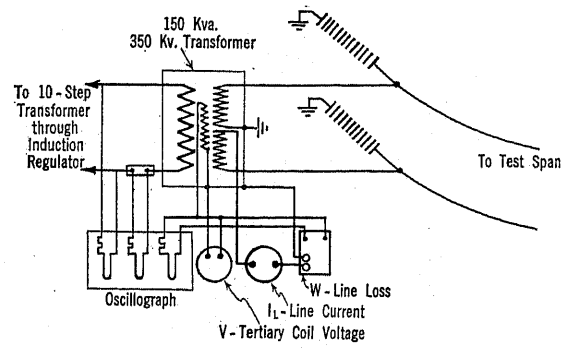

FIG. 1

loss with a wattmeter connected as shown in Fig. 1 were unsuccessful, probably due mainly to the fact that the amount of power going into corona loss on the connections from the high-voltage transformer to the test-cables was very large in comparison with the loss on the actual test-cables. It is also quite possible that variations in the wave form of the testing voltage were responsible for many of the great discrepancies encountered in corona loss curves made at different times, but with apparently identical conditions as to tem-

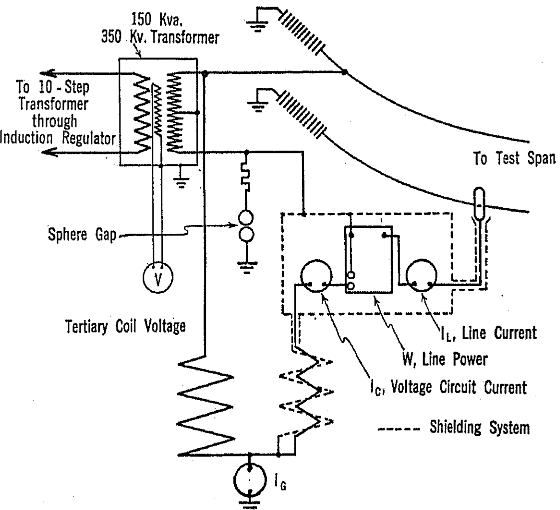

FIG. 2

perature, barometric pressure, and humidity. It is not possible to say that the earlier measurements could have been made successfully had the foregoing obstacles been removed, since there may have been still other sources of trouble that were quite masked by these prominent ones. However, it seems highly probable that the method could have been studied and refined until small losses were capable of accurate measurement.

EQUIPMENT—SUMMER OF 1923

The Source Transformer. The source of high voltage in the Stanford laboratory is a General Electric testing transformer bearing the following name-plate data: "No. 1198244, Type K, Form EV, Capacity 150 kv-a., volts 300,000-200/400/800." The transformer con-

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

tains a Hendricks tertiary "voltmeter coil" giving a faithful reproduction in volts of the secondary voltage in kilovolts. Continuous adjustment over the range of 0-350 kv. between terminals, or 0-175 kv. to ground is secured by employing a 3.6-kv-a. hand-operated induction regulator arranged by a suitable switching arrangement, including the full use of both its bucking and boosting actions through reversal of its primary winding, to cover the range between adjacent taps of a 50-kv-a. 10-step secondary 2200-220-volt transformer receiving the 60-cycle power from the University substation.

The Sphere-Gap. The sphere-gap used was constructed according to dimensions given by Farnsworth and Fortescue (TRANS. A. I. E. E., Vol. XXXII, 1913, page 733). 10-inch spheres were used and the calibration is that given in the A. I. E. E. Standards, 1922 edition, Table 204, for 250 mm. spheres. In operation, the bottom sphere was grounded and the distances from the gap to extraneous objects and to external parts of the circuit were maintained many times greater than those specified as minima in the Institute Standards.

Test-Cables. The facilities of the Stanford Laboratory permitted mounting only about 235 ft. of test-conductor in a single span between steel towers. Spans were supported at each end by a string of from 10 to 12 suspension insulator units. To form a balanced single-phase circuit, another piece of identical conductor is mounted on the other side of the towers. Voltage from the grounded-middle high-voltage transformer winding is applied to this test-circuit, but, since the measurements were made from line to ground, the losses per mile for the various conductors reported herein are based upon a test length of single conductor.

High-Voltage Low Power-Factor Wattmeter. During the winter of 1922-'23, Professor Harris J. Ryan developed at Stanford a wattmeter for direct observation of small amounts of power at high voltage and low power-factor. This instrument, in the earlier form in which the authors used it, is fully described in the paper at this Convention entitled "The High-Voltage Wattmeter" by P. C. Clark and C. E. Miller. The reader is advised to consult that paper for details of construction. The following very brief description of the instrument is given here for the reader's convenience. The feature of outstanding importance in the arrangement used by the present authors was that the wattmeter was operated at line voltage above ground. A direct connection from it to the line carried the line exciting current, while a complete system of electrostatic shielding was provided so that corona losses occurring in busses and connections were not included in the power measurement. Thus, in the application here described, the wattmeter was designed to read only the power consumed in corona losses on the test-cables or in insulator losses.

Fig. 2 is a diagram of connections, as this instrument[1] was used in the summer of 1923 in the measurement of the corona losses on the various specimens of line conductors that are reported in this paper. The large rectangle represents a shielding cage of copper screen completely surrounding those instruments which were operated at high potential. This cage was supported on an insulating pedestal and the instruments were read from a safe distance by means of grounded telescopes. The multiplier used for the watt-meter consisted of a 71-ft. length of ½-inch rubber garden hose coiled into a helix and carrying ordinary tap water supplied from a cylindrical tank hung by suspension insulators just above the helix. The shielding for the multiplier hose consisted of a second helix of similar hose concentric with, and surrounding, the multiplier helix and carrying tap water supplied from an annular tank surrounding, and forming a shield for, the first-mentioned tank. Approximately 25 kw. of power were consumed in the watt-meter multiplier and its shielding resistance when maximum voltage of 175 kv. to ground was employed. This amount of power supplied from only one-half of the high-voltage winding of the transformer would be sufficient to cause serious unbalancing of the two voltages applied to the single-phase test line from either cable to ground. Hence, during all measurements, balance was preserved by loading the other side of the transformer by a water-column connected from bus to ground, and carrying tap water from a supply contained in an insulated tank at the top. Valves were employed at the grounded ends of all water-columns to permit convenient adjustment of water flow. All water-columns discharged into a common watertank sufficiently well insulated from ground to permit the use of a milliammeter connected between this tank and ground to read the combined ground current, I_G. Obviously, when this current was reduced to zero by adjusting the rates of water flow on the two sides of the system, the transformer secondary voltages to neutral were balanced.

TEST METHODS—SUMMER OF 1923

General Procedure. The procedure to determine the power loss at any desired voltage was as follows: The sphere-gap was set according to the Institute curve for the one-sphere-grounded case. The water was started flowing at the proper rate in all three water-columns. By the use of the switches and the induction regulator in the primary circuit of the testing transformer, the voltage was increased continously until the sphere-gap sparked over. At the signal thus given, simultaneous readings were taken of the voltmeter, V; milliammeter, I_C; and wattmeter, W. If a sufficient

1. The instrument in its present refined form is described in the paper presented at this Convention by Carroll, Peterson, and Stray entitled "Power Measurements at High Voltage and Low Power Factor."

number of observers were available, the line exciting current, I_L, was also read. Observations were frequently made of the temperature of the metal of the tower in the shade and in the sun at points which were the approximate average height above ground of the conductor under test, and the average of these two readings was taken as the conductor temperature. Records were also kept of the readings of wet-, and dry-bulb thermometers (stationary-air type), barometer, time, and weather.

A Further Detail of Procedure. It was found expedient to begin taking readings for the corona curve of a conductor at its highest voltage point in order to have cooler, hence higher, resistance water in the water-columns. This reduced the likelihood of the wattmeter's voltage circuit current exceeding a safe value before the sphere-gap sparked over. Subsequent points at lower and lower voltages were less difficult to take since the water columns heated less rapidly on lower voltage. At very low voltages, it was generally found helpful either to reduce the rate of water flow, or to raise the voltage more slowly to allow time for the water-columns to heat and thus to increase the reading of the wattmeter, the increased reading being in proportion to the increased voltage circuit current.

Reduction of Test Data

Power. By dividing into the r. m. s. secondary voltage to ground, as given by the voltmeter coil of the transformer, the milliammeter reading, I_C, expressed

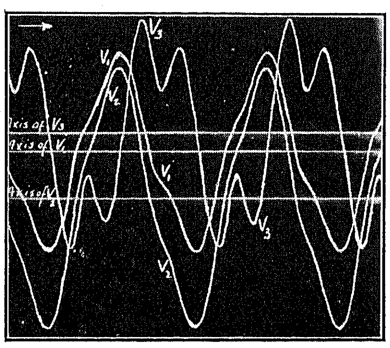

FIG. 3—OSCILLOGRAM TAKEN WHEN TRANSFORMER WAS SUPPLYING APPROXIMATELY 90 MILLIAMPERES TO BUSSES AND TEST-SPAN OF ½-INCH CABLE AT 285 KV.

V_1 transformer primary voltage.
V_2 transformer voltmeter coil voltage.
V_3 current in grounded middle of high-voltage secondary, approximately 90 milliamperes.

in r. m. s. amperes, there was obtained the total resistance in ohms of the wattmeter voltage circuit, and hence the value of the multiplier to be applied to the wattmeter readings due to the increased resistance in its voltage circuit.

Voltage Values and Wave Form. Correction for air density of the sphere-gap voltage reading was made in accordance with Section 2370, A. I. E. E. Standards, 1922 Edition.

At the higher voltages, when fairly large exciting currents were supplied to the test cables and buses, the induction regulator produced considerable distortion of the voltage applied to the primary winding of the testing transformer and, since exactly the same wave form was developed in the tertiary voltage coil (see Fig. 3) it seems reasonable to assume that the secondary (high) voltage is of practically identical distorted shape.

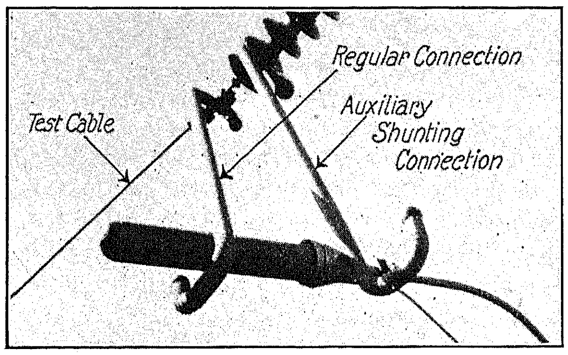

FIG. 4—METHOD OF SHUNTING OUT INSULATOR LOSSES

The sphere-gap was used for measurement of high voltage and the corona loss curves in this paper are plotted using for abscissas the r. m. s. values corresponding to crest values as given by the sphere-gap. This is in accord with the gas hysteresis theory of corona as established in the paper by Professors Ryan and Henline presented at this Convention. In that paper, it is shown that, with voltage waves within reasonable limits of distortion, corona loss is a function of the maximum, not the r. m. s. voltage.

Insulator Losses. By the use of an auxiliary connection from the shielding system to the cap of the insulator next to the cable under test, the power taken by one insulator string was shunted around the wattmeter, causing it to be carried by the shielding system. This auxiliary connection is shown in Fig. 4. In fair weather, no appreciable difference could be detected between a curve of corona loss taken with this connection and one taken without it. Therefore, it is concluded that the fair weather loss in the two insulator strings used to support each length of cable is negligible. A direct measurement of this loss on two strings in parallel mounted inside the laboratory confirmed this conclusion.

Errors in First Results and Methods of Correction

Using the experimental methods described above, the authors spent several weeks in the summer of 1923 in a strenuous effort to obtain as much test data as possible on fair weather corona losses for various cables. It was not suspected that considerable errors existed in the

power readings as given by the wattmeter; in fact, the anxiety to secure many readings while the laboratory was available operated against giving much critical analysis to the integrity of the results. The curves being secured were of a shape that seemed not unreasonable, although the apparent presence of appreciable power loss at voltages below the visual corona voltage was somewhat surprising and led to speculations as to the nature of a so-called atmospheric conduction loss, since it had already been established that insulator leakage losses were altogether negligible.

In the fall of 1923, J. C. Clark conceived the idea that the distributed self-capacitance of the helically-coiled water-hose multiplier might be the cause of some error in the watt-meter readings. Rough measurements of this capacitance were attempted and the result indicated that a very considerable subtractive correction for the leading component of the wattmeter voltage circuit current should be applied to the wattmeter readings. In the winter of 1923-'24 and the following spring, the foregoing and other errors of the original high-voltage wattmeter arrangement were thoroughly studied by Messrs. Carroll, Peterson and Stray. Their paper describes the work that was done to eliminate or to minimize various sources of error. As pointed out in the Carroll-Peterson-Stray paper, the aggregate error in the original arrangement is proportional to the square of the voltage to neutral. That the lower portions of all the curves observed in the spring and summer of 1923 obeyed a parabolic law, $W = k E^2$, was early noticed by Mr. Evenson, and for some months this fact had been held to indicate that there existed at such lower voltages a true conduction loss, $W = G E^2$, where G was thought to be a combination of insulator surface conductance and a possible "atmospheric conductance."

The curves shown in Figs. 7 to 11 inclusive are derived from the original ones observed in the summer of 1923 by the following process. First, the lower portion of the curve is fitted by a parabola, which, as shown by Messrs. Carroll, Peterson and Stray, is entirely composed of "error power;" *i. e.*, the aggregate effect of all the sources of error. This parabola is extended by the use of its equation over the entire range of voltages; finally, the complete parabola is subtracted from the original curve.

Cable Samples

An illustration of the cables tested is given in Fig. 5, and the principal physical data are given in the table of Fig. 7. The values given in the table for the pitch of the spiraling are only roughly approximate since they were the result of a very few direct measurements, and not the accurate values that would be obtained by counting the number of turns in many feet of cable.

Concentric Lay Lock-Wire Cable, Fig. 6. So far as the authors are aware, Sample F, the concentric lay lock-wire cable is new as a proposed electrical transmission conductor. In this cable, the individual strands in the outer layer may be roughly described as having a distorted dumb-bell section. These strands fit together in such a way that they hold each other in place. The periphery of the cable section is fairly smooth, closely approaching a circle. Sample F was made up on special order using dies that existed for the manufacture of

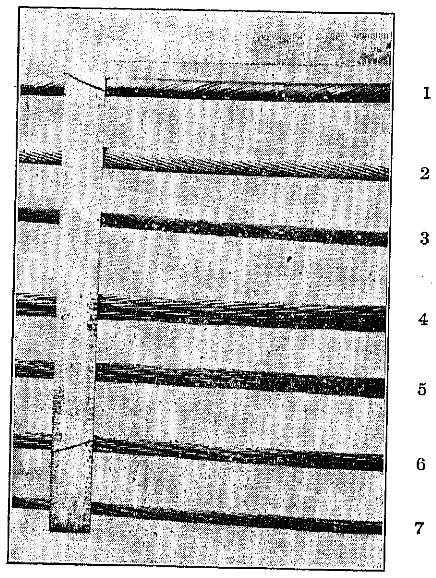

Fig. 5—Cable Samples

6. 375,000 Cm. Rope Lay
7. 225,000 Cm. Rope Lay

steel tramway cable. It is thought that, by the use of more carefully designed dies for drawing the lock-wires, the cable might be built to have a smoother surface, and hence a better corona characteristic than that of Sample F.

Steel Elevator Cable. For brevity, this cable, Sample E, is designated as a 49-strand rope-lay cable in the table of Fig. 7. However, it is really composed of six outer 7-strand ropes, with a hemp core taking the place of a central steel 7-strand rope. So far as corona losses are concerned, it is, of course, the equivalent of a 19-

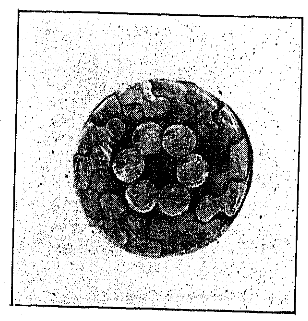

Fig. 6—Section of Lock-Wire Cable

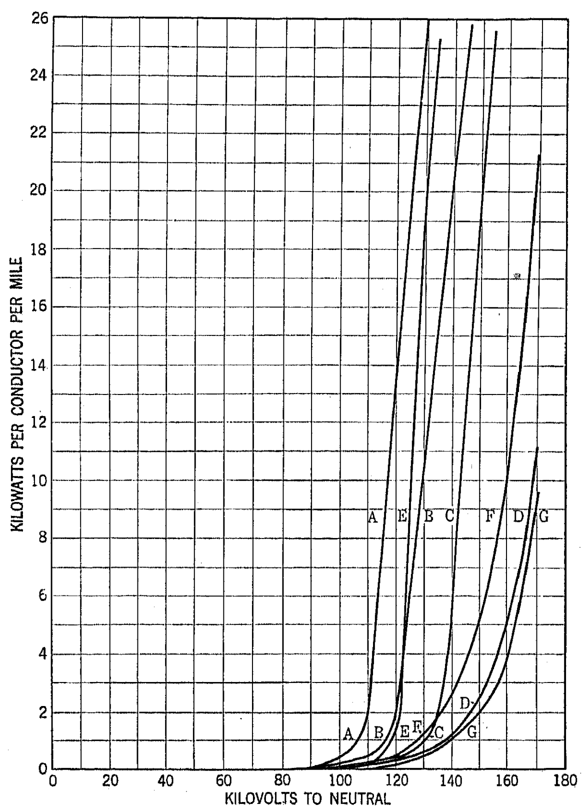
strand cable. The strands within the 7-strand ropes and the 7-strand ropes themselves, have a fairly short pitch in spiraling. This results in a cable having a considerable smoother surface than that of any of the copper rope-lay cables, samples A, B, C, or D, which all have rather long pitch spiraling.

The Other Samples. The remaining samples tested are in more common use as electrical conductors, hence require no special comment. All samples had been weathered for at least one year.

Results

The curves of Fig. 7 are representative of the results



obtained. Fig. 8 shows the same curves with the scale for power magnified ten times and with the voltage scale doubled, in order to bring out the characteristics of the cables in a range of economic importance. Fig. 9

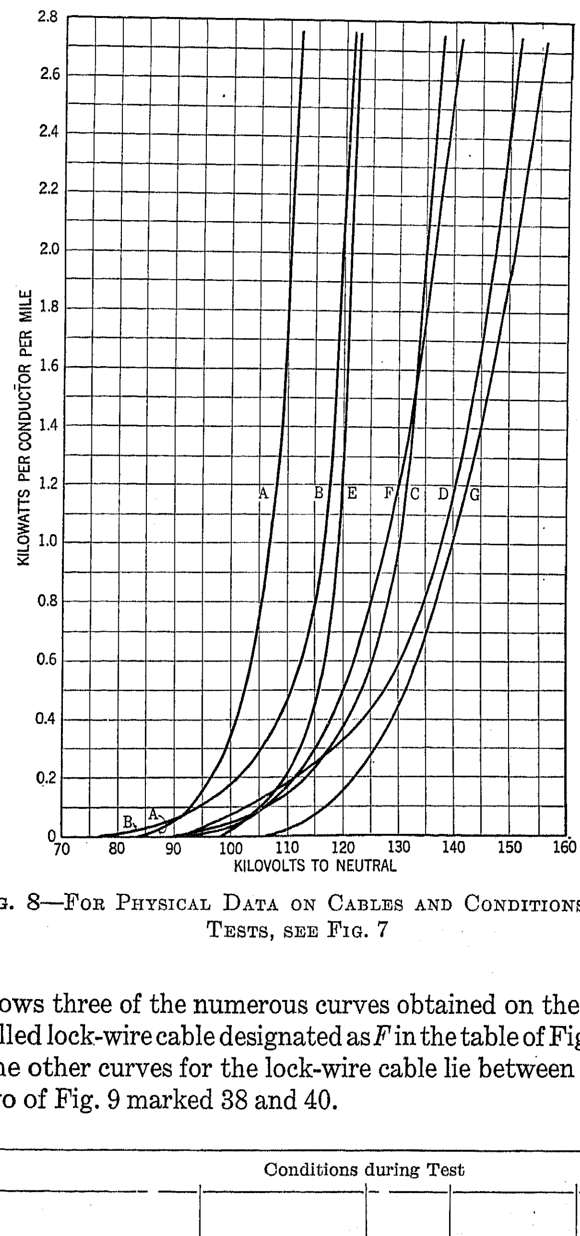


Fig. 8—For Physical Data on Cables and Conditions of Tests, see Fig. 7

shows three of the numerous curves obtained on the so-called lock-wire cable designated as *F* in the table of Fig. 7. The other curves for the lock-wire cable lie between the two of Fig. 9 marked 38 and 40.

Fig. 7—Kilowatts per Conductor per Mile

An effort was made to determine the losses over the insulator strings in an early morning hour when the dew was heavy, and Fig. 10 gives the curves obtained. The curves marked 92 and 93 were taken between 4 and 5 a. m., and they include, in addition to the loss on the cable, respectively the loss over one string, and two strings of insulators. Hence, by taking twice the differ-

ence between the two curves, the curve marked 2 (93-92) is obtained which may be assumed to represent the loss over two insulator strings. By subtracting this insulator loss from curve 93, the curve marked 93-2 (93-92) is obtained which may represent the loss occurring on the cable only. For comparison with this curve, the typical fair-weather non-dew run given by curve 42 is reproduced in Fig. 10. It is seen that, above about 135 kv., the curves are in rather good agreement, but that their lower portions are not in accord.

A series of measurements was made to determine the manner in which the loss for the concentric lay 1.008-inch aluminum cable (Cable G in Fig. 7) depends upon spacing. The results are shown in Fig. 11.

Numerous other runs were made besides those shown in the curves. Values taken from the corrected smooth curves are shown in the table of Appendix A in order that any one interested may plot the results of any of the fair-weather runs that were made.

For illustration of the nature of the original test data, the method of their reduction to values for plotting, and the correction for error power, see Appendix B and Fig. 12.

It will be noted from the curves and from the other data tabulated in Appendix A, that curves taken on the

same cable vary from each other considerably. Independently of conditions of humidity, temperature, and barometric pressure which, of course, all cause some divergence among observations at any given voltage, there exist the difficulties of deriving the results by the methods available. Since the test-piece of cable was short, the readings on the scale of the wattmeter were

low. This made it necessary for a number of the lowest readings to estimate the position of the pointer to the nearest one-tenth (occasionally one-twentieth) of the lowest one of the 150 equal divisions of the 15-watt instrument that was used prior to test 94. For test 94 and subsequent tests, a 1.5-watt instrument was available and much improvement was made in the plotting of the lower portions of the curves. As will be seen by a study of Fig. 12, the process of subtracting rather large amounts of "error power" may be expected to yield curves for true corona loss showing considerable variations in their lower portions.

With the greatly improved facility now available in the present instrument which no longer includes appreciable "error power" in its readings, it should be possible to make measurements of the same order of accuracy as that of the readings of the calibrated instruments with which the measurements are made. The opportunity for such measurements on the cables discussed herein has not yet been available.

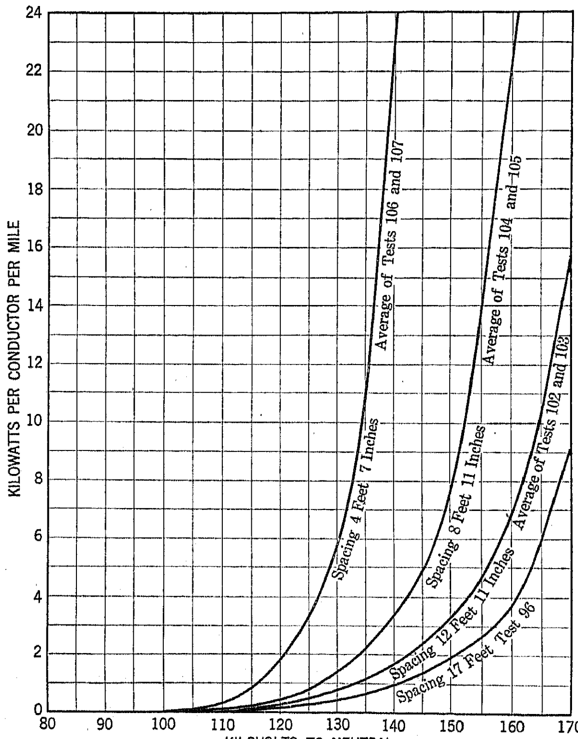

FIG. 11—ALUMINUM 37-WIRE CONCENTRIC STRAND LOSSES AT FOUR DIFFERENT SPACINGS

Conductor Diameter 1.008 inches.

ACKNOWLEDGMENTS

The authors are greatly indebted to the following who have aided this investigation in the ways stated:

The Pacific Gas and Electric Company for the donation of the 500,000-cir. mil rope-lay copper cable,

The Bureau of Power and Light, Department of Public Service, City of Los Angeles, for the donation of the 225,000-cir. mil, 375,000-cir. mil, and 900,000-cir. mil. ropelay copper cables; and the 700,000-cir. mil concentric lay lock-wire copper cable,

The Stanford University for the use of the High Voltage Laboratory, and for many other facilities; also for the power service during the tests,

Professor Harris J. Ryan for his cordial interest and encouragement manifested in innumerable ways. Without his high-voltage wattmeter, these measurements could not at this time be reported.

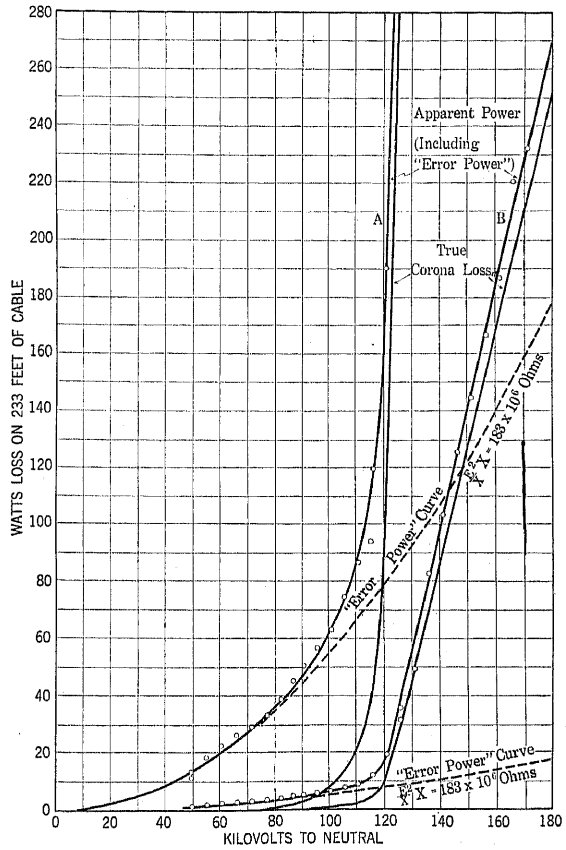

FIG. 12—375,000-CIRCULAR MIL ROPE-LAY CABLE 17-FOOT SPACING

Test Number	79
Date of Test	July 26, 1923
Time	11:31 A. M.
Temperature (Mean)	80.6 Deg. Fahr.
Humidity	58.2 Per cent
Barometer	30.00 Inches
Weather	Clear, Slight Breeze
Conductor	49-Strand Rope-Lay
Diameter	0.80 Inch
Area	375,000 Cir. Mils
Spacing	17 Feet
Length Tested	233 Feet
Conversion Factor to Mile	22.66
Test by	J. C. Clark and F. F. Evenson
Method:	Ryan's High Voltage Wattmeter

Note: Curves *A*, Read Directly. Curves *B*, Multiply Watts by 10.

NOTES

The word "corrected" in the column headings means simply that the original readings have been corrected by the use of calibration curves for the various instruments.

To obtain the factor by which the corrected wattmeter reading (column 5) is multiplied to give the true watt loss (column 7): Divide the r. m. s. voltage to neutral by tertiary coil voltage (column 4) expressed in volts by the multiplier current through water column (column 6) expressed in amperes. This gives the total resistance of the wattmeter voltage circuit. The ratio of this resistance to that of the normal 150-volt wattmeter voltage circuit, 4432 ohms, gives the desired factor.

The following is an illustration using the figures for the first observation in the above table:

$$\frac{174800}{0.07469} \times \frac{1}{4432} \times 4.937 = 2320.$$

IMPORTANT: The above calculated losses in watts are for the test length of this cable, 233 feet. The losses in Column 7 of the table include the "error power," and to obtain the net true power, there must be subtracted from the curve for the given *test length*, the error power curve:

$$W = \frac{E^2}{183 \times 10^6}$$

where E is in volts,
W is in watts.

To obtain the losses in watts for one mile of cable, multiply the net corona loss curve by 22.66.

Discussion

For discussion of this paper see page 1162.

Corona Loss Tests on the 202-Mile 60-Cycle 220-Kv. Pit-Vaca Transmission Line of the Pacific Gas and Electric Company

BY ROY WILKINS
Associate, A. I. E. E.
Pacific Gas & Electric Co., San Francisco, Cal.

Review of the Subject.—*A description is given of the physical and electrical characteristics of the Pit-Vaca 220-kv. transmission likely to affect corona loss. The line contains three distinct configurations and two sizes of conductor. Corona loss measurements were made from Pit Power House on the three configurations and from Vaca Substation on one of the configurations. Three methods of measuring corona losses were used at Pit and four at Vaca.*

The measured corona losses were found to follow exponential laws in three distinct phases: below visual corona, visual corona and visual corona with losses sufficiently high to produce voltage distortion. At no point did the losses follow a quadratic law. A review of the reports of the results of corona loss tests on other lines indicates that the corona losses followed exponential laws.

At the time the Pit No. 1 plant was put in operation, late in 1922, the transmission line to Vaca-Dixon Substation went into service at 110 kv. first, because some parts of the line hardware and insulators were not available in sufficient quantities to equip the line for 220 kv., and second, because there was no need for the higher voltage to transmit the power then available.

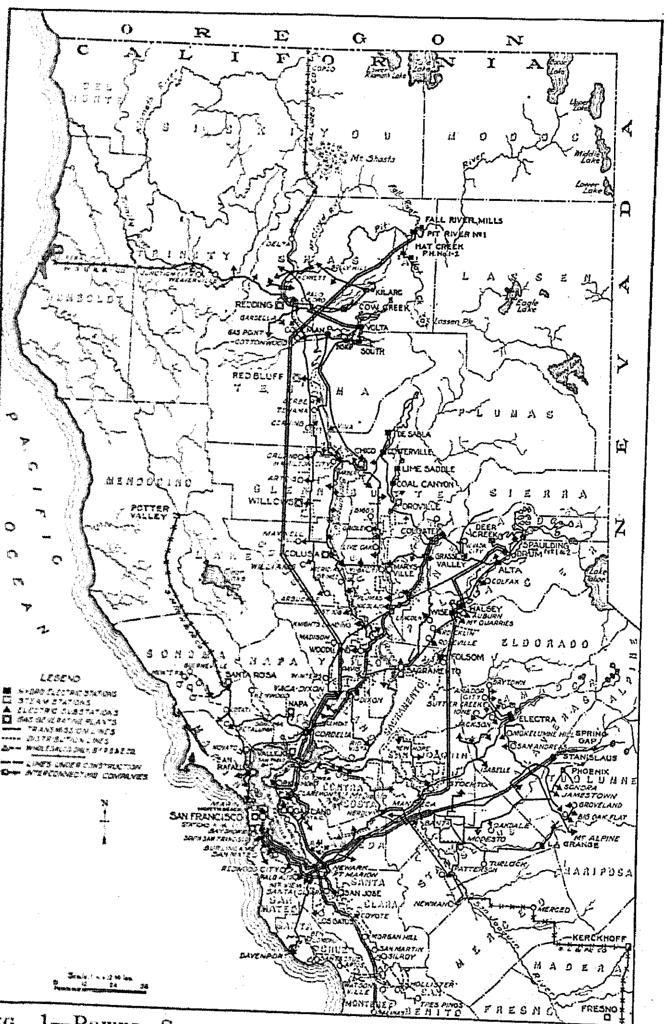

FIG. 1—POWER STATIONS. PACIFIC GAS & ELECTRIC CO., SAN FRANCISCO, CAL.

Between that time and November 1st, 1923, the original line was insulated for 220 kv. and the second line was built and insulated for 220 kv., but both were operated at 110 kv. Before the original line was put into operation at 220 kv. during the first part of November, 1923, corona loss tests were made quite carefully on such sections of the line as could conveniently be handled at the power house.

These lines will both be operated at 220 kv. as soon as the power from Pit No. 3 is available, sometime in 1925. In the meantime they will be operated as they were at the time of the test, one at 220 kv. and the other at 110 kv.

An idea of the geographical location may be gained from the map of the Pacific Gas and Electric Company's transmission system and an idea of the elevations from the following table:

TABLE I

Location	Miles	Elevation
Pit	0	2800 Ft.
Maximum elevation	15	5200 "
Round Mountain	27.5	2157 "
Elevation	40	1000 "
Cottonwood	60	433 "
Williams	143	125 "
Vaca	202	83 "

The line insulation is shown in a chart included, and the tower data on the following table:

For the first 27½ mi. from the power house, these lines are of steel core aluminum and each circuit will ultimately be on its own tower line with a horizontal spacing of 19 ft. between wires and 75 ft. between center wires of the two circuits.

At the present time the 110-kv. line has its towers complete as called for in the ultimate plans.

The 220-kv. line was at the time of test and is now operating on "*H*" type wood poles with standard single-

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

circuit towers at angles and places where it was thought that the poles were inadequate.

These poles have a conductor spacing of 16 ft. and are spaced much closer together than the towers on the 110-kv. circuit, giving the required 30 ft. minimum clearance

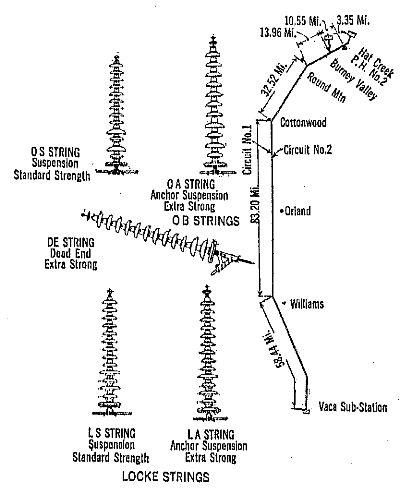

Fig. 2

Section	From	To	Conductor	
			Circ Mills	Material
1	Pit River PH No. 1	Hat Creek PH No. 2	518,000	SC. A1.
2	Hat Creek PH No. 2	Round Mtn.	518,000	SC. A1.
3	Round Mtn.	Cottonwood	500,000	Cu.
4	Cottonwood	Williams	500,000	Cu.
5	Williams	Vaca	500,000	Cu.
6	Pit River PH No. 3	Burney Valley	518,000	SC. A1.

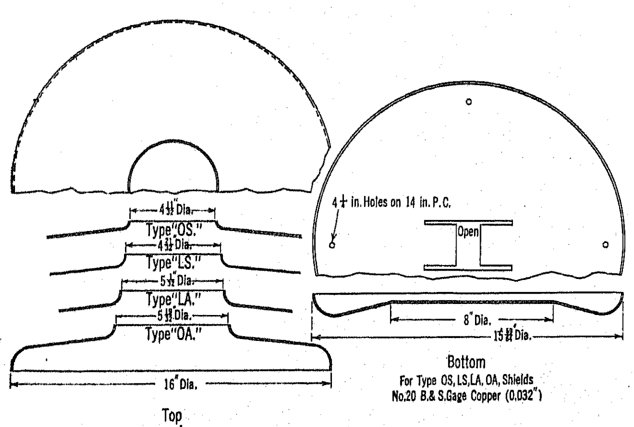

Fig. 3

to ground, but having an average clearance of less than would be indicated by the tower data.

There are 202 pole structures and 98 towers from Pit to Round Mountain and 320 pole structures and 39 towers from Round Mountain to Cottonwood. These give, as nearly as can be determined from the profiles, an average of 17 ft. from Pit to Round Mountain and 16.3 ft. from Round Mountain to Cottonwood.

The aluminum conductor is made up of 42 strands 0.112 in. in diameter around a 19 strand steel core, each strand of which is 0.111 in. in diameter.

The weight per mile is 5900 lb., of which the aluminum is 2560 lb.

The next 32½ mi. is of 49 strand rope lay copper, 500,000 cm. in area with the configuration and spacing as noted above.

The copper is of 7 by 7 strand M. H. D. rope lay, made up of 7 strands 0.101 inch in diameter with a left

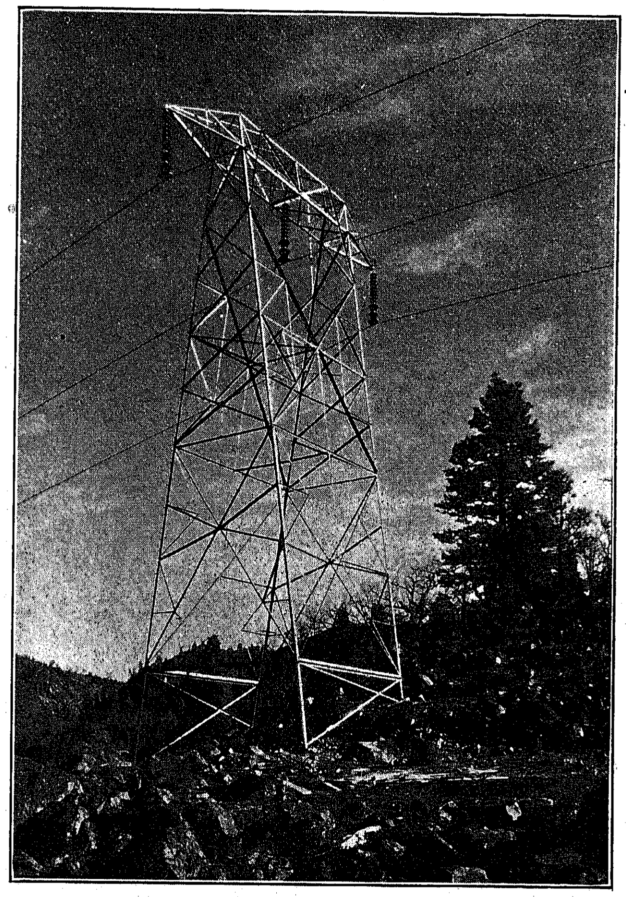

Fig. 4—Tower in Horizontal Configuration, Aluminum Section

hand lay, and a pitch of 5 inches; of these, 7 are in turn cabled into a rope with a 15 in. pitch right hand lay. A circle enclosing the cable is 0.91 inches in diameter.

From this point 142 mi. to Vaca-Dixon Substation, both lines are on the same twin circuit tower with 15 ft. vertical spacing and 24 ft. between circuits, using the copper conductor described above. The lines are completely transposed with respect to the ground and communication circuits, and each circuit with the other. Complete barrels have an average length of 15.5 mi. as shown in the diagrams.

The transformers at the power house are 16,667-kv-a. single phase, 127,000 to 11,000, connected Y-Delta

TABLE II

with the ground terminal of the high tension permanently grounded, giving 220,000 normal operating voltage on the line. Those at the substation are 16,667-kv-a., 115,500 to 63,600 auto-transformers with an 11,000-volt delta winding which is connected to 20,000 kv-a. synchronous condensers.

The lines are equipped with a reverse power and

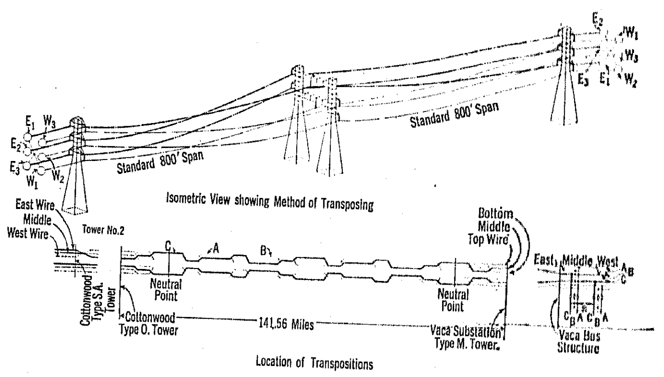

Fig. 6

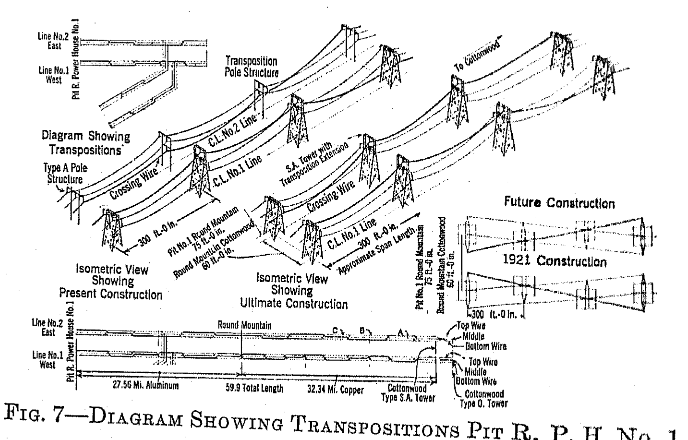

Fig. 7—Diagram Showing Transpositions Pit R. P. H. No. 1 to Cottonwood

residual relay combination allowing the clearing of a line in trouble on much less than normal current for grounds or phase unbalances, and having directional

features so that it functions equally well with either one or both lines in operation.

The transformers are protected by balanced relays and the generators by over-voltage and balanced relays.

Switching is done on trouble on the 220 kv. in the same way that the lower voltages are handled.

When switched out, the lines are energized by charging with a generator at reduced frequency, starting a condenser at Vaca, building up the speed and paralleling at the substation.

When the tests were contemplated, it was decided to use at least two methods of measurement with calibrated instruments and instrument transformers on the low-tension side of the transformers for one set of readings and the current in the ground side of the high-tension winding of the main transformers, together with a calibrated water hose resistance, for the other set.

This hose resistance is made up of two ½ in. garden

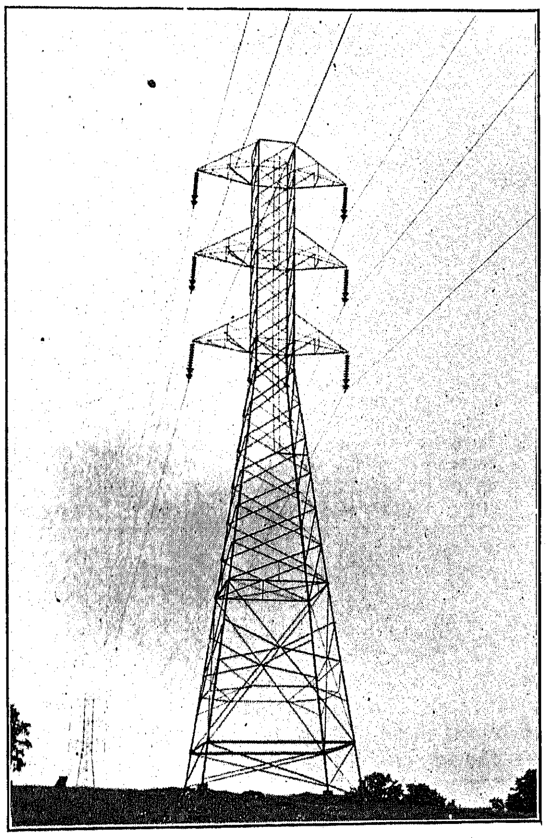

FIG. 8—LINE IN VERTICAL CONFIGURATION WITH TOP OF TRANSPOSITION IN BACKGROUND

hose approximately 75 ft. long in parallel, connected to the 220-kv. line at the top and grounded at the bottom. Water is forced up one hose and flows down the other, and the voltage used is shunted off a few inches of the ground ends.

In addition, the turbine gate opening was calibrated in generator kilowatts output, giving a fairly accurate check on total losses by a totally different method. At each reading, oscillograms were taken and some of the representative curves are included in this report.

Transformer iron losses were accurately measured on the transformers in place, and copper losses were calculated and checked against factory measured values.

The $I^2 R$ due to charging current in the line was calculated by the method proposed by Jacobsen appearing in the A. I. E. E. PROCEEDINGS. This was checked against the method used by Lewis in the A. I. E. E. of June 1921 and was finally determined by graphically integrating for five-mile intervals.

Using the low-tension readings as a standard, the

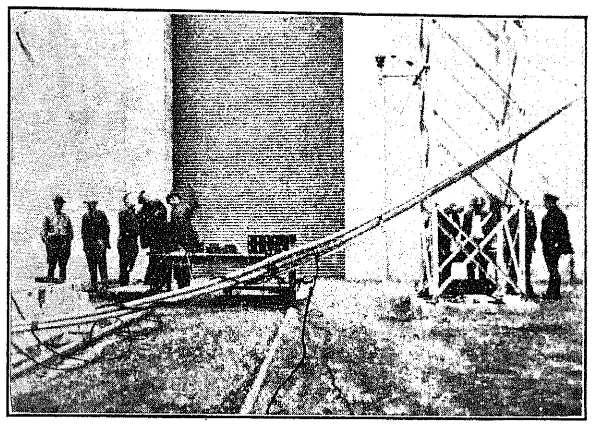

FIG. 9—HOSE AT PIT NO. 1

several loss curves were plotted, using values corrected for instrument and instrument transformers and having the transformer losses subtracted.

These values having the $I^2 R$ of the line subtracted were next plotted and finally the values per wire per mile were plotted. As originally taken, the values for the 15-ft. vertical spacing were obtained by subtraction of two tests and correcting for voltage rise, inasmuch as these values were lower than those on the 19-ft. horizontal spacing. A test was made at Vaca-Dixon Substation charging back 59 mi. to Williams. The agreement between these two curves, 29 and 31 is very good and as all the values at Pit are checked against the

waterwheel output, it is felt that reliable results are obtained.

Test Results:

There are included four sets of data:—

1—A test from Pit to Round Mountain from which Curves 21 and 27 are plotted.

2—A test from Pit to Cottonwood from which Curves 22, 25 and 28 are plotted.

3—A test from Pit to Williams from which Curves 23, 26 and 29, are plotted.

4—A test from Vaca-Dixon to Williams from which curves 24 and 30 are plotted.

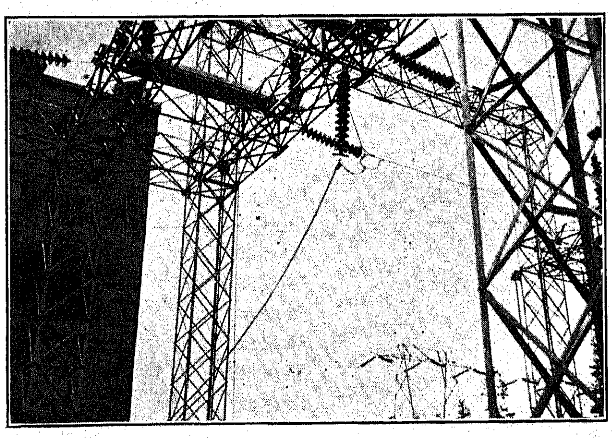

FIG. 10—HOSE AT PIT NO. 1

There is included a curve of the hose calibration, the water-wheel calibration, the transformer losses, one comparing the high-tension readings, and finally, curves plotted on semi-log paper showing the general law of the loss measured. There is also given measured single and three-phase impedance.

Calibration Low-Tension Readings. The instruments were calibrated at the approximate power factor used before the test and after completion rechecked at the test power factor and load readings. The instrument

V. M. Res. 3623 Ohms

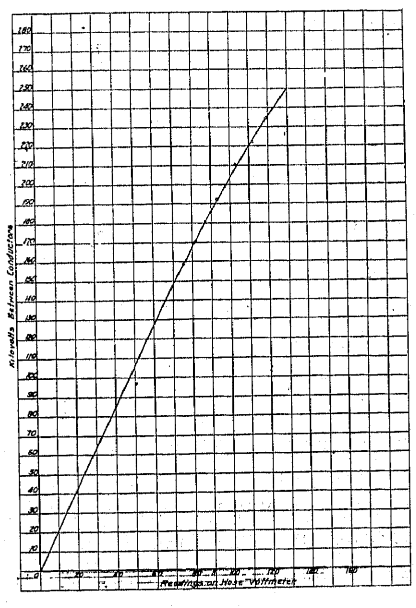

FIG. 12—HOSE CALIBRATION

transformers were calibrated for ratio and phase angle and the values for correction taken from curves. These corrections individually were never more than 1.2 per cent when applied to the low-tension readings, and when combined, were less than the individual corrections as they were in error in opposite directions.

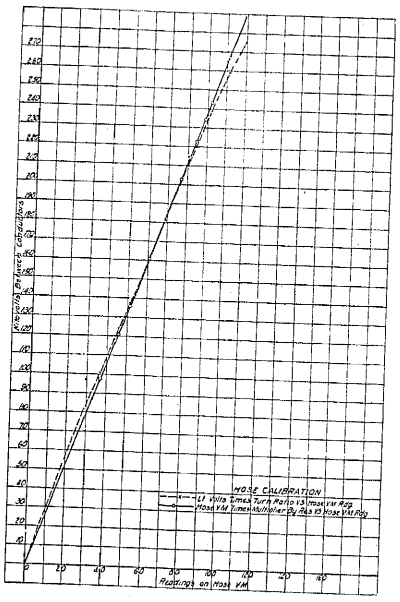

FIG. 13

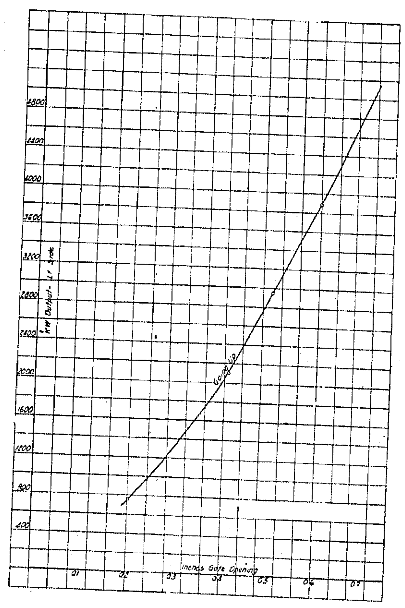

FIG. 14—CALIBRATION OF NO. 2 WATER-WHEEL KW. READ ON 11 KV. AT 1 POWER FACTOR

These corrections were applied, although it is believed they are very close to the accuracy with which it was possible to read the meter. Inasmuch as the losses were considerable, at times over 20,000 kilowatts, the readings were for the most part well up on the meter scale.

Calibration High Tension. The voltmeter on the

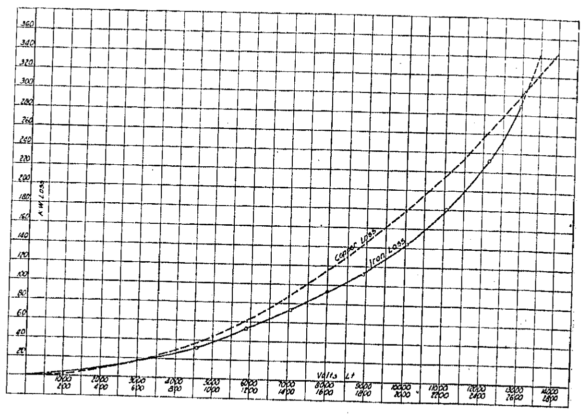

FIG. 15—THREE-PHASE TRANSFORMER LOSSES NO. 2 BANK PIT NO. 1 3-16667 KV-A. 220 KV. Y-GROUNDED TO 11 KV.

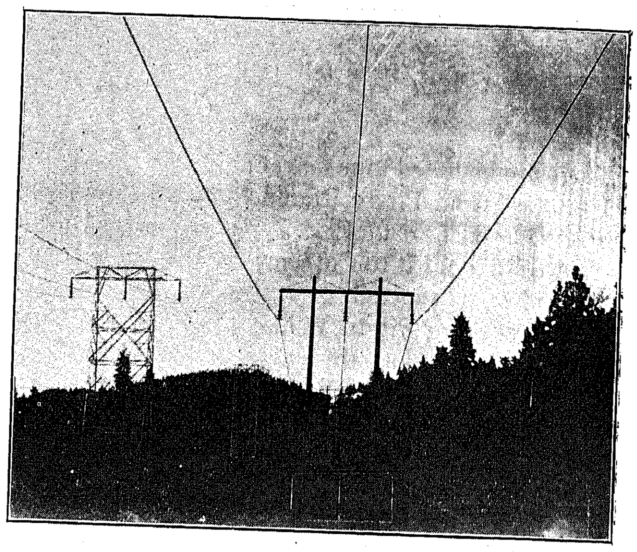

FIG. 16—ALUMINUM LINE AT ROUND MOUNTAIN LOOKING NORTH TOWARD PIT FROM THE FIRST TOWER ON THE ALUMINUM SECTION. ONE HOUR EXPOSURE, PANCROMATIC FILM

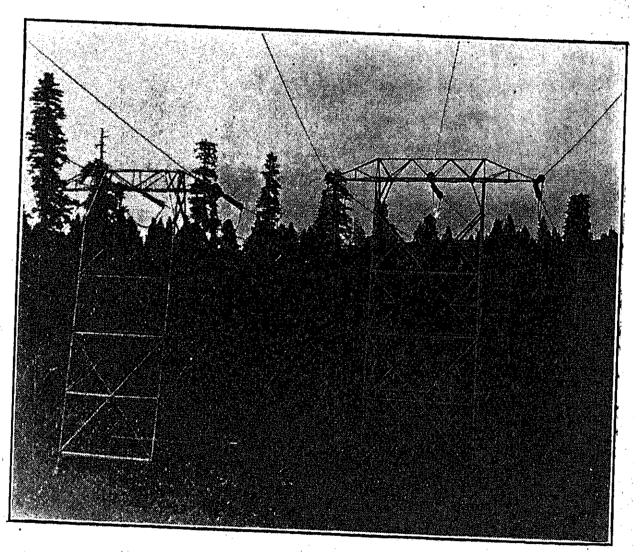

FIG. 17—VIEW OF COPPER LINE AT ROUND MOUNTAIN LOOKING TOWARD PIT FROM THE FIRST TOWER IN THE COPPER SECTION. ONE HOUR EXPOSURE, PANCROMATIC FILM

high tension was calibrated, first, by using the *lowtension* voltage at the turn ratio with the transformer alone

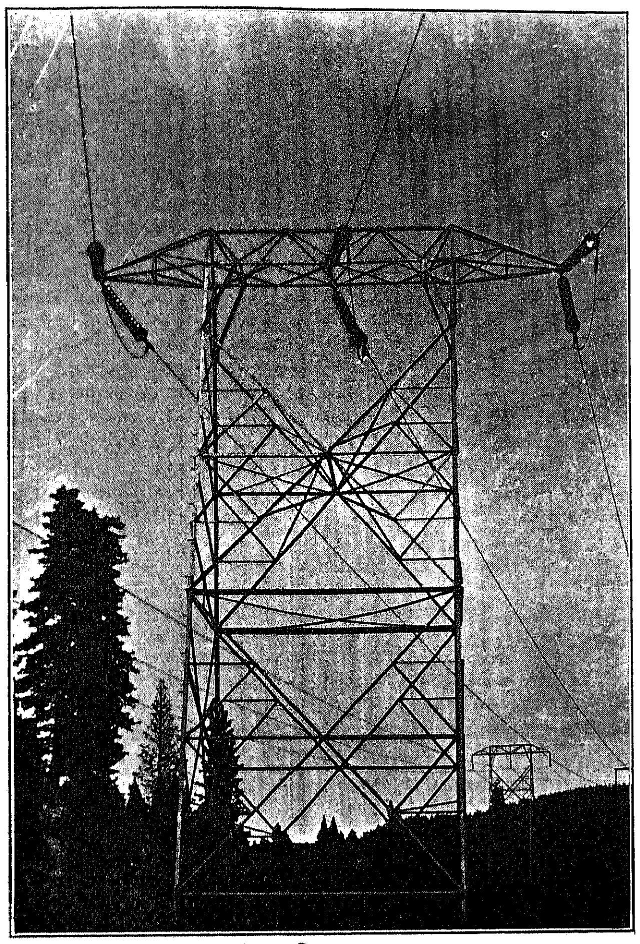

FIG. 18—VIEW OF ALUMINUM LINE, FIRST TOWER NORTH OF ROUND MOUNTAIN, DEAD END. ONE HOUR EXPOSURE, PANCROMATIC FILM

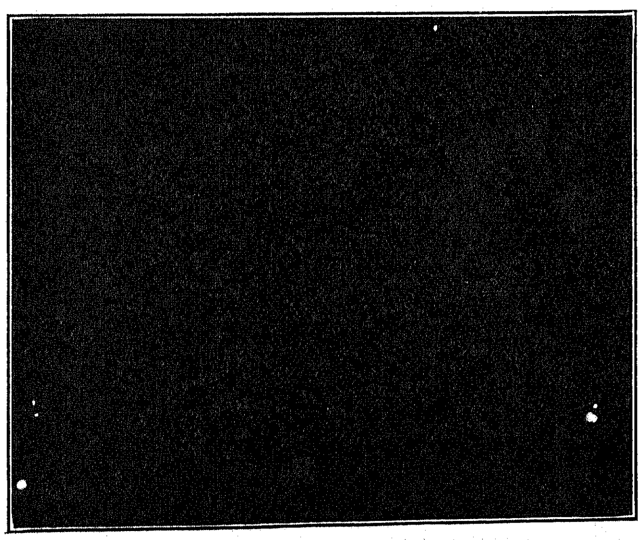

FIG. 19—TOWER AND INSULATORS ON ALUMINUM SECTION. QUARTZ LENS. TEN-MINUTE EXPOSURE, PANCROMATIC FILM

excited from the low tension, and second, by measuring the hose resistance by two independent methods and using this resistance in the usual multiplier formula, correcting by several approximations for the shunted part of the hose. Both of these calibration curves are plotted.

The high-tension wattmeters were calibrated for approximate power factors but on test showed very consistent curious reversals which were studied somewhat further and will be discussed later.

Water-Wheel Calibration. The water-wheel was calibrated in kilowatts generator output against gate

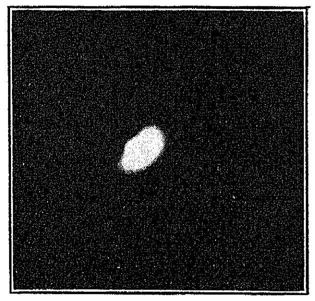

FIG. 20—CORONA SPOT ON ALUMINUM CONDUCTOR. QUARTZ LENS, SIX-MINUTE EXPOSURE, PANCROMATIC FILM

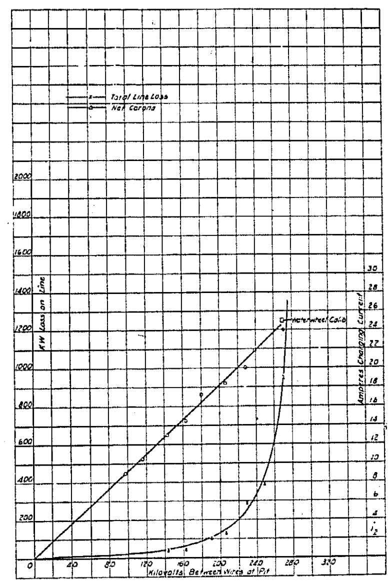

FIG. 21—CORONA LOSS AND CHARGING CURRENT FROM PIT NO. 1 TO ROUND MT. CORRECTED FOR TRANSFORMER LOSS—27.5 MILES OF ALUMINUM HORIZONTAL 17—FOOT SPACING

opening, using special small current transformers at unity power factor.

While somewhat crude, these readings are manifestly unaffected by power factor, phase angle, etc., and give considerable assurance when they check the more precise measurements.

Barometer and Temperature. Barometer and temperature readings were taken and are included in the data. No attempt has been made to reduce these values to sea level and 25 deg. cent. for the reason that

the only correction formulas available contain several unknown factors not directly measurable, and inasmuch as the results depart from the general law of which these factors are a part, it was thought best to give the data as secured.

Considerable effort was exerted in trying to find out if there were any corona or other emanations or disturbing influences present around the insulators that could be photographed, all giving negative results. The views given with their titles are self-explanatory and are representative.

Observed Corona. Under normal running conditions photographs of the line with a very high grade commercial lens and a quartz lens loaned by Mr. Peek, were made and are included.

It should be borne in mind that most of the exposures are for considerable time and therefore show more corona than would be visually observed under the same conditions; and that a film of the character used is much more sensitive than the eye to corona discharge.

It is noticeable, as before noted, (Lewis, TRANS.

A. I. E. E., p. 1079, 1921) that corona is the most profuse on the middle conductor and in proximity to ground; also it can be noted that the conductor next to the parallel circuit on the horizontal spacing has more corona than the outside one. Inasmuch as the conductors are transposed on the circuits under test, the individual conductor losses check, as demonstrated repeatedly during test. It is difficult, however, to include any such effect in a general formula, taking account only of the mean geometric spacing of conductors.

No storm losses are so far available but observations of storm conditions were made on the valley section of vertical spaced copper conductor and are included.

Only a representative set of data is given for each test. For instance, four complete curves were taken from Pit to Round Mountain during two consecutive days, in order to check the high-tension wattmeters, giving points that fall exactly on the same curve, as nearly as can be plotted.

The several instruments were read by more than one person to avoid any personal errors and every pre-

caution used to see that no faulty connections or equipment were used.

In all there were used:

1—Calibrated turbine gate opening.

2—Low-tension k-w., amperes and volts.

3—High-tension voltage from hose.

4—High-tension kw. from the ground end of the high-tension transformer winding, and voltage from the ground end of the hose.

5—High-tension kw. from the line end of the transformer high-tension winding and the high-tension end of the hose.

6—High-tension kw. using the ground end of the transformer high-tension winding and potential from the spare transformer and an 11-kv. potential transformer.

7—Oscillograms at each reading.

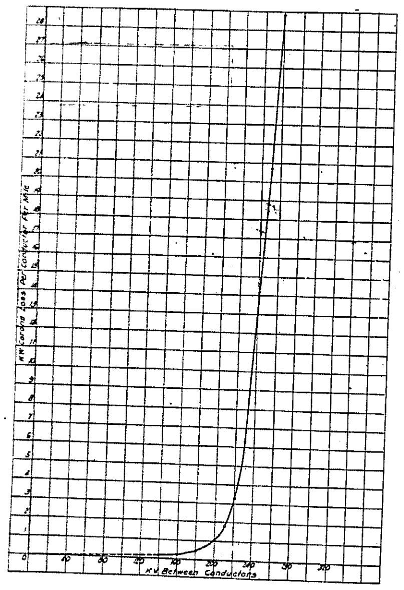

FIG. 30—CORONA LOSS ON ROPE STRAND 500,000 CM. COPPER

A study of each of these leads to the following conclusions:

1—The turbine gate opening calibrated in kw. generator output at unity power factor is, of course, approximate, due to the difficulty of reading accurately, but being affected by neither power factor nor phase angle it gives an added assurance when it checks the more accurate methods.

2—The low-tension kw. were used as a standard, and every precaution used to secure accurate data.

The curves given are based on these readings and the several other methods considered as checks against them.

3—High-tension voltage was measured directly on a voltmeter and the hose described above.

This hose was left in service several days to determine whether there would be any deterioration or change due to difference in water resistance.

For the same conditions no change could be detected, though for conditions which caused considerable leading current to flow through the transformers, the voltage rise above the turn ratio was greater than the usual calculations indicate. (See Lewis, A. I. E. E., 1921).

4—In the original scheme it was decided to use the current in the ground side of the transformer high

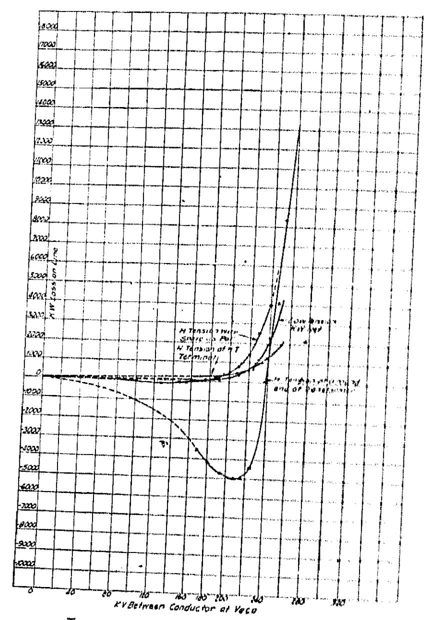

FIG. 31—CORONA LOSS CURVES FROM VACA-DIXON TO WILLIAMS Cor. for Meters and Transformer Losses. 59 Miles Copper. 15 ft. Vertical Spacing

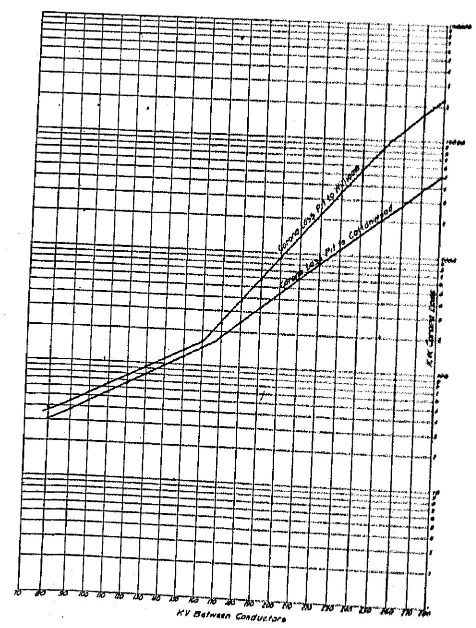

FIG. 32

tension and potential from the ground end of the hose, giving the loss on one conductor.

In practise, it was found that the wattmeter reversed part way up the curve and gave apparent losses much higher than the known generator load.

It was finally decided that this was due to phase angle, but no practical field method of calibrating it could be found.

An attempt was made to shield the hose by enclosing it in a larger hose, running water up the inside and down between the two sizes of hose and using the inner hose on the wattmeter with no practical change in results.

5—The wattmeter was shielded and its current coil put directly in the line using the top part of the hose for potential.

This gave high results at low voltages and low results at high voltages.

6—During the time that the tests were carried on at Pit, an attempt was made to measure the loss in one conductor from Vaca to Williams using the ground of the transformer high tension and the spare transformer, together with an 11-kv. potential transformer to supply voltage.

This gave similar results to the original hose combination, being negative at low voltage and high at high voltages, the negative values being much less as shown in curve 31.

Some two weeks later this was checked in addition to low-tension readings and for the same physical conditions even though read by a different person on another meter. The curve, so far as could be read, was exactly the same and showed an appreciable negative loop at low voltages.

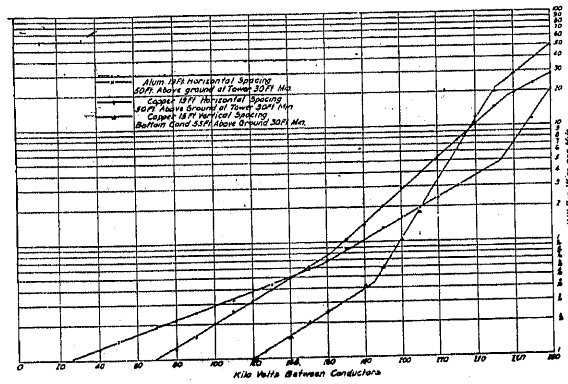

Fig. 33—Corona Loss in Kw. per Wire per Mile

The low-tension readings checked very closely the losses determined at Pit for the same configuration.

These several combinations of high-tension readings are plotted in curve together with the low tension for the same configuration.

By applying a correction for phase angle, these check the low-tension readings and while the phase angle could be calculated approximately, no direct measurement could be taken. They are therefore included only as a matter of interest and an indication of the difficulties of direct high-tension measurements.

The method of correcting for instruments, transformers and $I^2 R$ losses has been described and mention has been made of the voltage correction.

From Pit to Round Mountain the voltage rise was of very little importance being in the order of one kv.

With more lines added, as from Pit to Williams, the rise is appreciable and since it was desired to determine the loss from Round Mountain to Cottonwood and Cottonwood to Williams, the voltage rise was calculated, using the values of line constants determined by the test in the convergent series formulas.

It was discovered that the losses as taken followed an exponential law and plotted a straight line on semi-logarithmic paper. This allowed us to correct the losses in small enough sections that the voltage rise over that section was inappreciable.

This voltage rise correction was not thought to be essential but was carried out for the loss from Round Mountain to Cottonwood and from Cottonwood to Williams.

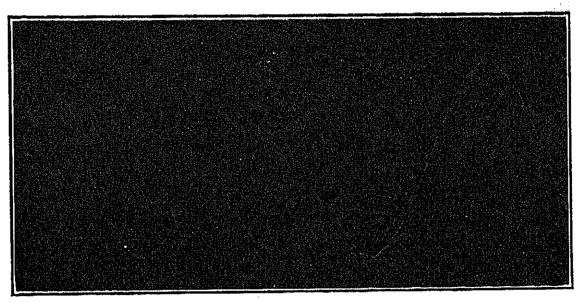

Fig. 34—Pit No. 1. Wave Form No. 2 Generator. Normal Speed, Normal Volts Disconnected

This last was checked by an entirely separate test from Vaca to Williams taken at Vaca and plotted for voltage at Vaca.

This checks almost exactly the corrected curve from Cottonwood to Williams, indicating that the method used was correct.

The final results are given in loss per mile per wire on a line in which the rise in voltage was very small and so can be used to build up the losses on a similar line of any length, provided the voltage along it is known and short sections used; it also allows us to determine what the losses under load conditions would be on a line with a lower voltage at the receiving than at the sending end.

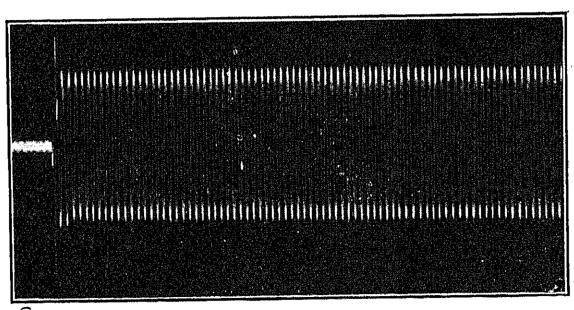

Fig. 35—Corona Loss Tests Pit-Vaca 220 Kv. Line

Switching on Line at Vaca. Record at Pit with Line open except for Hose to Ground. Steady state 133,700 Volts to Ground at Pit.

From the final results it will be noticed that the portion of the line having a comparatively low horizontal spacing has a higher loss for low voltages (even with the

conductors farther apart), than the higher vertical spacing.

On the higher voltages the closer spacing has the higher loss. This indicates that the distance to ground has considerable effect on the loss, and may at times overshadow the distance between conductors.

As the voltage is increased, a point is finally reached where the slope of the curve changes so that the increase in loss per kv. increase in voltage is less than on the lower part of the curve.

At this point the current wave begins to be distorted and a 180-cycle ground current flows, which at the higher voltages, reaches values of one-third of the total charging current.

This is clearly shown in Figs. 36, 37 and 38 wherein the oscillograph remained unchanged, only the line voltage being raised. This has been discussed in previous papers, though the fact that the actual corona loss does not increase as fast with increase in voltage as at the lower voltages does not seem to have been noted. (Peek, Lewis, p. 1155, p. 1079, TRANS. A. I. E. E., 1921).

For the aluminum wire this point could not be reached because of the larger conductor and comparatively short line.

There is, however, a break in the aluminum loss line at about 155 kv. between conductors. This is below the visual corona and it has been suggested that it is connected in some way with the insulating film on the conductor and the ionization around it.

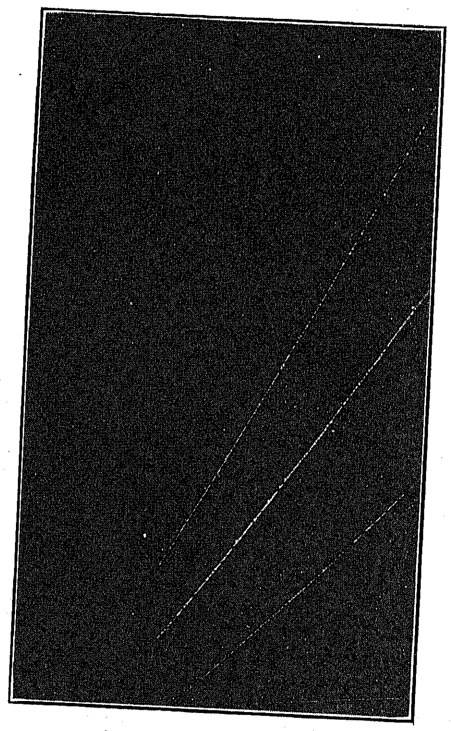

FIG. 39—CORONA AT NIGHT IN RAIN. PIT-VACA 220-KV. LINE AT 3 MILES FROM VACA

The curves secured seem to divide the corona loss into three phases as regards line voltage:

1—Losses below the point where the corona is visual, called by Professor Ryan dark brushes and discharging free ions.

2—The visual corona in which the losses are considerable and the increase in kw. loss per kv. rise in voltage is greater than in Case 1.

There, visual brushes are formed and ionization by collision is the important loss medium.

3—At a point sufficiently high in voltage a considerable third harmonic flows, deforming the current wave (see oscillograms Figs. 36, 37 and 38, and decreasing

the slope of the curve, *i. e.*, having less loss increase in kw. per kv. increase than 2.

The loss has the nature of a gas electrical hysteresis with half arc characteristics and at this point the charging current deviates from a straight line indicating that the dimensions of the conductor have in effect increased (see Curve Fig. 23) as suggested by Peek (A. I. E. E., July 1921).

There has not so far been sufficient data accumulated to make any attempt to formulate a law or fit to the

existing laws in order to determine what the loss would be for conditions other than those under which the data were taken.

So far no actual mesaurements have been taken during storm conditions. Observations have been made, however, and a kodak picture taken during a comparatively heavy rain storm at night.

After dark and during the time that rain is actually falling the conductors are faintly luminous and can be traced between towers.

On inspection at close range the luminous area is made up of corona tufts or brushes, some two inches long, starting in a bright core and ending in a blue brush at the points where a rain drop comes near to the conductor.

Their position would give an average spacing of from 12 to 17 in. during heaviest rainfall, and at times when few rain drops fell, of probably two or three feet.

There is no regularity in either their position or direction and they seem to flit back and forth along the conductor remaining only a fraction of a second in one place.

It was noticed that no rain drops collected on the 220-kv. conductors as they did on the 110 kv. of the same size conductor in the same tower.

In the higher elevations the same effect is noticed with the snow, it being harder, of course, to see just what happens to the brushes.

Roughly, from station meters, the corona loss seems to be approximately doubled, dropping back to normal again as soon as the storm ceases.

A great many engineers have stated that it is advisable to run below the visual corona point. This statement is open to question and the final solution is economic rather than technical.

The $I^2 R$ loss on the line under discussion at full load is 8500 kw. approximately. As the voltage is lowered to decrease corona the $I^2 R$ increases and conversely when the voltage is raised to decrease $I^2 R$ corona in-

creases. There is therefore a certain point most efficient which in territory subject to storms would be lower than that for the same conductor in a more advantageous climate.

At present there seems to be no way of determining what the corona loss on a proposed line will be at the voltage present practise gives it to operate, and this is the particular region in which power company engineers are interested.

The losses at voltages below visual corona are con-

siderable and if known might in certain cases vary the size of conductor used 100 per cent (see Jakobsen, TRANS. A. I. E. E., p. 91, 1918).

On the line tested, the losses are greater for a line close to the ground even though it has a greater spacing. This is not accounted for in present formulas.

In lines where several constructions of line are alternates this will affect the design and therefore the cost, and is important.

The curves as finally plotted, together with such tests as have been published from time to time by the Institute, give a series of straight lines on semi-logarithmic paper throughout their entire range corresponding to the several physical changes noted.

These curves are plotted from the original data as given in the several references, the changes necessary to reduce them to kilowatt loss per conductor per mile being also noted.

In tests such as those of Lewis the condition nearest approximating the 220-kv. test configuration and connections was plotted.

These curves were plotted to compare with the form of curve observed on the test and all of the actual transmission line tests obtainable seem to show this exponential form.

From the original test made in 1921 on a 300-ft. section of the copper conductor, the irregularity factor was given as 0.68. After reviewing the tests as made on the line, this has been changed to 0.72. Both of these values are used in the quadriatic formula under test conditions of temperature and barometer and plotted together with the values of the test in Curve 20.

The observed loss would indicate for the test conditions approximately 22,000,000 kw-hr. per year, the value of 0.68 and the quadratic law 43,000,000 kw-hr. per year and the value of 0.72 approximately 24,000,000 kw-hr. per year.

These represent losses in the order of $100,000 per year and bear out the statement that it is desirable to know the loss under operating conditions. A more thorough understanding of the physical causes and mechanics of corona loss is gradually being reached. This is hopeful and if, from lines existing and now being built, it is possible to secure the data for determining these losses, it will be more and more worthwhile as longer lines and higher voltages come to be used.

Discussion

PAPERS ON CORONA

(RYAN & HENLINE, CLARK & MILLER, CARROLL, PETERSON & STRAY, CLARK & EVANSON, WILKINS)

PASADENA, CAL., OCTOBER 13, 1924

F. W. Peek, Jr.: It is my opinion that apparent discrepancies in the corona papers presented are not due to error in the different investigations, but rather to the difficulty of comparing different conditions. To illustrate what I mean by one example: An aluminum cable strung at Stanford in a grassy field and another strung at Pit after being dragged over the sharp lava rocks should be expected to give different losses near the critical voltage. It would be difficult to predict the result of the mutilation by the lava beds without direct measurements.

I will point out here briefly a few of the outstanding facts concerning my early work which may apply to the present measurements:

Tests were made on indoor lines and on outdoor lines in actual towers under all kinds of weather conditions and at temperatures varying from below zero to 90 deg. fahr. Probably one hundred thousand different readings were taken. Measurements were always duplicated on both the high-and low-voltage sides of the transformer by wattmeters especially calibrated for low power factor. The transformer loss was small. These readings checked. I have great faith in readings made on the low-voltage side because the probably error can be determined readily. It

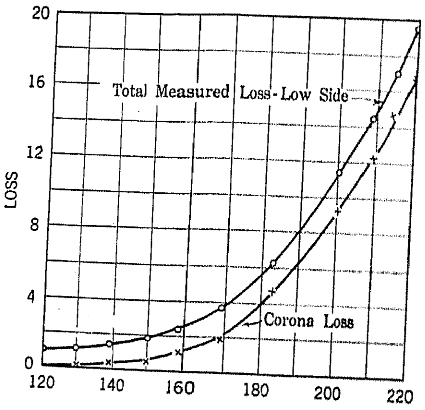

FIG. 1

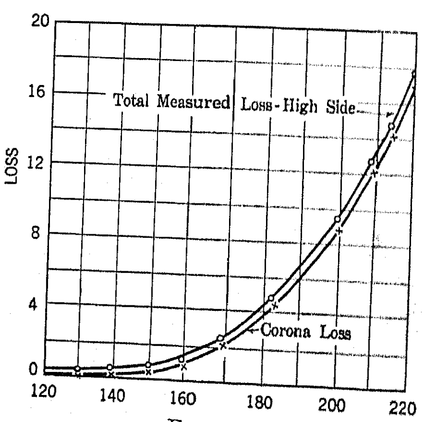

FIG. 2

FIGS. 1-2—COMPARISON OF HIGH AND LOW SIDE CORONA LOSS MEASUREMENTS

was small. Wave shape and the maximum of the wave was determined by an oscillograph. Voltage was not measured by gaps but determined by calibration of the voltmeter coil with step-down transformers. A small error in voltage is equivalent to a larger error in power. Figs. 1 and 2 herewith give an example of the total loss measured on the high and low side and the net corona loss. It is not difficult to determine the possible error, which is small. In Fig. 3 the losses obtained on high and low sides are plotted on a single curve. There is good agreement.

A study of these data showed that the quadratic law applied very closely above the critical voltage. The criterion for the quadratic is that the curve between the voltage and the square root of the power loss is a straight line. The test for the quadratic law is thus quite simple. Near the critical voltage there was an excess loss depending upon irregularities, dirt, moisture, etc., on the conductor surface. This caused a loss in excess of the

quadratic law which followed the probability law. I found no loss due to direct leakage through the air. What excess loss there was below the true critical voltage was found to be due to

actual brushes at local points. The loss at this part of the curve is very sensitive to dirt and moisture on the conductor surface. This is fully discussed in my first paper.

Professors Ryan and Henline presented today a very interesting paper on the theory of the mechanism of corona. I am pleased that the corona values which they have measured and calculated check so well the values calculated by my quadratic

law as shown in their table. There is no doubt that part of the corona loss is a per-cycle loss, but in addition there is a component loss which does not depend upon the frequency. There is also considerable corona loss on direct current, The loss on a wire

apparently varies for the two halves of the a-c. wave. For this reason, I have never thought of this loss as a hysteresis loss.

I have always thought of the quadratic law as rational. Energy is stored in the dielectric until the critical point is reached on the voltage wave. At this point the brushes start to short circuit part of the dielectric. Part of the energy is not returned. This energy should be as the square of the excess voltage above the critical voltage.

The measurements of Professors Clark and Evenson are interesting. I would like to call attention to the fact, however, that the correction which they find it necessary to make in order to get the net corona loss is much larger than the transformer-loss correction for measurements made on the low side. Such

a correction is uncertain, whether it is made on paper or in the instrument.

The high-voltage wattmeter when fully developed should be a very useful tool.

Mr. Wilkins' measurements are very important from both the theoretical and practical standpoint. Investigations of this character are of great value to the industry. Two types of conductors are used: Concentric-lay aluminum cable in the lava country of the Pit and rope-lay conductor in the valley. Since the rope-lay conductor is irregular in a uniform way, the surface should not be much affected during stringing. The uniform aluminum conductor should be quite badly mutilated by dragging in the lava and should, for this reason, be expected to give large excess loss near the critical voltage. It is naturally difficult to estimate the effect of such treatment for any particular case. Mr. Wilkins' measurements show this excess loss for the aluminum conductor. The measured and calculated losses check very closely for the rope-lay cable. This is illustrated for the two different types of conductors in Figs. 4 and 5 herewith giving calculated loss and measured points taken from Mr. Wilkins' paper. Fig. 7 shows the measured and predicted loss for the line. Mr. Wilkins finds that the measured losses do not always follow a quadratic. This should be the case on a long line for the following reasons: There would be at least several critical voltages along the line due to the different conductors, difference in elevation and temperature. The wattmeter reads the sum of the losses for all of the sections at different critical voltages. If the losses in each section follow the quadratic law, the sum of these quadratic curves, which is what the wattmeter reads, could not be expressed by a single quadratic but would be a curve similar to the ones found by Mr. Wilkins. This is shown in Fig. 8. Each section should be calculated separately and added to obtain the total. A small error in voltage would also make a large error in power. I note that there is a considerable difference in voltage measurement on the low side and by the hose on the high side. This would also contribute towards the difference noted.

Mr. Wilkins states that no corrections were made for temperature. This would also cause difference between his measurement and calculations. I would like to ask if loss measurements were also made during the warm summer months. The quadratic law shows that the loss would be much higher at the higher temperature. If Mr. Wilkins has such measurements they would be a check on the quadratic law.

It is my opinion that it will generally not be economical to operate a line above the fair-weather e_o voltage. The loss during fair weather at this voltage is generally not of great importance since the controlling factor is the rain loss. With

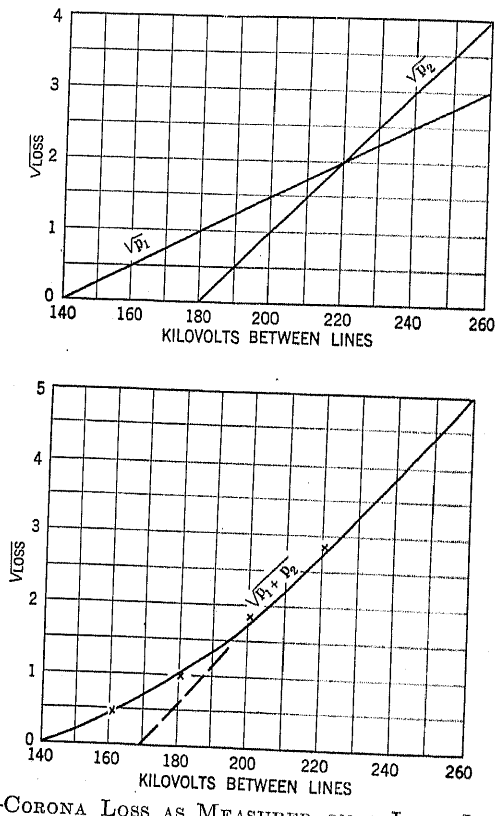

FIG. 8—CORONA LOSS AS MEASURED ON A LONG LINE WITH DIFFERENT CRITICAL VOLTAGES

Upper Curve—Two quadratic corona loss curves with different critical voltages

Lower Curve—If two corona loss curves with different critical voltages are added, the sum cannot be represented by a quadratic, although each component curve is, in itself, a quadratic.

rain only 10 per cent of the time the greater part of the annual loss would occur during storms.

The large amount of power transmitted on 220-kw. lines will generally require conductors so large that the critical voltage is above the operating voltage. If this does not occur, the diameter of the conductors can be easily increased by a central core to meet this condition. In other words, why have any appreciable loss when it is so readily prevented? The exact calculation of the annual loss is thus not always as important from the practical standpoint as from the theoretical standpoint.

In conclusion, the loss measurements on which the quadratic

law was based were made in duplicate on high and low sides of the transformer and were always in good agreement. Voltage was measured by step-down transformer and voltmeter coil. The wave shape was determined by oscillograph.

This law holds over a very large range of voltage as shown by the curves in my discussion of Professor Harding's paper.

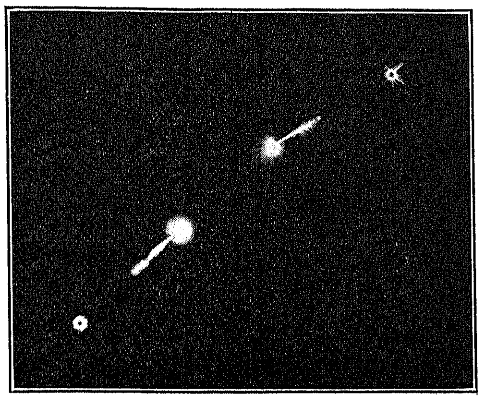

Fig. 9

Measurements made in 1924 check those made in 1910 although made by different men with different apparatus.

The reasons for apparent and actual deviation from the law indicated by some of the curves in the papers presented today were for the most part observed and discussed in my 1911 paper.

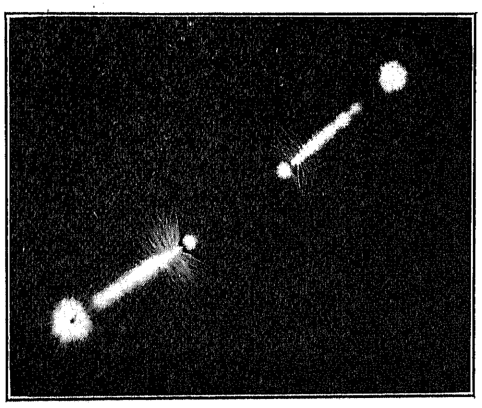

Fig. 10

Predicted loss is in good agreement with the actual loss on the 220-kv. lines.

It will generally be desirable to operate below the e_0 voltage. If the conductors are not large enough the diameter can be increased by a core.

R. W. Sorensen: The Steinmetz-Hayden paper, entitled High-Voltage Insulation, presented at the 1923 Pacific Coast Convention held in Del Monte, showed some very interesting phenomena, the reasons for which we would all like to know. Thinking that some Lichtenberg figures might help to work out the reasons, I have some photographs which may also help explain the hysteresis character of corona loss as found by Professor Ryan and his colleagues.

Fig. 9 is made with about 10,000 volts d-c. applied to two needle points spaced about 1 3/8 in. apart. The point at the right is connected to the positive terminal and the one at the left to the negative terminal. In these figures is seen the characteristic difference between the positive and negative records, both as to appearance and distance from the electrode, marked by the emanating electrons.

Fig. 10 shows two similar points with alternating current impressed upon them.

Fig. 11 shows a cylinder and a needle point, the nearest approach one can make to having a plate represent the discharge between a point and a sphere. In this case, the voltage applied was alternating current. The voltage on all slides shown is below visible corona voltage.

Fig. 12 shows a double phenomena, the cylinders being charged

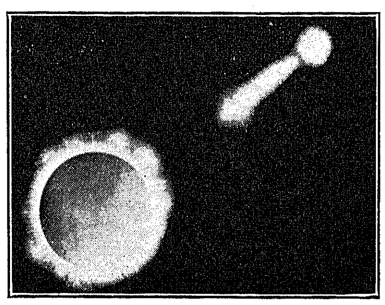

Fig. 11

positively and negatively used in conjunction with negatively and positively charged needle points, respectively. This photograph was made by Mr. H. E. Mendenhall, a graduate student at California Institute of Technology.

An examination of these photographs shows the greater range of electron travel from the positive electrode as compared to the range from the negative one.

An inspection of these figures leads one to the logical conclusion

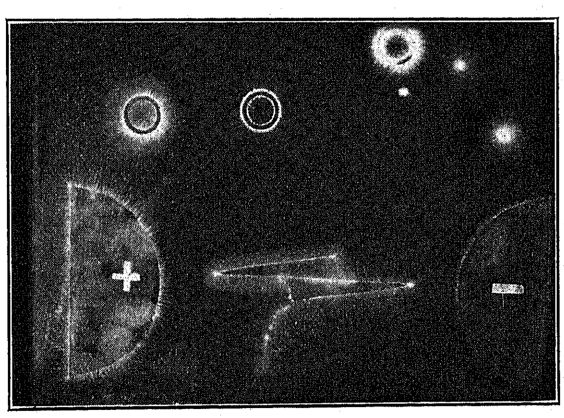

Fig. 12

that the reason for the results of the tests made by Steinmetz and Hayden is that when a point is connected to the positive terminal, the electrons travel a much greater distance for a given applied potential gradient than is the case when the point is negative and the sphere positive. Extending this reasoning to explain the results of tests which are now under discussion, is it not possible to assume with a fair degree of certainty that this also explains the reason for hysteresis effect of a-c. corona. During the half cycle a conductor is positively charged its electrons have a larger field of travel than during the half cycle it is negatively charged, thus making it impossible to account for a complete balance or neutralization of charges.

W. A. Hillebrand: While the electro-motive force increases up to a certain point, your charge is directly proportional until

your critical voltage is reached. As you descend the curve and reach zero electro-motive force there is a residue charge which should be neutralized. A somewhat similar relationship occurs during the other half wave. That means that within certain limits the energy loss per cycle is constant regardless of frequency. To me that has been extremely significant. The time effect as commented on by Professor Ryan does not enter over the lower range of frequency; as frequency increases the time effect does enter. We have another relation of interest: That you have a loss by electrical conduction which is a nice parabola. Is it possible that at a certain point we begin to develop the self-propagating streamers? That is, the Peek high-frequency effects? If that is so, it is to my mind important that we understand still more about the fundamental periods at which a transmission line will oscillate (I am not referring to the frequency of the line as a whole) in order to determine whether or not the fundamental frequency is at a point where you will develop the possibility of self-propagating streamers.

A wattmeter that will measure one watt, or a fraction of a watt at 110,000 volts, is, I think, as everyone who deals with measurements will agree, a remarkable achievement. I hope that it will be found possible, through the medium of this instrument, to develop further information with regard to the current-carrying capacity of liquid films that will lead to understanding the question of surface leakage.

For example, there is a transmission line in our neighborhood that has gone out simply due to surface loss over the insulators. It is a 60-kv. circuit. When the line is dead, and suddenly energized, the loss is too great to start it going.

J. B. Whitehead: In the first of these papers we have a further contribution to the problem of the measurement of small losses at low power factor in high-voltage circuits. It is a problem that has been attacked for years; and which has caused great trouble because of the difficulty of maintaining the current in the voltage circuit of a wattmeter, of whatever type, exactly in phase with the applied voltage.

Professor Ryan's work is notable in three particulars, I think: First of all he is putting the entire wattmeter system in the high side of the line. Ordinarily, in work of this kind, we find that instrument at the central neutral point. He does not eliminate however the problem of screening the voltage coil and resistance.

The next point is the method used for screening the voltage circuit and making certain that the current in that circuit is not only proportional to the voltage, but that it shall be in phase with the voltage. Care must be taken of both of these things. Professor Ryan has done it by adjusting the relation of the series resistance, or voltage multiplier, as he calls it, to the electrostatic field. I like, particularly, the ingenious method that he has used for maintaining a uniform electrostatic potential gradient over the resistance. He has placed it between two external shielding rings and has studied the field between those rings making sure that the water coil, as it spirals down, takes a constantly descending electrostatic potential as well.

The use of water is the third point. I think it is not very common to use water as a resistance. The difficulties are due to low conductivity and to heating. Professor Ryan has attempted to avoid them by letting his water flow continuously and I see no reason why that is not a perfectly sound method for meeting the difficulty provided, only, that the temperature is properly regulated.

It is not, perhaps, as well known in this country as it should be that the screening of such resistances, so as to make sure the electrostatic error is avoided, and a method for studying the degree of such error, and controlling it, has been published. It was published in Germany first by Professor W. B. Kouwenhoven of Johns Hopkins University, and subsequently by Washington University, of St. Louis. It is a very complete examination of this question of electrostatic error in connection with resistances and well worthy of examination by anyone who is contemplating making measurements at high values of voltage.

Professor Ryan and his associates in the second paper, are investigating the question, why the measurements of different observers on corona loss, particularly, in the initial stages, are not always concordant and are subject to doubt. The first reason, is the question of the accuracy of the measurements to which we have just referred. The second reason is due to the fact which Mr. Peek has mentioned, and which, is also clearly in Professor Ryan's mind, that it is impossible to obtain perfectly uniform conditions on a conductor in the open and, particularly, in a long line of such conductors, with alternators in the character of the conductors themselves, the spacing, etc. Most work that I have done has been within the laboratory where we could control conditions. There is never any doubt in such experiments as to what is going to happen after you have made a number of those experiments and the results may usually be given as definite laws. In the open your conductors are not smooth; you may have cable of various make-ups; these cables are scratched and dirty; you no longer have the question of what is the law of corona, but you have the question as to how dirty your wire is and how many needle points it has on it, or how many drops of water it has on it. It seems to me that that is the principal reason why so many of these studies that are brought before us lack the punch of authority.

Now, Mr. Peek, in his first work, met this situation squarely by recognizing the fact and pointing out we must increase the voltage above the initial loss value before we get to the region subject to definite law. We must reach a voltage where the irregular point discharges unite in increasing the diameter of the conductor and making it equivalent to a smooth conductor and for that reason Peek found it necessary to introduce two critical voltages. One was the voltage at which the conductor would start into corona had it been perfectly smooth. The visual critical voltage was something lower.

I am not sure that we are going to get anywhere by trying to study this intermediate range. It seems to me that it is a question of entirely indefinite nature, and the corona voltage may vary from point to point and from line to line. I like very much better the plan adopted by Mr. Peek of simply inserting an engineering constant or factor, having different values for different conditions, into the law for smooth conductors. That seems to me a sound engineering method.

Professor Ryan's second paper deals with this intermediate region of irregular corona formation. He is trying to find some law, as I read his paper, which will enable us to predict what is going to happen within this initial stage. The pictures that he shows and also those by Mr. Peek, make me question whether there is not perhaps something else to the matter. The location of these individual brushes, the fact that they stick as you raise the voltage, and the fact that the pictures show no approach to a uniform appearance as the voltage is raised, makes me ask the question, whether it is permissible to say that above a certain voltage corona becomes a uniform cylinder and that further increase with voltage will be in accordance with a definite law. Frankly, I don't know how to feel about it. Professor Ryan has opened the question anew, and shows that we must study further before we can say that we know all about the law of corona.

I now pass to Professor Ryan's paper in which he is suggesting that the phenomena of corona has a hysteresis character. There have been numerous explanations of the process of breaking down of the air. They ask us to think about the motion of electrons between molecules and to picture the process of ionization by collision. But I don't think that present physical theory is easily followed by engineers. It is, therefore, perhaps just as well if we can confine ourselves to some picture of the loss process due to corona which makes a less extended demand upon our attention. So, Professor Ryan has made this very interesting

suggestion that the loss due to corona may take on the character of hysteresis. He has been led to it by the shape of the power curves taken with his electrostatic wattmeter and taken originally, I believe, with the cathode-ray tube.

Magnetic hysteresis is distinctly a molecular phenomenon, so far as we know it. The nearest we can come to picturing the mechanism of it is that it is some kind of a friction between or within the molecules. Magnetic hysteresis, for years, was the only type of hysteresis that we knew anything about. We next heard of dielectric hysteresis, the loss in dielectrics due to an alternating electric field. Here too, such attempts at explanations as we have had, picture these losses as due to some type of successive orientation on the part of the molecule, or the atom, causing frictional loss.

Now, for these reasons, I am raising the question as to whether the use of the term "hysteresis," which implies molecular friction, is as helpful in explaining corona as the idea of straight electric conduction; that is, conduction through the air by means of the motion of charged molecules or aggregates of molecules known as gaseous ions? You can study the motion of these ions; you can feel them, under certain circumstances; if you put a hole in a grounded cylinder in the middle of which there is a corona-forming conductor, you can feel the motion of ions that come out of that hole under the impetus of the electric field. There are numerous other evidences of conductivity of the air. Experiments with continuous voltage will show you conductivity directly; you can put obstacles in the path and stop the flow of the ions and I don't see exactly how, with Mr. Peek, we are going to think of the hysteresis character of corona, or think of corona as a hysteresis effect and at the same time take care of these evidences of conductivity.

Now, the suggestion of the hysteresis nature of corona by Professor Ryan is based on the shape of the curves taken with the electrostatic wattmeter in which he finds a maximum value of the induction, a shape similar to the magnetic hysteresis loop, and a loss in proportion to the area of that loop, all of which are most suggestive. But it seems to me that the shape of these curves can be completely explained in terms of the conductivity of the air. Taking his Fig. 5, the discharging point is directly opposite one of the plates of the wattmeter and as soon as the point begins to discharge, the plate takes up some charge; that charge is going to stay on that plate because it is insulated, until it is neutralized by an opposite charge in the next half cycle. While the charge is on the plate it will naturally modify the distribution of the electrostatic field that was there before the point began to discharge, consequently, he has a shifting of the sides of his curves, but these remain straight. Why? Because they have a definite charge upon them from the preceding half cycle and he has simply changed the potential of the plate by a uniform amount and the central line of his diagram is carried out to the side of the loop, but always parallel to itself. As he pushes the voltage higher and higher the sides of the cycle will become more and more curved because it takes a longer and longer time to neutralize the charge due to corona on the preceding half cycle.

R. J. C. Wood: I was a little disappointed at the stand that Professor Whitehead took, or, perhaps, I misunderstood him. What I gathered was that we should not try to formulate any laws about this region of corona, which is between the starting point and the point where it follows Mr. Peek's law. On the other hand, Professor Whitehead said we should get all the data we could in that region so that we could establish factors of safety. Perhaps, I misunderstood him entirely and we all mean the same thing. We all want this data because it pertains precisely to that region on the voltage curve, wherein we most probably will have to work for economic reasons.

There is another point of view on this question, namely, that in order to employ anything like 220,000 volts there must be a very large block of power to transmit and a very great distance to transmit it in order to make it an economic success. Having that very large block of power and long distance the economic conductor will be so large that corona losses will be practically eliminated.

There are some points in the paper that I would like to mention. The great trouble with all this corona data has been in bringing the results of different observers into conformity. There are one or two things which occur to me that do not seem to have been specifically mentioned, which may account for these differences. One of them is the deposit which forms on the conductor after it has been in use at a high voltage. Our Big Creek line, of aluminum conductors, was first operated at 150,000 volts and down in the lower altitudes where there was considerable smoke and dust in the air the conductor became coated with what might be called a black enamel. It was hard and so closely adherent to the conductor that it required some force to scrape it off with a knife blade. Up in the higher altitudes, above 3000 or 4000 ft. where the air was pure, that conductor was not so black, and, in fact at the highest altitude of 5000 ft. it was almost as bright after several years as at the time when it was first installed. When we went to 220,000 volts the conductor very quickly blackened, even in the higher altitudes. Now, it was noticed when we were running our experimental line, 27 mi. long, previous to the energizing of the total line up to 220,000 volts, that when we first energized that line some new connections we had put in of new bright cable were very luminous and emitted a considerable noise. We could hear the crackling of corona quite a distance, but after the voltage had been on for two or three weeks these conductors blackened like the rest of the line and the noise decreased very much. That brings up the thought that in some of these semi-laboratory tests, by which I mean tests where there is a length of line in the open energized from a laboratory, possibly the conductor may not have reached the ultimate surface condition. For example somebody wants to test a piece of new kind of conductor with a naturally bright surface when it is received, and it is hung up on the experimental line and tested, possibly before it has gone into the steady condition. A line will afterwards be built of that same kind of conductor and after it has been in service for a little while the black deposit may have formed and then, naturally, the tests on the line as a whole will not conform with the laboratory tests made on the new conductor.

I have a suggestion, which may or may not be of any value as to the measurement of these losses. The great difficulty lies in the low power factor and it occurred to me that, perhaps, a way out of the difficulty would be to raise the power factor, and that can be done by putting a synchronous condenser on the end of the line. In case of a long transmission line there would be two advantages, a better power factor at the sending end where the meters were and the ability to control the rise of voltage over the line and have practically uniform voltage over its whole length. The only objection I see would be in evaluating the losses in the condenser, but I believe one could study these and arrive at what they were quite closely.

J. S. Carroll: The water-column resistance used as the multiplier for the high-voltage wattmeter is of vital importance. The studies made at Stanford last gave us a little insight into the solution of some of the problems of electrostatic shielding. To begin with, the original water column was built of 75 ft. of ½-in. garden hose. Last year it was shortened to 20 ft. using ¼-in. air hose. Just before coming to the convention some brief measurements were made with a water column 5 ft. long and 0.095 in. in diameter. A stout glass tube was used in this case. On account of this smaller diameter the water pressure had to be raised to about 130 lb. per sq. in. in order to keep the temperature within reasonable limits. The water column was mounted in the vertical position between two horizontal metal plates of sufficient size to produce a fairly uniform field at the center where the water column was located. The bottom plate and the lower end

of the water column were connected to ground, the upper end of the column was connected to the instruments and the upper plate was connected directly to the high-voltage terminal of the transformer.

Unfortunately, in this case, water has a very large negative resistance-temperature coefficient, so that the voltage gradient will not be exactly uniform down the column on account of the heating effect of the current. However, it is possible to adjust the field between the two plates until it very nearly matches the gradient down the water column. Even if the two fields are not exactly the same throughout their entire lengths the total error produced will be very small on account of the small capacitance of this short water column. In regard to the test as to when the fields are matched, a similar method will be used that was used last year in which the resistance of the water column was decreased by cutting down the flow of water and allowing it to warm up. There is a little objection to this method but it was not as serious last year as I had thought, but now we are getting down into corona and related matters, to where we are having to split hairs over those values near the x-axis. To test for correct shielding of this short water column, instead of changing the conductivity of the water by reducing the flow which would change the shielding slightly, we will change the conductivity by the introduction of a salt solution and the temperature of the water will be kept constant by controlling the flow. No doubt there will be a few problems to solve before this method will be free from objection, one of which will be the proper mixing of the solution beforehand to prevent an unsteady flow of current. However, with the crude apparatus now set up this method seemed to work very satisfactorily. With the voltage held constant the current was gradually raised from 30 milliamperes to 60 milliamperes. With this arrangement we have an ideal multiplier the multiplying factor of which can be controlled easily and made any value between rather wide limits. Not only can we evaluate error due to the capacitance of the water column and tell when it is eliminated but we can also keep the current through the voltage coil of the wattmeter at a relative large value for the low values of power which will increase the deflection of the wattmeter four to six times.

This year we hope to be able to keep the wattmeter on the line continuously. Tanks which have hitherto been used and require emptying or filling at intervals will not be used. A nozzle will be used to spray the water to the ground from the upper end of the water column. It was found by test that a 6 ft. spray effected a complete break in current at 175 kv.

J. P. Jollyman (by letter): Mr Wilkins' paper is a noteworthy contribution to the knowledge of corona loss. The Pit transmission system offers an unusual opportunity to secure accurate data on the corona loss of three distinct configurations and two conductor materials.

The comparison of the results of the several methods of measurement employed is most interesting and clearly demonstrates the difficulties of high voltage measurements. The determination of generator output from the output of the prime mover is to be especially commended as a method of check. This confirmation of the accuracy of the readings taken on the low-voltage side of the step-up transformers gives great confidence in the results.

A study of the results of the tests as shown in Fig. 33 reveals some interesting information. The corona loss is found to be a function of the total applied voltage with a law of the form:

$P = Ke^v$

where P = KW corona loss
K = a constant
V = total voltage in kv.
e = naperian base.

For a given configuration K has a certain value up to a certain value of v which may be regarded as a "critical voltage." Above this value of v, K has a different value such that P increases more rapidly for a given increase in v. At a still higher value of v or possibly of P, K again changes and the increase of P for a given increase of v is less than in the preceding stage. This second change in the law marks the beginning of a voltage-wave distortion. This point was not reached on the aluminum conductor due to limitation of voltage which could be applied. Not enough data are available to determine with certainty whether the second point of change is determined by the total loss per mile or by total load on the generator. The indications are that the total loss per mile for a given configuration is the important factor.

Mr. Wilkins calls attention to a curious change in the corona loss of the aluminum conductor below the "critical voltage" not found with copper conductors.

The discovery that the measured corona loss on the Pit transmission followed exponential laws with exact precision led to a review of the data on the best available tests reported by Lewis, Faccioli and others. This study is shown in Fig. 40. Every curve but one follows exponential laws and this curve records the results of tests on a short sample. The tests made on the long lines where carried over a sufficient range of voltage exhibit the three stages of loss observed on the Pit tests.

The most important conclusions that can be reached from Mr. Wilkins' paper are:

1. Corona loss follows exponential laws both below and above the "critical voltage."
2. Factors not heretofore considered important, such as capacity to earth and configuration, have a marked effect on corona loss.
3. Aluminum has certain characteristics with respect to corona not possessed by copper.
4. Losses below the "critical voltage" are large enough to be of commercial importance.
5. Direct high-voltage measurements by methods heretofore employed are likely to contain errors due to phase angles and change in ratio, the correction of which are extremely difficult, if not impossible.
6. A new investigation of the subject of corona loss is required to establish the laws of corona loss within the commercial range. Such an investigation should be made on outdoor three-phase circuits of considerable length, so arranged that the configuration may be varied to conform with the several arrangements used in practise and transposed to give a complete barrel.

The commercial range of corona loss may be regarded as including corona losses from small values up to values about equal to the $I^2 R$ losses considered reasonable for a certain conductor. Under present-day costs, an increase in conductor size may be justified when corona loss exceeds one-quarter of the $I^2 R$ loss.

C. A. Jordan (by letter): It is merely the desire in this discussion to call attention to a fact which may be significant, but which appears to have escaped attention of Messrs. Ryan and Henline.

In Figs. 1 and 8 of this paper, it will be noticed that the longitudinal axes of the corona loops obtained with increasing voltage rotate about the origin with increasing angular displacement from the straight-line no-loss card as the applied voltage becomes higher. This denotes a gradual change in the voltage-charge relationship, and hence a change in the capacitance which determines that relationship.

It has been commonly, and apparently reasonably, supposed that ionization of the surrounding atmosphere increases the effective capacitance of a conductor. Unfortunately conclusive evidence on this point is not forthcoming from the paper under discussion. In Fig. 8, the axes of the corona-loss cards lead the straight-line no-loss card, indicating a decreasing capacitance with increasing loss. In Fig. 1, the axes of the corona-loss cards lag behind the zero-loss card, indicating an increasing capaci-

tance. May it be supposed that the two sets of cards, made at times separated by an interval of years, were not obtained under the same conditions of instrument polarity, or that one set of cards has been incorrectly sketched for reproduction? If it be accepted that the effective capacitance of a conductor does increase with corona loss, some interesting conclusions are possible.

Referring now to Fig. 2, attention is invited to the loop axis, X-Y. The reciprocal of the slope on this line is the effective capacitance. The axis X-Y as drawn implies a constant capacitance, not only for all applied voltages, but for all values of the same applied voltage. If, however, the capacitance is increased by ionization, the axis cannot be a straight line. In this case (considering the first quadrant of the figure and starting with zero applied voltage) as the voltage is increased the conductor charge will vary in linear relation, determined by the reciprocal of a constant capacitance, until the critical disruptive voltage is reached. At this point, capacitance will begin to increase and the slope of the axis to decrease by increasingly greater amounts until the crest value of applied voltage is reached. The same thing will occur in the third quadrant in the opposite sense, and the axis will then represent an elongated letter S, being concave downward in the first quadrant and concave upward in the third quadrant.

Having disintered the skeleton, may we attempt to construct the body? Such a skeleton immediately suggests the classical hysteresis loop teminating in sharp points. If this be the case and were it possible to determine for all physical, electrical and meteorological conditions the factors which determine the shape and size of the loop, it is probable that a relatively simple, exact law for corona would result. Undoubtedly Equation 2 of the paper is an approximation of such a law, but the equation seems subject to error through the use of a constant conductor capacitance.

It remains to reconcile the actual corona diagrams given in the paper and the familiar hysteresis loop surmised above. Two thoughts immediately come to mind: (1) Is the cathode-ray cyclograph capable of faithfully indicating or reproducing the instantaneous relations between voltage and charge? and (2) Do the diagrams indicate corona loss alone, or a combination of true corona and gaseous-conduction losses?

Picture a number of sharp-pointed hysteresis loops of increasing sizes, and possibly slightly different shapes, drawn about a common origin with sides generally parallel. Then consider the pointed ends rounded off as might be done by a lagging instrument. Are not the resulting diagrams similar in shape and inclination or rotation to those given in the paper, especially when it is remembered that the slope of the experimental loops is determined by the *average* capacitance?

Again, were test voltages carried to such high value that, in addition to corona, gaseous conduction occurred, the resulting cyclograph diagrams would be deformed from the pointed loop to an elliptical form, as stated so well on Page 4 of the paper.

M. H. Gerry, Jr. (by letter): There is an important difference between conditions affecting the transmission of power and its distribution, although many of the problems are common to both. In many discussions of late there has been a tendency to confuse the two.

High-tension distribution is an economic necessity for the future, but it does not require voltages beyond the range of present practise. It involves delivery of power over an area and in practise functions through a network. Its problems are those of regulation, continuity of service and commercial efficiency.

Actual transmission of power is a distance problem and involves the transfer of energy in quantity from its source to a far removed center of distribution. Its further extension requires the employment of higher voltage.

Consider now, the transmission of power as the problem of transferring a large block of power a distance of say, a thousand miles. Can this be done commercially, and if so, how? At the present time power is being transmitted about three hundred miles, which appears to be near the distance limitations for sixty cycle three-phase current at the voltages now permissible.

A great forward step in the art is required if there is to be a material extension of the distance of power transmission, and only in this way will it be possible to make available in the centers of population the vast undeveloped water power resources of the nation.

The papers presented at this meeting go to the heart of the problem. Engineers must employ higher voltages for transmission but in what form or how applied we do not know. One important step is a clearer understanding of the nature of corona losses and another is their quantitative determination. Such losses must be suppressed or reduced to a small amount before progress is possible in this direction.

The study by Professors Ryan and Henline of the hysteresis character of corona is not only a contribution to knowledge and a clear experimental demonstration of certain facts, but it points the way to still more important fields of investigation and should give the engineering profession courage to believe that the limitations of voltage as applied to the transmission of power has not yet been reached.

Harris J. Ryan: Replying to Mr. Peek: In our studies of corona losses occurring from power transmission lines so far, we have found only "per cycle" losses. Succeeding *half-cycle* losses are not independent but parts of the total loss per corresponding cycle. We are partly but not altogether in agreement that the corona loss is due to the collapse of the air as a dielectric adjacent to the conductors. In our understanding the loss occurs in reversing the charges on the free ions that surround the conductors in approaching and receding from voltage crests that are higher than corresponding critical voltage. The charge between opposing groups of ions is automatically limited to equality with the increase of charge between the conductors due to increase of applied voltage from critical to crest values. The *ion-attached charges* must be reversed in passing each voltage crest. The energies stored in such charges are not reactive as is the case for *conductor-attached charges*, and must all be degraded to heat, *i. e.*, molecular friction. This is the understanding that led to the derivation of equation (2) in our paper. In his discussion of Professor Harding's corona paper Mr. Carroll has shown that this equation and the corona loss-voltage relations found therein are in excellent agreement.

Corona, when existing on actual power lines is known to consist in few or many individual brushes, as the case may be. We have called attention to the hysteresis character of corona formation for a better understanding of brush formation and the loss of power therein. Our endeavor has been to accomplish a better understanding of the corona loss-voltage relations for power transmission lines when the losses are below 7.5 kw. per conductor-mile, or thereabouts. That is the range in which our equation (2) does not apply because therein the brush pattern is not fixed. We regard equation (2) as a criterion for fixing the corona-loss limits, below which, brush patterns are unstable.

In continuous-voltage corona formation the ions of like signs that are driven forth from a charged conductor meet and combine with corresponding ions carrying unlike charges driven forth from the oppositely charged return conductor. This is conduction by convection. Manifestly, the frequency can be lowered and the distance between the conductors lessened in alternating-voltage corona formation until conduction by convection also occurs. Physicists have determined in conduction by convection that, for an air-density factor of unity, negative and positive ions travel 1.83 and 1.35 centimeters per second in an electric field due to one volt per centimeter. The restricted conditions for which alternating-voltage corona will produce loss by convection may, therefore, be calculated.

Professor Sorenson's photographic studies are yielding helpful results. Years ago in an effort to observe the E-Q relation in

the glass dielectric of a plate condenser fitted with tin-foil electrodes, the corona at the edges of the tin foil on the opposite faces of the glass plate yielded well defined hysteresis loops. The study of similar phenomena photographically must surely add to our understanding of the differing behavior of the free positive and negative ions in determining the hysteresis character of corona.

Mr. Hillebrand helpfully calls attention to the importance of knowing the carrying capacities of liquid films that will lead to an understanding of the problem of surface leakage over insulators. The high-voltage wattmeter is sufficiently sensitive and accurate for the promulgation of such studies.

Dr. Whitehead has contributed a number of helpful criticisms and suggestions with most of which we are in hearty accord. Formerly we shared his views and those of Peek himself that "We must increase the voltage above the initial loss value before we get to the region subject to definite law. We must reach a voltage whereat the irregular point discharges unite in increasing the diameter of the conductor and making it equivalent to a smooth conductor." Our understanding is that "the region subject to definite law" is due to the formation of a stabilized brush pattern and not that "the irregular point discharges unite in increasing

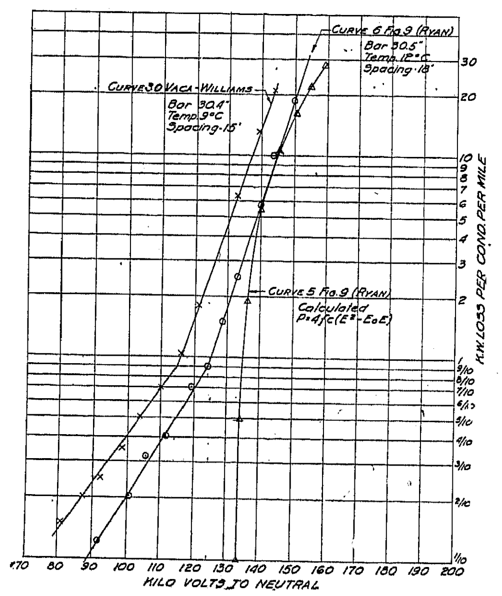

FIG. 13

the diameter of the conductor and making it equivalent to a smooth conductor." Mr. Jollyman points out that "under present-day costs an increase in conductor size may be justified when conductor loss exceeds one quarter of the $I^2 R$ loss. Such loss occurs entirely within the *unstable-brush-pattern range.*" Ardent study of the corona loss-voltage relation occurring in unstable brush patterns must, therefore, continue. As Mr. Wood states, these data are wanted because "they pertain precisely to that region on the voltage curve wherein we most probably will have to work for economic reasons." The unstable-brush-pattern losses are related to the total line voltages. We are convinced that law and order exist among them, though the factors are many and too little is known about them as yet. When the corona losses have increased sufficiently to sustain stable brush patterns in clear weather their values vary much as do squares of the crest voltages in excess of the corresponding critical crest voltage. We cannot, however, conceive of the effective use of engineering constants or factors by which to derive unstable brush-pattern losses from the corresponding losses due to stable brush patterns formed at higher voltages.

Magnetic hysteresis is due to the presence of definite quota of molecular magnets left stranded in their polar orientation by atomic friction that cause alternating flux to lag with respect ot the corresponding alternating m. m. f. These residual molecular magnets are reversed as each flux crest is passed with a cor-

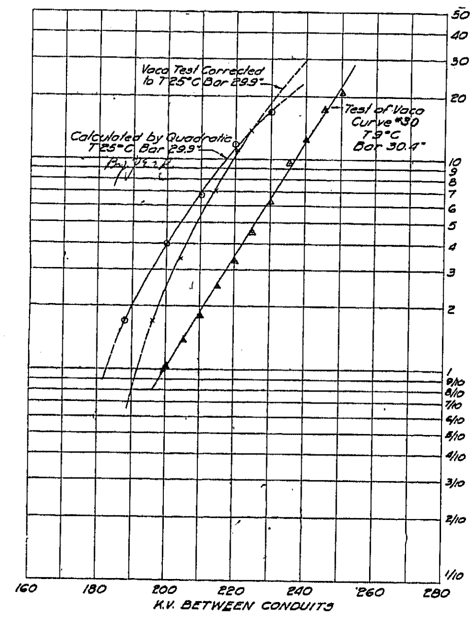

FIG. 14

responding loss of energy. In a strikingly similar manner when 60-cycle electric fields of ionizing strength are set up in air, residuals of ions are left about the conductors that cause the electric field also to lag by definite amounts with respect to their cor-

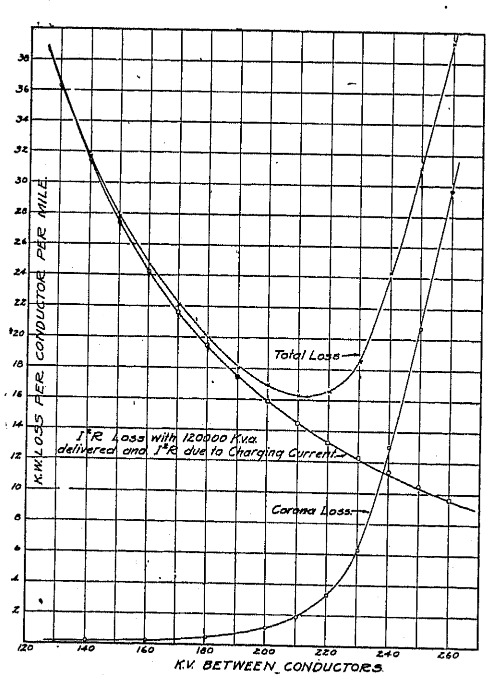

FIG. 15

responding e. m. f. s. Such stranded ions have their charges reversed as each voltage crest is passed. The energy stored in placing these charges about the conductors must be degraded to heat through molecular impact (friction) when by recombination and replacement their charges have been reversed.

Mr. Jordan notes the gradual rotation of the longitudinal axes

of the corona loops with increasing voltage and concludes that such effect is due to a corresponding change in capacitance. This use of the term capacitance is apt to be misleading. Capacitance of a conductor is the quantity or charge it accepts per volt. The quantities recorded in the cyclograms in excess of the corresponding conductor charges were employed in setting up the space charges on the free ions left by the corona between voltage crests. Conductor capacity is not altered in value by the presence of such space charges. In the course of our work many of the highly reasonable conjectures of the character brought forward by Mr. Jordan were also encountered. It would, however, have made our paper too long to have included a record of them and what we did in their regard. Equation (2) was the result of a large amount of study beyond that of the make-up of the voltage-charge diagrams.

R. Wilkins: Fig. 13 herewith shows Prof. Ryan's Curve No. 6, Fig. 9 plotted on semi-logarithmic paper, together with a curve from the data of the test on the Vaca-Williams section of the Pit line at approximately the same temperature and barometer and a spacing of 15 ft. All of this section of the line had an elevation of less than 1000 ft.

There is also his calculated Curve No. 5, of Fig. 9, and I would point out that at 127,000 volts to ground we are running on a part of the curve which does not check.

By reference to Dr. Steinmetz, it seems necessary for comparison, to plot the curve in such a manner that the test data will form a straight line or a series of straight lines. Fig. 14 herewith shows this same test curve No. 30 with the temperature and barometer as indicated under constant weather conditions and taken at an altitude of less than 1000 ft. plotted on semi-logarithmic paper giving a straight line. There is also plotted a calculated quadratic curve for these conditions and also the curve shown by Mr. Peek of a correction of this test to a temperature of 25 deg. cent. and a barometer of 29.9 inches. By using a correction developed for a quadratic curve on the test data an entirely different character of curve is developed. It would seem more accurate to calculate the curve for test conditions.

Fig. 15 bears out the statement made in the paper that it is not economical to run below the corona point at least on this particular line. There is a decided minimum to the loss curve for a given kw. transmitted.

In closing, I will say that for values of corona loss on 300-ft. sections of the rope-lay cable taken in two of this country's best high-tension laboratories before the line was erected the variation from the test values taken on the Pit line in place at the operating voltage was somewhat over 500 per cent and the errors were in different directions. Any such variations in losses having a value of $100,000 per year is worth further study.

It seems worth while to make a plea for tests under practical operating conditions because as higher voltages and longer lines are used, it means dollars to the ultimate consumer.

The Corona as Lightning Arrester

BY J. B. WHITEHEAD
Fellow, A. I. E. E.
Johns Hopkins University, Baltimore, Md

Review of the Subject.—Occasional suggestion has been made in recent years that the properties of the high-voltage corona might be utilized as a protection against lightning and other similar types of disturbance on transmission lines. The idea in these suggestions is that since the ionization attending corona renders the air conducting, the excess voltage following the lightning discharge will be relieved or lowered by leakage between lines or to ground. It has been stated that lines operating in the highest range of transmission voltages are more immune from lightning disturbances than those of lower voltage, and that this is due to the fact that they operate nearer to corona-forming voltage, and that abnormal rises of voltage are thus prevented by the relatively low value at which corona forms. This paper aims to present additional evidence that the suggestion mentioned is not only sound but has important possibilities. Experiments are described indicating a relatively simple and inexpensive method of equipping transmission lines to take advantage of the protective properties of the corona, without incurring its disadvantages.

Conductivity Due to Corona

The conductivity of the air, resulting from corona, constitutes a leakage conductance of the line. This general constant of the electric circuit is usually assumed to be zero in a transmission line, although its presence and importance in telephone circuits is well known and understood. Shunted or leakage conductance increases the attenuation or rate of decay of electric waves or impulses, and if present when a disturbance due to lightning passes over a line, must of necessity tend to retard or smooth it out.

We may estimate the value of the conductance due to corona from Peek's[1] expression for the power loss. The loss increases with the excess of voltage above the critical value and also with the frequency, hence the conductance will also have a wide range of value. As examples, two No. 00 wires, discharging corona at 10 kv. above the critical value, might under ordinary conditions have a corona loss of 2.8 kw. per kilometer, and this is equivalent to a shunted conductance of 0.77×10^{-6} mhos per kilometer. Also, suppose this line to be placed 30 ft. above the earth, that it operates at 50 kv., and that it is arranged, by methods described below, for a critical corona-forming voltage of 55 kv. If this line should suffer a lightning disturbance causing a rise of voltage to a value of 60 kv. above ground, the resulting corona power loss would be about 13.8 kw., equivalent to a conductance of 3.8×10^{-6} mhos per kilometer. The foregoing values of conductance pertain to a frequency of 60 cycles. For higher frequencies and for higher voltages the values of conductance will also be higher in accordance with Peek's formula.

Assuming, as now generally accepted, that a chief danger from lightning disturbances lies in the steepness of wave front associated with high-frequency oscillations or sudden pulses, the question before us is as to the influence of leakage conductance, in the amounts suggested above, on the rate of decay of high-frequency transients on power transmission lines.

The Attenuation Due to Corona

The question of the change in shape of the front of a pulse or wave is one of the attenuation or decay of its component frequencies. In considering the value of corona as a protective device, it is necessary to interpret its functions as closely as possible, in terms of the usual constants of the line, and their occurrence in the general equations of wave propagation. The presence of leakage conductance in certain types of telephone circuits has been known a long time and its influence on speech distortion is well understood. In the analysis of transmission line phenomena, however, leakage conductance has always been considered negligible, and the values of the normal circuit constants to remain the same at all frequencies. It is only recently that Steinmetz[2] has studied the variation of the attenuation constant with the frequency, and proposed an explanation of the known rapid decay of steep wave fronts on transmission lines. He concludes that owing to the skin effect and to electromagnetic and electrostatic radiation, the attenuation constants pertaining to the higher ranges of frequency rise to enormous values, and that these frequencies constituting the steep slopes of wave pulses, are rapidly damped out, thus accounting for the relatively limited distances over which the steep fronts of such pulses persist. The values for the attenuation constant as computed range from 70 at commercial frequencies, through, 287 at 10,000 cycles, to 7×10^6 at 5×10^6 cycles; the enormous values at high frequencies are due principally to the loss of energy radiated into space.

In these estimates of the values of the attenuation constant, the leakage conductance is assumed to be zero. If any is present it must, therefore, still further increase the attenuation, and accordingly tend to slow up all frequencies still more rapidly. Now it happens that the values of leakage conductance due to corona lead to values of attenuation constant much higher in the lower range of frequency than those computed by Steinmetz. The latter increases with the frequency more rapidly than the former in the upper range, but the corona attenuation is the higher over the entire range up to 1.5×10^6 cycles where the two values are about equal; beyond this the Steinmetz value is the

---

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

higher. Thus the effect of corona is to greatly increase the attenuation constant over the entire range of the more important frequencies entering into the usual high frequency line transient. It is at once evident, if these estimates and assumptions are correct, that the corona must have the effect of slowing up high frequency and steep wave front transients even more rapidly than now observed and computed.

To arrive at an estimate as to the influence of corona, we may conveniently follow Steinmetz, using both his examples and his method for determining the progressive alteration of several types of transients but using new values of attenuation constant to include the influence of corona. He considers the alteration by attenuation of three types of disturbance likely to arise from lightning or other similar cause; the quarter-wave oscillation, the periodic rectangular wave, and the flattening of a steep wave front. In each case departure is taken from the summational expression representing the Fourier series and involving the succession of terms of increasing frequency making up the wave or pulse. The influence of the attenuation constant, u_n, appears always as $\epsilon^{-u_n t}$, u_n however taking continually increasing values with increasing frequency. The values of u_n are computed as influenced by unequal current distribution (skin effect), electromagnetic, and electrostatic radiation, but the effect of each is reduced to the equivalent series resistance r, or shunted conductance g, per unit length, for ready adaptation to the well-known general circuit equations, as treated by Steinmetz, through the value

$$u_n = \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right)$$

To include the influence of corona we may add another term to the above expression for u_n, by increasing g by the amount due to corona leakage conductance at the frequency n. Using the proper values of conductance and capacity, we find for the case of two No. 00 wires 6 ft. apart and equipped so as to give a normal corona discharge at 40 kv., and undergoing a 60 kv. lightning pulse, a value of u_n due to corona alone of 4800 at 10,000 cycles, with values increasing approximately proportionally with the frequency. And for the same two wires 30 ft. above ground and equipped for corona discharge at 55 kv. between lines, when subject to a pulse of 60 kv. above ground a value of u_n due to corona alone of 24,000 at 10,000 cycles; the value of u_n at this frequency if no corona is present, is 288. Thus under conditions quite likely to arise in practise, it is possible to look for a greatly increased attenuation constant over that of the normal line, by arranging the line so that a normal corona discharge curve may begin a few kilovolts above normal line voltage. This may be accomplished in various ways, one of which, suitable for existing lines, is described below.

Now it happens that the value of u_n due to corona, is many times greater than the value as computed on the assumption of no leakage conductance, throughout the entire lower range of frequency, and in fact is exceeded by the latter only at frequencies above 1.5×10^5 cycles. Thus for the line described above the attenuation constant, no corona present, is 70 at 10^3 cycles, 287 at 10^4 cycles, 3710 at 10^5 cycles, and 291,500 at 10^6 cycles. The corresponding values due to corona are 495, 4800, 48,300 and 483,000. The effect then of ordinary corona discharge is to greatly increase the attenuation constant throughout the lower range of frequency and to add substantially to its value in the upper ranges. There is good evidence, therefore, that corona may be expected to slow up and smooth out irregular pulses even more rapidly than the rates computed by Steinmetz for corona-free lines.

Steinmetz's assumption that the attenuation constant is rapidly increased at higher frequencies through the phenomena of the electro-magnetic and electrostatic radiation has been seriously questioned.[7] However, the influence of these factors on the values of the total attenuation constant including corona formation is very small. The values of u_n, as deduced by Steinmetz, are far surpassed by the value on a corona-forming line for all frequencies below 1×10^6 cycles. At 1.5×10^6 cycles, the Steinmetz value, and that due to the influence of corona alone, are about equal, while for higher frequencies the Steinmetz values become greater than those for corona. If, as claimed, therefore, the Steinmetz assumption as to radiated energy is erroneous, the effect on the conclusions below is to be found only at frequencies above 1.5×10^6 cycles per second. As the range of frequencies above 1.5×10^6 cycles plays but a small part in the total ranges of the several types of wave considered below, the conclusions reached would not be as seriously affected.

Question may arise as to the time interval required for the setting in of corona, and its power loss, at high frequencies. There is little available experimental evidence here, but such as there is appears to be in the direction of assisting the attenuation influence of corona. In the lower range of frequency a number of observers[3] have noted a slight decrease in the critical voltage with increasing frequency. Ryan's experiments indicated a marked lowering at 40,000 cycles, and those of Peek[4] that the law of corona power loss holds up to 100,000 cycles.

The Damping Influence of Corona on Lightning Disturbances

In the following, the attenuation, caused by corona, of three types of lightning disturbance on a line consisting of two No. 00 B and S wires, 30 ft. above ground, and 100 km. long, is studied and compared with behavior of the corona-free line. The examples are those of Steinmetz and his ingenious methods of approximation to the true values have been followed, with the exception, however, that the attenuation constants at the various frequencies have been increased so as to include the effect of corona.

Quarter-Wave Oscillation. A particular case of a steep wave front is the rectangular wave resulting from the connection of voltage to a transmission line open at the far end, or the sudden short-circuit of such a line. In these cases there is the possibility of the natural frequency or quarter-wave length oscillation, with superposed harmonics, of the line against ground. It is found that except for points very near the end of the line where the disturbance arises, the maximum voltage gradient, or steepness of the wave front, at time t, and distance $1 = 3 \times 10^{10}\, t$ is, approximately:

$$G = \frac{E}{l_o} \sum_{0}^{\infty} {}^{n}\, \epsilon^{-u_n t}$$

in which E is the line voltage, l_o the length of the line and u_n the attenuation constant for the frequency $(2\,n + 1)\, f_o$, f_o being the natural frequency of the line.

Table I gives the values of maximum gradient of wave front, in volts per meter, length of wave front in meters, and equivalent frequency, for a 100 km. No. 00 B and S two-wire line 30 ft. above ground with no corona present, and also the values of the same quantities when the line is discharging under corona at a voltage about 10 per cent above the critical value. The rapid fall of the voltage gradient on the wave front, and the consequent lengthening of the wave

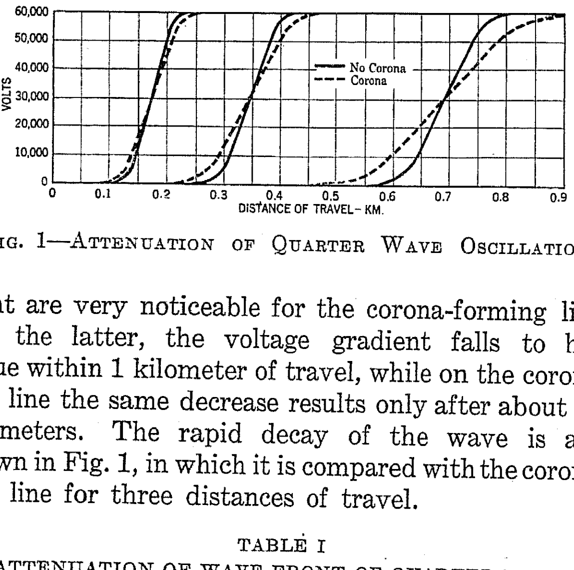

Fig. 1—Attenuation of Quarter Wave Oscillation

front are very noticeable for the corona-forming line. On the latter, the voltage gradient falls to half value within 1 kilometer of travel, while on the corona-free line the same decrease results only after about 2.5 kilometers. The rapid decay of the wave is also shown in Fig. 1, in which it is compared with the corona-free line for three distances of travel.

TABLE I
ATTENUATION OF WAVE FRONT OF QUARTER WAVE OSCILLATION ON CORONA FORMING LINE

Time t micro-seconds	Distance of Travel km.	Voltage Gradient Without Corona	Voltage Gradient With Corona	Wavefront Meters Without Corona	Wavefront Meters With Corona	Equiv. Kilocycles Without Corona	Equiv. Kilocycles With Corona

11.5	3.45	184	53	510	1780	147	42
230.0	69.00	36	3	2500	..	30	..

Rectangular Wave. In the case of the pure rectangular wave, made up of all odd harmonics of the fundamental frequency of 60,000 cycles, and represented by

$$e = \frac{4\,E}{\pi} \sum_{0}^{\infty} {}^{n}\, \frac{\epsilon^{-u_n t} \operatorname{Sin}(2\,n + 1)\,\varphi}{(2\,n + 1)}$$

the high values of u_n, due to corona at the lower frequencies, cause a rapid vanishing of terms with increasing values of n and t. This causes the wave to lose its rectangular shape rapidly. As shown in Fig. 2, in less than 10 microsecond, or 3 km. of travel, on a line on which corona is present, the rectangular wave has assumed practically a sine shape, and its amplitude is rapidly decreasing. If the line is not discharging under corona, only the highest frequencies are rapidly damped and the wave is still flat-topped after 40 microseconds or 12 kilo-

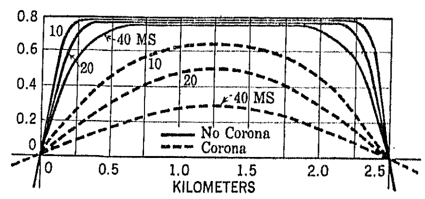

Fig. 2—Attenuation of 60,000-Cycle Rectangular Wave

meters travel, and its amplitude is still higher than that at 10 microsec. (3 km.) on the corona forming line.

Flattening of Steep Wave Fronts. The general expression for the maximum voltage gradient of any steep wave front or pulse of any length is shown to be:

$$G = \frac{2\,E}{3 \times 10^{10}} \int_{-\infty}^{+\infty} \epsilon^{-ut}\, f\, d\,(\log f)$$

in which t is the time since the origin of the pulse, and u, the attenuation constant, a function of f, the frequency. The relative values of this integral for one No. 00 B. and S. wire 30 ft. above ground and for values

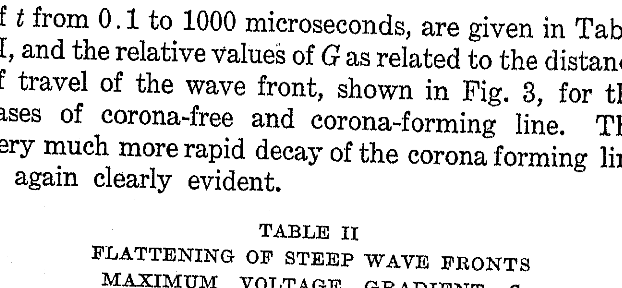

Fig. 3—Flattening of Steep Wave Front by Corona

of t from 0.1 to 1000 microseconds, are given in Table II, and the relative values of G as related to the distance of travel of the wave front, shown in Fig. 3, for the cases of corona-free and corona-forming line. The very much more rapid decay of the corona forming line is again clearly evident.

TABLE II
FLATTENING OF STEEP WAVE FRONTS
MAXIMUM VOLTAGE GRADIENT G

Time, seconds	10^{-7}	10^{-6}	10^{-5}	10^{-4}	10^{-3}
Corona-free line	20.2	6.84	1.86	0.635	0.119
Corona-forming line	16.8	3.71	.672	.07	0

In each of the foregoing examples a most striking improvement as regards the elements of danger of a lightning disturbance is shown for the corona-forming line. While the figures must be taken as only the roughest of approximations, it is nevertheless believed that they are of the correct order of magnitude. Particularly important is the indication that only relatively short lengths of corona-forming line are necessary, for this minimizes the elements of complication and danger, and reduces costs. In view, therefore, of the apparent advantages to be gained, it remains to examine the problem of a corona-forming line in the light of some of the conditions of normal line construction and operation.

Disadvantages and Difficulties

Looked at from the standpoint of application to existing lines and normal operating conditions, there are several questions which arise and which may constitute serious disadvantages to the use of corona as a protective device. Perhaps the most important is the variation in the value of corona-forming voltage with atmospheric conditions. Corona voltage is raised by an elevation of pressure, and lowered by an elevation of temperature; the influence of temperature is the more important. An annual range of temperature of 60 deg. cent. in any one location is not unusual, and this would mean an elevation of 25 per cent of the cold weather, over the hot-weather, critical voltage. When, however, we note that very short lengths of corona-forming line are indicated as necessary for protection, there would appear to be no difficulty in setting the corona-forming voltage at the value insuring protection under all conditions, and allowing the line to discharge continuously during the periods of high temperature. On an average line, an elevation of voltage of 12½ per cent above the corona-forming value would result in a continuous loss due to corona, of the order of about 1 kw. per mile, so that if the line were set for the average conditions as regards density of the atmosphere, a good measure of protection would result in cold weather, and excellent protection in warm weather, at the expense only of the relatively low value of loss mentioned.

Several writers have attempted to estimate the extent of the protection available through corona, by comparing the probable amount of energy stored in a line at the time of lightning discharge, with the normal rate of power loss from corona. A cloud overhead induces charges on a part of the line. When the cloud discharges, charges are left on the lines immediately raising their potentials. If the rise of voltage exceeds the flashover voltage of the insulators, it is discharged at once; if not, the wave front of voltage advances down the line oscillating back and forth and gradually leaking to ground. If the flash-over voltage of the insulators be taken as the maximum value reached by the lightning voltage, and a length of line of the order of 20 miles be taken, it may be shown that the total amount of energy liberated will be of the order of 2000 or 3000 joules. If this energy is estimated to traverse the line at the velocity of light, the instantaneous values of power are seen to reach very high values, values in fact which are not appreciably lowered by the known rates of dissipation of energy by means of corona. For these reasons some doubt has been expressed as to the value of corona for the purposes in view. If the discussion in the preceding paragraphs of this paper is correct, it is obvious that the entire charge liberated by a lightning discharge cannot proceed down the line with the velocity of light, and it is not so much a question of the total amount of stored energy, as of the steepness of the wave front with which the charge, or voltage, proceeds down the line. Assuming then that the values of stored energy as estimated above are correct, the indications are that the initial steep and dangerous impulse would be quickly retarded, and the total amount of energy would finally dissipate itself by repeated oscillations back and forth along the line, with wave fronts of continually decreasing steepness.

There is also the question of the influence of frequency on the value of corona-forming voltage, as already mentioned. Experimental evidence was cited here, indicating that if frequency does have an influence, it is in the direction of lowering the corona voltage at higher frequencies.

It is quite obvious in connection with all of the above questions that experiment and trial only can answer them. The principal purpose of this paper is to point out the value of shunted conductance as a means of lightning protection, whether or not this conductance be obtained by corona formation, by the use of small line conductors, points on the usual size of conductor, or by any other form of distributed parallel-connected resistance. Furthermore, it is evident that owing to the short lengths of line, and the low values of loss involved, it would be a comparatively easy matter to make a test of the use of corona as a protective device.

Artificial Corona for Existing Lines

Examination of the relation between voltage, size of wire, and spacing for corona formation, shows at once that within the range of practise, only those lines operating at very high voltages and in high altitudes approach in any way nearly the critical corona-forming condition. Usually the corona-forming voltage is from two to three times the normal operating value. In order, therefore, to bring such lines to a corona-forming voltage differing by only a small amount from the operating value, it is necessary either to modify the spacing or to change the size of the conductor. For most values of transmission voltage and size of conductor, the spacing necessary for corona formation is so short as to constitute serious danger of the swinging together of the wires in the spans, or of flashover. The reduction of the size

of conductor is the more effective means of lowering the normal corona voltage on existing lines. For example, on a line of 1.6 cm. diameter, aluminum cables, with 9 ft. (274 cm.) spacing, reduction of the diameter of the cable one-half value, would result in a reduction of the corona-forming voltage of 33 per cent. A still further reduction in size of the conductor, therefore, would often be necessary in order to produce corona in accordance with the laws for round conductors. Such reductions in diameter would be possible in some instances, by the use of copper clad steel or other conductors of high tensile strength. It is probable, however, that this method of reducing the corona voltage would not be attractive to the average line superintendent. For these reasons it has appeared worthwhile to investigate the possibility of equipping existing lines of standard spacing, with some form of point or stud of such design that the line would give a corona discharge curve equal to, or better than, the normal corona power loss curve, at a voltage as nearly as desired to the normal operating value, and which, in addition, might be applied to the line with relatively little difficulty and expense.

No priority is claimed for this idea, except, perhaps, as regards this country. The power of point discharge for relieving high voltage has long been known. In particular, experiments with short barbed wire lines have been performed by R. Nagel[5] in Germany, who states that two power companies have announced intention to install experimental stretches of barbed wire as lightning protection. However, no notice of this work appears to have been taken in this country, and transmission engineers have not been impressed with the value of the suggestion of corona protection. These facts in large measure prompted the present work.

The experiments of Nagel are especially worth noting, as they give direct evidence of the value of corona or point discharge in reducing high voltage line pulses. He worked with two out-of-doors lines each 250 ft. long. One line consisted of smooth wires, and the other of commercial barbed wire, both of iron. The barbed wire line showed point discharge beginning at 30 kv. Each wire of each line was equipped with a reactance coil at the far end, and across these coils spark-gaps were placed. Spark-gaps were also placed across the two wires of each line. Electrostatic impulses of 40 kv. were sent at rapid intervals into each of the two lines. The voltage rises at the end of the line between wires was measured by the gaps between wires, and the steepness of the wave by the gaps across the reactances. The barbed wire line showed much lower voltages and flatter waves, the maximum gap lengths for discharge being from 30 per cent to 60 per cent of those for the smooth wires.

Barbed wire, while eminently suitable for such initial experiments, is probably not the best type of discharge conductor. Better results are likely with other and more regular shapes of discharge point. Moreover, the suggestion to replace a section of transmission line with a length of barbed wire is so unattractive that it would probably be refused at once by most transmission engineers. The following experiments then were undertaken with the aim of devising a simple form of stud or clip which may be readily applied to existing lines, which may be so designed as to discharge at any desired value of voltage, and give a discharge power curve as steep or steeper than the normal corona loss curve.

The Experiments

The method of studying the relative corona conductivities of different forms of discharge points is indicated in Fig. 4. A is the conductor to be studied, B a surrounding metal cylinder 30.5 cm. in diameter, and 178 cm. long. This cylinder is perforated with a large number of 1.6-cm. diameter holes, over the whole surface of a central region 76-cm. axial length. Immediately outside this central perforated section, and

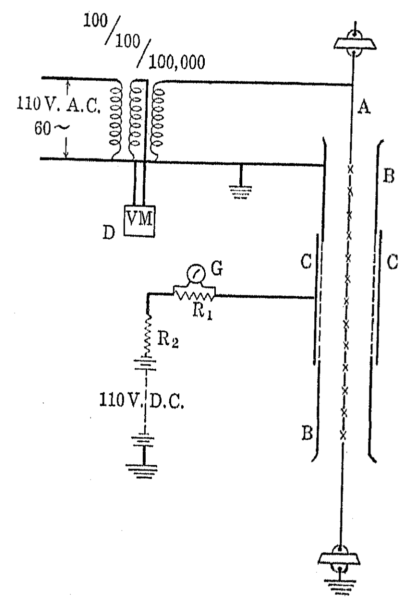

Fig. 4—Diagram of Connections, Conductivity Due to Corona

separated from the outer wall of the cylinder B, is an outer surrounding cylinder of sheet metal, C. This outer cylinder C, well insulated from B, is connected to ground through the resistances R_1 and R_2 and a source of continuous voltage, usually 110 volts. A sensitive galvanometer G is connected across the terminals of the resistance R_1. Cylinder B is connected to ground, and the galvanometer, therefore, indicates the conductivity of the air layer between cylinders B and C. This conductivity sets in as soon as corona appears on the central conductor A, due to the elevation of voltage by the transformer T, the value of voltage being read by the voltmeter D connected to a tertiary coil of the transformer. This is a very simple and convenient method of studying the relative conductivity of different types of corona-forming conductor. It has been described in detail in the author's papers on the corona voltmeter.

As typical of the types of discharge curves to be observed with this equipment, see Fig. 5. The two curves C are given by a nickel-plated steel rod with carefully smoothed surfaces, as used in the corona voltmeter[6]. These curves show clearly the sharply marked critical corona voltage, the absence of conductivity below the critical voltage, and the steep ascent of the discharge curve. Curves A and B were taken on a 1.58-cm.

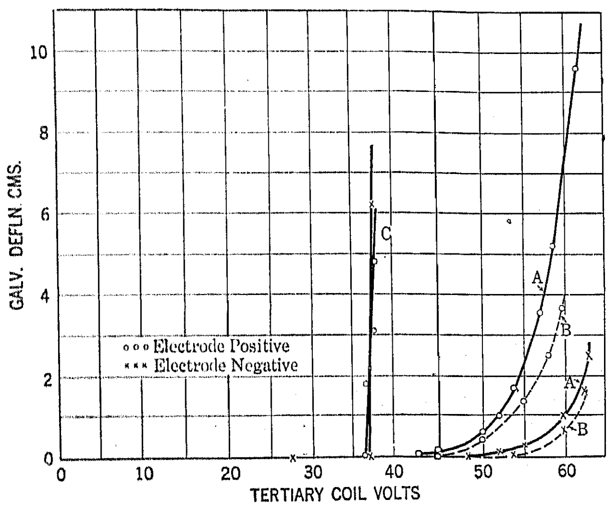

FIG. 5—CORONA DISCHARGE

diameter, 19-strand aluminum cable; A in the fresh state as taken from the reel, and B after operation for a number of years on the transmission lines of the Pennsylvania Water and Power Company. Two curves are given in each case showing the galvanometer deflections with the electrode C positive and negative. The curves with positive electrode begin earlier and rise more rapidly. This is due to the greater velocity of the negative ions and indicates that for experiments of the present type, the electrode C should be charged with positive potential as being most sensitive to the beginnings of corona. The slightly lower critical voltage of the new cable is probably explained by the fact that its outer layer of strands was not tightly in place. The pitch of the spiral of the weathered cable was nearly twice that of the new, and all the strands of the former were snugly in place.

The Pennsylvania Water and Power Company's lines operate at 70 kv. three phase, 25 cycles, and the samples of cable were kindly furnished by the officials of that Company. This cable was, therefore, taken as a convenient example for a study of possible methods of altering its normal corona discharge curve. The discharge curve of Fig. 5 indicates that this line is operating at a voltage somewhat less than one-half the value of that at which corona would form under normal conditions. The experiments were, therefore, directed toward the development of a suitable point or stud on this cable which would give a discharge curve starting in the neighborhood of 22 volts (tertiary coil) and which should rise from that value as sharply as possible.

The properties of commercial forms of barbed wire were first studied. Six different types were investigated, consisting of twisted pairs of various forms of round and square wires, with points at intervals of from 7½ cm. to 15 cm. The points in all cases were about 1.25 cm. radial length, with jagged points resulting from ordinary cutting processes. The curves of three of these wires are shown in Fig. 6 and are typical of them all. The curves indicate, especially that of sample 3, that barbed wire may be constructed so as to give a fairly steep curve of discharge. All of the types of barbed wire investigated, however, have the disadvantage that their discharge curves all begin at about the same value of voltage and that they are, therefore, not readily susceptible to selection for a specific value of voltage. Moreover, the value of the voltage of initial discharge is

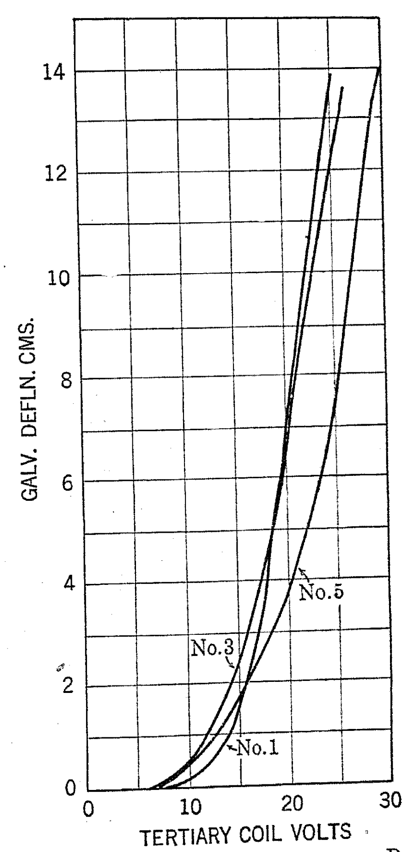

FIG. 6—DISCHARGE CURVES. COMMERCIAL BARBED WIRE

No. 1. Four 5/8-In. Points 3-In. Spacing
No. 3. Four 5/8-In. " 6 3/8-In. "
No. 5. Two 5/16-In. " 5 1/2-In. "

very low, being, for the case of the line in question, about 25 per cent of the value of the normal operating voltage.

The influence of the number and the spacing of the points on ordinary barbed wire was also studied. A number of special samples was constructed, consisting of two 10 B. and S. copper wires twisted together and with points ½ inch long placed in pairs at different distances of separation. The points were those result-

ing from the cutting of the wire with pliers. The curves of Fig. 7 show some of the results. Curve No. 0 shows the discharge of the twisted pair without any points; No. 1 with points spaced at 25 cm.; No. 2, at 12½ cm., etc. It will be noted that the effect of increasing density of points, *i. e.*, the number of points per unit length, is to increase the steepness of the discharge curve up to a certain point. In the present case the spacing of 3½ cm. shows the maximum and steepest discharge curve. A closer spacing as shown by curve 5 evidently has the

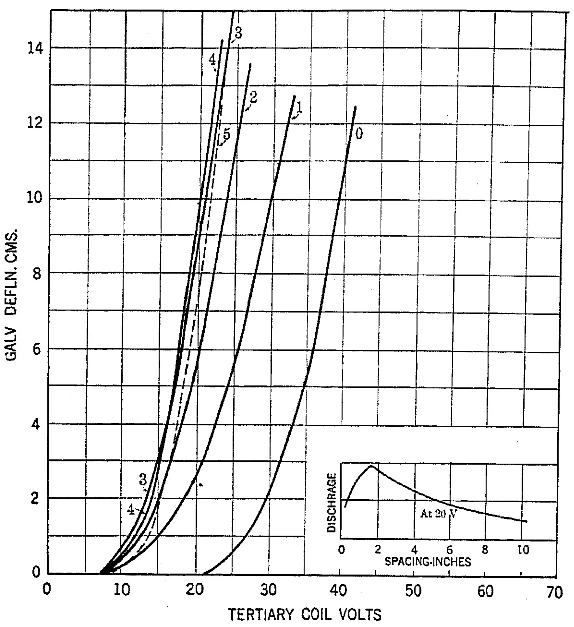

Fig. 7—Influence of Number of Points on Discharge Curve, Uniform Spacing

0	No Points	
1	Spacing 25	Cm.
2	" 12.5	"
3	" 6.25	"
4	" 3.1	"
5	" 1.75	"

effect of reducing the electric intensity at the ends of the points, due to their mutual electrostatic influence. The small inset curve shows the variation of the discharge with the density of points, for a particular value of voltage. The influence of point spacing is also shown in the curves of Fig. 6 in which curve No. 3 with a spacing of points twice that of curve No. 1, nevertheless shows a steeper gradient. The curves of Fig. 7 also show the disadvantage of barbed wire mentioned above, that the discharge begins at a very low value of voltage, and is not susceptible to a variation of critical value.

A large number of different types of discharge point was tried with the 19-strand aluminum cable. In one form narrow bands of sheet iron or aluminum were clamped around the cable with points cut in the metal and bent outward. Points of this character having angles of from 15 deg. to 30 deg. give discharge curves similar to those of barbed wire; that is, they begin from low values of voltage. For a point cut square on the end, the result is only slightly better than that for sharp points. Conical bosses stamped into sheet metal result in higher value of critical voltage, but show discharge curves with a very slow rise.

Some of the results of these experiments are shown in Fig. 8. Curve No. 1 is that pertaining to two 30 deg. sheet-steel points 1.25 cm. long, projecting radially at opposite ends of a diameter. Curve No. 2 is that of two 0.32-cm. diameter brass studs 1.25 cm. long, also at opposite ends of a diameter. Curve No. 3 is that resulting from wrapping around the cable in spiral form a No. 8 B. and S. copper wire at the same pitch as that of the strands of the cable, but in opposite direction. Curve 4 is that of the bare aluminum cable. Curve No. 1 for sheet steel points is not suitable for reasons already mentioned. Curve No. 3 is the steepest curve observed throughout the experiments and, therefore, appears to have marked advantages. However, it should be noted that this curve has a critical value of voltage about the same as that pertaining to the bare cable. It is possible that a lower value might be obtained by the selection of a different size of wire, or perhaps a ribbon of special type of cross-section. Since, however, the application

No. 3. No. 8 Wire Spiralled on Cable
No. 4. Bare Cable

of such a spiral or ribbon to existing lines would be troublesome, if not thoroughly impracticable, experiments were not carried further in this direction.

The studs used for Fig. 2 were the only simple and convenient method encountered in which the point of initial discharge could be readily controlled. These studs were turned from brass rod and were of uniform cross-section throughout their length and their ends were rounded to hemispherical shape. The length of stud, diameter, and the radius of curvature of the end,

determine the initial value of discharge voltage; the spacing or linear density of the points along the cable determines the steepness of ascent of the discharge curve. A number of studs of this type were tried and the dimensions given are those selected for a curve starting at about 20 volts (tertiary). The curves of Fig. 9 show the influence of the number of points in increasing the steepness of the discharge curve, and that a 15-cm. spacing gives a discharge curve somewhat steeper than that of the bare cable. A closer spacing might give an even steeper curve, but the gain would be small as compared to the number added. For these reasons it is concluded that the corona-forming voltage of any existing line may be adjusted to any value below that pertaining to the bare cable, by mounting on it in pairs radially projecting studs at a spacing between pairs of about 15 cm. The studs should be of uniform circular cross section with rounded ends. The dimen-

No. 6. Bare Cable

sions of the studs will determine the voltage of initial discharge, and they can be determined most readily for each new case, by the simple experimental method described above.

A simple and effective method for mounting the points on the cable, is shown in Fig. 10. The brass studs have thin flat heads, somewhat in the manner of rivets. The studs are placed, points outward, through holes in the ends of a thin but stiff spring clip, which is then slipped over the cable. The clip embraces more than half the circumference of the cable, and the two studs are thus a little nearer together, on the open side of the clip, than one half the circumference. By this means the heads of the studs grip the strands of the cable, resulting in a firm attachment of spring clip and studs.

Experiments to test the value of the suggestions

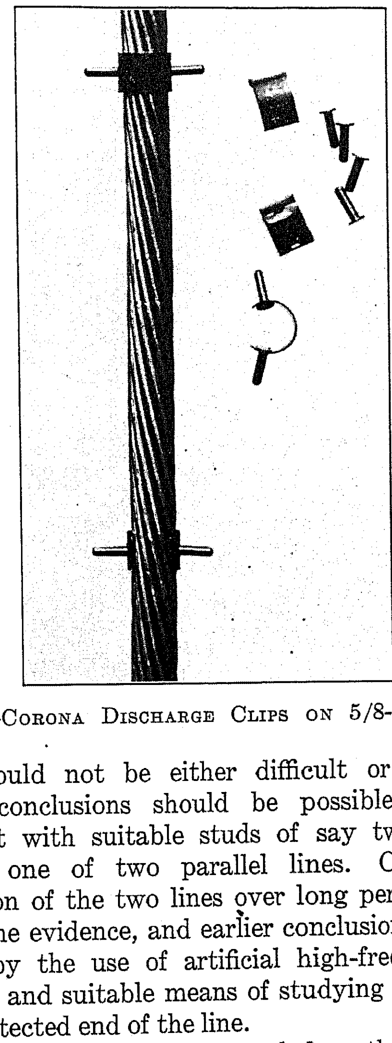

Fig. 10—Corona Discharge Clips on 5/8-In. Cable

above should not be either difficult or expensive. Definite conclusions should be possible from the equipment with suitable studs of say two terminal miles of one of two parallel lines. Comparative observation of the two lines over long periods should afford some evidence, and earlier conclusions would be possible by the use of artificial high-frequency disturbances and suitable means of studying their effects at the protected end of the line.

The author gratefully acknowledges the assistance of Mr. N. Inouye throughout the experiments.

Conclusions

1. The conductivity resulting from corona on transmission lines is sufficiently high to cause large values of attenuation constant, and the value of corona as a protection against high-frequency and steep wave fronts resulting from lightning and other causes is pointed out.

2. It is indicated that only short lengths of corona-forming line, say one or two miles, are necessary for a large measure of such protection.

3. To take advantage of this method of protection, the corona-forming voltage should be slightly above the operating value. On existing lines this may be

accomplished by reducing the spacing and size of conductor, resulting in uniform corona, or, when this is objectionable, by equipping the conductors with suitable discharging points.

4. The relative discharge values of various types of point are studied experimentally. A simple form of spring clip and stud is proposed, which gives a discharge equivalent to that from corona, and which may be readily mounted on a transmission line conductor.

5. The method has some disadvantages, and its predicted value depends on several assumptions requiring proof. In view of its simplicity and the short lengths of line involved, experiments on the scale of practise should be not only practicable, but attractive, in view of the high degree of protection promised.

Discussion

F. W. Peek, Jr.: In a paper that I presented at Swampscott last year I described some tests in which the variation of the steepness of the wave front and the voltage of a wave were measured as it traveled along a line on which there was considerable corona loss.

It is not necessary to repeat this description here. Briefly, the tests show that the voltage and steepness of the wave rapidly decrease as the wave travels over the line. In this work the effects of choke coils, capacity, open-ended lines, series resistance, etc., were also investigated.

The method of making the tests was simple. Some years ago I found that the sphere-gap measured the correct voltage of a transient while the needle indicated a voltage that depended upon the steepness of the wave. The ratio between the needle and sphere voltage was called the impulse ratio. The character of the wave is determined by making measurements by sphere and needle at different parts of the line.

There is no doubt that corona and other losses reduce the voltage of the wave and the steepness of the wave front as it travels over the line.

John C. Damon: Lightning arresters for high voltages have been remarkably expensive and if the transmission line could be the lightning arrester, too, it apparently would save all of the arrester expense. The trouble is, however, that the transmission line has to be designed to carry the load, to prevent corona from giving too much loss, to give reasonable regulation and to string at such a tension that the towers will not be unduly expensive. These are not independent variables. It has recently become possible to get cable with the outside diameter independent of the cross section of the conductor which will doubtless permit the future design of lines to act as lightning arresters in addition to their other functions.

V. Bush (by letter): The influence of corona on traveling waves is an exceedingly interesting topic, and I greatly appreciate the courage of Dr. Whitehead in making a mathematical attack on the problem. In such a complex phenomenon it is, of course, necessary to make some limiting assumptions in order to make it possible to formulate the problem at all; and it is hardly just to be too critical of mathematical short cuts when employed in connection with such a difficult matter. Yet I feel that he will agree that a discussion of the nature of his assumptions, and of the logic employed, will be of assistance to those who are intimately interested in this subject.

Dr. Whitehead represents the effect of corona as a constant ohmic leakance. Of course its effect is really cyclic in nature and complicated in many ways. As is so ably considered by Prof. Ryan and Prof. Henline, there is a hysteresis effect, so that corona leakance cannot be expressed even as a discontinuous function of voltage alone; but the function, if it can be formulated, must contain the time also. It has also been considered by some that there is also a cyclic change in capacity due to to corona, but in view of later work, and especially some at the Massachusetts Institute of Technology shortly to be published by Mr. M. F. Gardner, it is certain that this capacity effect is small, if it exists at all. In view of the complexity of the actual phenomena it is good judgment to make the first, admittedly only roughly approximate, formulation of the problem by the assumption used by Dr. Whitehead of a constant corona leakance.

But having made this assumption I cannot understand why the author attempts a new mathematical treatment. The progress of waves on wires, under the assumption of four constant line parameters, was first solved by Heaviside (Electromagnetic Theory, Vol. I, Ch. IV; Vol. II, p. 312, Electrical Papers, Vol. 2). It has received much attention by Poincare, Fleming, and later by Carson and Manneback. The mathematical solution has also been experimentally checked at M. I. T. for the exact case considered.[2]

Moreover, this solution of Heaviside's shows clearly that, when the four circuit parameters,—resistance, inductance, capacitance, and leakance,—are assumed constant, a perpendicular wave front of current or voltage remains strictly perpendicular as it propagates at the velocity of light. The wave front is attenuated in magnitude, and there may be distortion of the tail of the wave, but there is no change in perpendicularity at the wave front itself.

Corona may indeed cause the wave front to become non-perpendicular, for corona is not properly represented by a constant leakance; but any mathematical treatment which makes the assumption of four fixed constants should lead to a sustained perpendicular front, or else should substantiate its direct clash with the classic treatment.

The mathematical method of the paper was earlier used by Steinmetz. It represents a traveling wave by a Fourier series, gives physical meaning to the separate terms of this series, and applies to each a modifying factor, due in this case to the effect of corona. This method is bound to lead to error. Having formulated the differential equations of a system on the basis of certain constants, and made a solution, we cannot then introduce the effect of new factors into the separate mathematical terms of this solution without endangering the correctness of our conclusions. We should instead reformulate the differential equations for the conditions obtaining with the new factors introduced as a part of the original premises. Stated in another way, we cannot solve for the Fourier series expressing a traveling wave on a line, and then modify separate terms of our solution in accordance with the effect which leakance would produce on terms of that nature if existing independently, without destroying the dependability of our results.

The danger involved will perhaps be clearer if we carry the method to extremes. The Fourier expression for a rectangular wave of current traveling down a line is a function of distance

x and time t, such that it sums up to zero everywhere outside the wave, and to a constant value of current everywhere inside the wave. The separate terms of this series are sinusoids. Suppose we ascribe to each a separate physical existence, and assume that each produces independently its own resistance loss. Since these terms are continuous along the line we are led to the absurd result that we will compute a loss in the wire at points to which the wave has not yet penetrated. The result is exactly the same if we treat a wave of voltage, and the leakance loss.

The paper states that it is a generally accepted belief that a chief danger from lightning disturbances lies in the steepness of wave front. I agree, but not that this is *the* chief danger. The chief dangers are voltage amplitude, and duration of application of voltage due to traveling waves. The steepness of wave front is sometimes of interest, but not often. We usually are concerned with the amount of voltage our terminal apparatus is called upon to sustain, and for how long. We are rarely concerned with how fast it is applied. Steepness of wave front has been overemphasized. We apply the steepest possible wave front, without worry, every time we connect a transformer bank directly to live bus bars. Why be concerned if it is nearly as steep as this when a line intervenes? We do care, though, about amplitude. Corona has its effect on amplitude also of course.

J. B. Whitehead: I regret that I have failed to include reference to the experimental results of Mr. Peek on the attenuation of the voltage pulses on a corona-forming line. Under his reminder I now recall them well. They are strong indications in support of the assumption that corona has value as a lightning arrester.

Professor Bush does me too much honor in suggesting that I have made a mathematical attack on this serious problem. I have not done this. The complexity of the phenomenon, emphasized in the paper and reiterated by Professor Bush, was a sufficient deterrent. The purpose of my paper has been, as clearly indicated, an approximate answer only. While I am well aware of the criticism which has been directed to the use of the Fourier analysis in problems of this character, I have been glad to find at hand in the Steinmetz paper referred to a series of computations which lent themselves so readily to the addition, to other attenuation factors, of that due to corona. Professor Bush appears to have overlooked the fact that the Steinmetz analysis does not assume fixed values of circuit constants. The fact that the analysis takes account of the changes of both resistance and conductance with frequency was one of the reasons why it appealed to me for my present purposes. The method is especially helpful if the conductance is assumed to vary with the frequency as has been done in making the corrections indicated in the first paragraph above.

As for the use of Heaviside's methods, Professor Bush's partiality for them seems to have arisen since the appearance of his very valuable paper on Transmission Line Transients in December 1923, for in that paper he emphasizes clearly the difficulty of using the Heaviside treatment for cases in which the transmission engineer is interested, and also the laborious computations involved in the attainment of numerical results. I suppose he will hardly recommend Heaviside's analysis or any of its extensions for cases in which the resistance and conductance are unknown functions of the frequency. Perhaps the most important thing is that we now have good experimental evidence that the presence of corona on lines not only tends to diminish the gradient of a pulse but also to decrease its maximum value. If, as seems to be true, Steinmetz's method of analysis is open to serious criticism it is obvious that the application of some more correct method to this problem would be a service of great value. I hope that Professor Bush will be led to undertake this, using those methods which seem to him more suitable and convenient.

Corona Losses Between Wires
at Extra High Voltages—II

BY C. FRANCIS HARDING
Fellow, A. I. E. E.
Head, School of Electrical Engineering, Purdue University, Lafayette, Ind.

Review of the Subject.—Results of corona loss tests upon three sizes of cables at voltages varying from 100 to 620 kv. and spacings from 18 to 38 feet are reported from the Engineering Experiment Station of Purdue University. These tests results, reduced to the standard 1000 feet of transmission line, are compared with corresponding values calculated from Peek's formula for similar conditions of operation. A description of the tower line and method of measurement of the losses in the high-voltage circuit is included.

An empirical equation has been developed which approximates quite closely the relation between corona loss and voltage for different spacings. The variations of the empirical coefficient of this equation are indicated for 2/0 and 4/0 cables.

Three methods of attacking the problem of modified transmission line design for the elimination of excessive corona losses between wires at extra high voltages have been outlined for further research and study.

I. Calculation of Capacity and Corresponding Radius of Equivalent Coronal Conductor and Its Relation to Voltage between Wires.

II. Determination of Corona Losses between One Wire and Ground.

III. Photographic Reproduction of Equivalent Electrostatic Field Surrounding Model Conductors with Proportional Spacings between Wires and Ground.

The paper should be considered a progress report to be enlarged and analyzed further at a later time.

CORONA losses upon transmission lines may reach values worthy of the serious consideration of the designing and operating electrical engineer at or above potentials of 100 kilovolts between wires, depending upon the size and spacing of the wires, the weather conditions and the elevation of the line above sea level.

The critical voltage at which corona occurs upon a given transmission line and the magnitude of the power loss due to corona for definite line conditions may be calculated by means of the formulas developed by F. W. Peek, Jr., based upon certain empirical constants which were determined by him in early laboratory and experimental transmission line tests.[1] These tests included voltages up to a maximum of 250 kilovolts.

Tests carried on at Purdue University upon an experimental line 1380 feet in length were reported to the Institute in 1912.[2] These results were compared with those obtained upon other lines already in operation, as well as those calculated from Peek's formula. These tests were made with instruments connected in the high-voltage circuit and therefore were subject to no error depending upon the efficiency or power factor at which the step-up transformers were operating. The following significant conclusions may be quoted from the latter paper:

"Corona loss may be readily and accurately determined with instruments connected directly into the high-tension circuit.

"Corona loss curves are parabolas, the constants of the equations being different above and below the visual critical voltage.

"Test values checked results calculated from Peek's formula for points above the visual critical voltage with a fair degree of accuracy, especially at the wider spacings between wires.

"Variations from Peek's formula were in the direction of greater losses for a given voltage than those given by the formula. This was also found to be true of the tests which have been made upon operating lines, when the latter were reduced to a common standard for comparison."

This paper sets forth the results of tests carried on at Purdue University during the past two years with a single-phase line designed for 600 kilovolts. The corona losses were measured upon three standard sizes of cables at various spacings by means of a wattmeter in the high-voltage circuit operating at voltages as high as 620 kilovolts. These losses have been compared with values calculated by means of Peek's formula for similar cable size, spacing and operating conditions and representative curves have been plotted for both test and calculated values. The applicability of this formula and the possible error to be expected in its use therefore became apparent for calculations of corona losses at voltages in excess of those within which the original empirical constants were determined. In all cases, the test and calculated results have been reduced to the standard length of line of 1000 feet. Since there is now a practical demand for transmission lines to be operated at voltages in excess of those considered a maximum at the time the former tests were completed, it becomes a matter of particular concern to determine and record these corona loss measurements and their relation to calculated values.

The line upon which these tests were made was 1710 feet in length. It consisted of three equal spans of cables supported upon semi-flexible steel towers 65 feet in height. The towers at either end of the line were of similar design longitudinally guyed to withstand the

2. "Corona Losses between Wires at High Voltages I" by C. Francis Harding, TRANS. A. I. E. E., Vol. XXXI, Part I, p. 1035, 1912.

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

dead-end stresses. The cables were supported by means of standard suspension insulators of fifteen units each, hung from movable carriages which were designed with rollers to operate transversely upon a steel cross arm 40 feet in length supported upon each tower. The spacing between the two cables in the same horizontal plane could thus be readily changed by increments of from two to four feet between the limits of 18 feet and 38 feet. Three sizes of stranded aluminum cables with steel cores rated as 2/0, 4/0 B & S and 500,000 cm., have been tested to date.

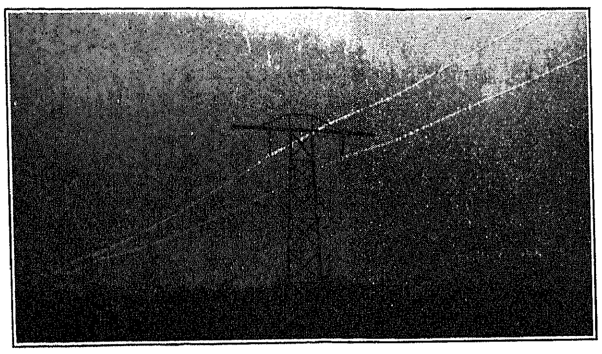

Fig. 1—Corona at Night 600 Kv.

The feeders connecting the test line with the transformers of the high-voltage laboratory were of particularly large cross-section and were spaced relatively far apart in order to reduce the tare losses which were subtracted from the gross power measurement to determine the net corona losses upon the test line.

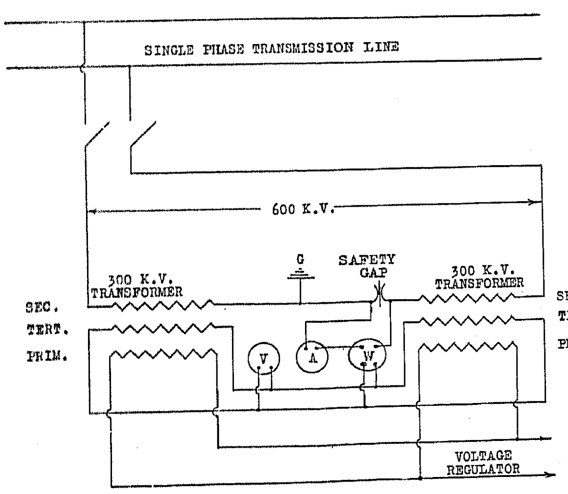

Fig. 2—Diagram of Transformer Connections

Two identical transformers, purchased from the Westinghouse Electric and Mfg. Co., rated as 135 kv-a., 300 kv., 60-cycle oil-insulated units with 1900-volt double-coil primaries were used for the power supply. One secondary terminal of each transformer was connected to one side of the single-phase circuit through a condenser bushing, while the other end of each secondary winding was connected to ground through the indicating instruments. Safety spark-gaps were shunted around the instruments for protection in case of an open circuit. The secondaries of the two transformers were connected in series for line voltages in excess of 300 kv., while the two coils of each primary winding might be connected either in series or in parallel for the varying ratios of transformation desired.

The variation of voltage was accomplished very satisfactorily without wave-form distortion, by means of an auxiliary regulating transformer with tapped primary, whose connections were varied by means of a motor-driven drum controller. The entire ranges of voltage, up to maximum values of 150, 300, or 600 kv., could be readily traversed throughout 480 equal increments at a definite predetermined rate, or any desired voltage could be held constant, or varied slightly at will, by means of the auxiliary hand control.

The gross power output of the two 300-kv. transformers with their secondary windings connected in series (Fig. 2) was measured very accurately by means of a specially calibrated indicating wattmeter whose current coil was connected in series with the high-voltage transformer winding. The voltmeter and the potential coil of the wattmeter were supplied with a voltage proportional to the line voltage through the agency of a tertiary coil in each transformer. These tertiary coil voltages were very carefully calibrated by means of the A. I. E. E. standard 50-cm. sphere-gap measurements under the two different conditions of the line being connected and disconnected from the step-up transformers.

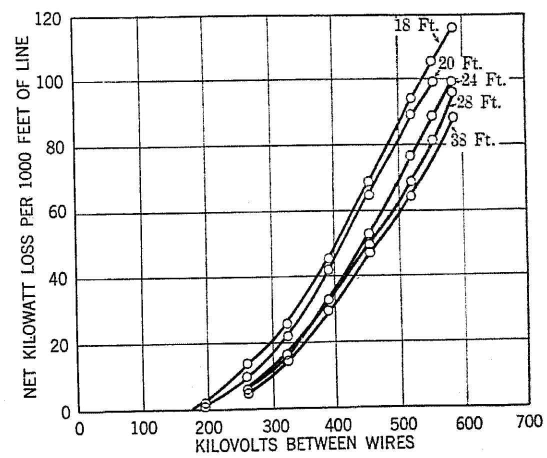

Fig. 3—Net Corona Loss per 1000 Ft. of Line 2/0 Cable

An additional check was made to insure the accuracy of ratio of line to tertiary coil voltage applied to voltmeter and wattmeter measurements under test conditions with large corona loads upon the line. A standard A. I. E. E., 50-cm. sphere-gap with neither sphere grounded was connected across the line, and readings taken of tertiary coil voltmeter at the moment of spark-over of the sphere-gap at various standard settings. These calibrations were made over the entire

range of voltage involved in the tests. As the experimental line, although open-circuited at the further end, is not long enough to cause abnormal voltages to be induced therein, it is believed that the losses due to corona, at the voltages herein specified, have, therefore,

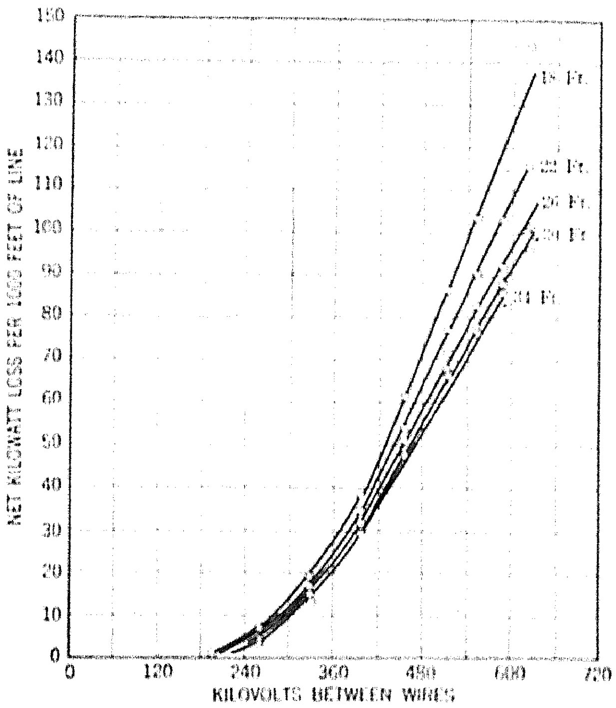

Fig. 4—Net Corona Loss per 1000 Ft. of Line: 4/0 Cable

been accurately determined. Furthermore, it is probable that the leakage losses over insulators which necessarily form a part of the net losses on the line proper after the feeder corona and insulator tare have been

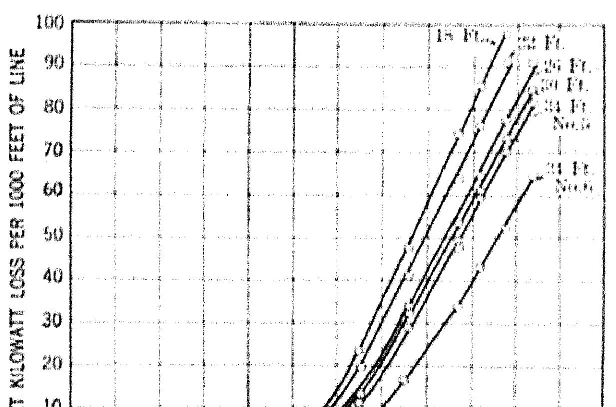

Fig. 5—Net Corona Loss per 1000 Ft. of Line: 500,000-Cm. Cable

subtracted, are entirely negligible. This may be assumed to be true because only four suspension insulators per cable were involved and for the further reason that great care was exercised to make sure that all units were in good condition throughout the series of tests. In previous tests reported to the Institute[3] in which precautions were taken to subtract the line insulator leakage losses, it was found that such were negligible with the insulators in first-class condition.

Results of Tests

In the Appendix, Tables I to XIX inclusive, will be found the results of the tests upon the three sizes of wires under consideration for five or more spacings. The weather conditions, including temperature and barometric pressure at the time of the test, are also recorded. The latter data provide means for calculating the values given in the last column of the tables from Peek's formula, for which a typical solution will be found for one test condition in the Appendix as an illustration of the method followed.

The curves of Figs. 3, 4 and 5 also represent the net corona losses, reduced to a standard length of 1000 feet of line for the three sizes of cables tested at spacings

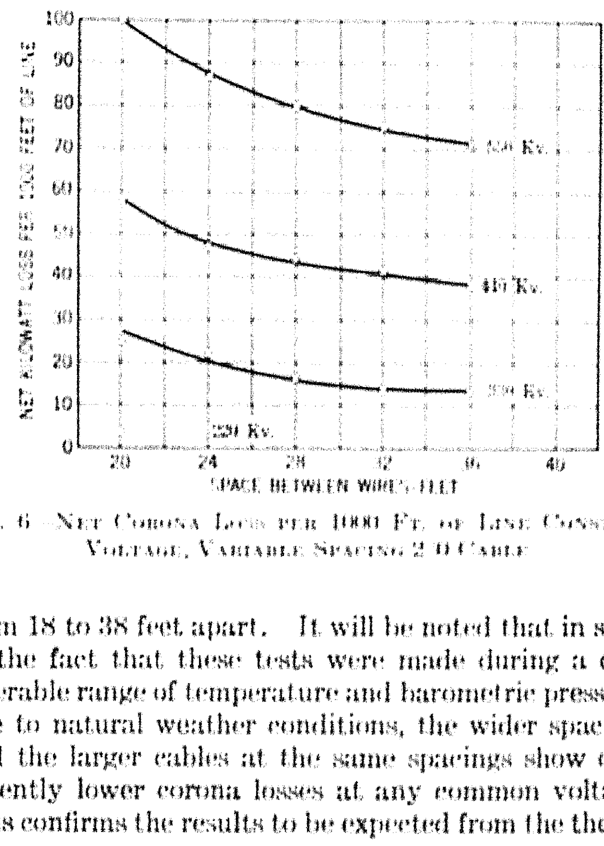

Fig. 6—Net Corona Loss per 1000 Ft. of Line: Constant Voltage, Variable Spacing 2/0 Cable

from 18 to 38 feet apart. It will be noted that in spite of the fact that these tests were made during a considerable range of temperature and barometric pressure, due to natural weather conditions, the wider spacings and the larger cables at the same spacings show consistently lower corona losses at any common voltage. This confirms the results to be expected from the theory of corona.

The relation between corona losses and cable spacing are shown in Figs. 6, 7 and 8 at three definite voltages, determined graphically, from curves of Figs. 3, 4 and 5. These points, with two minor exceptions, fall upon smooth curves, apparently following a definite law which indicates, as would be expected, a marked and regular decrease in loss with increased spacing between cables.

3. "Corona Losses between Wires at High Voltages I" by C. Francis Harding, Trans. A. I. E. E., Vol. XXXI, Part 1, p. 1036, 1912.

These curves further indicate the zones of voltage and spacing for the three sizes of cables within which the losses are not excessive from the practical standpoint. For example, if it soon becomes desirable to operate a line at 330 kilovolts, the losses are found from Fig. 8 to be moderate for the 500,000 cm. aluminum stranded cable. However, with 2/0 and 4/0 cables these losses

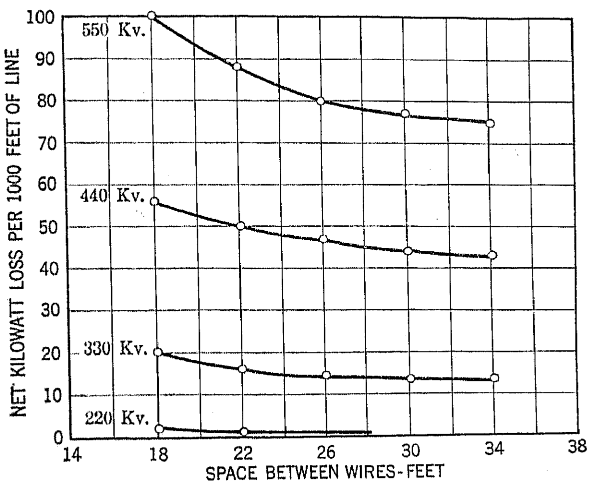

FIG. 7—NET CORONA LOSS PER 1000 FT. OF LINE CONSTANT VOLTAGE, VARIABLE SPACING 4/0 CABLE

are objectionably large, particularly at the narrow spacings. At 220 kilovolts between cables, a potential at which some lines are already operating, the corona losses are negligible, especially for the largest size of cable.

It should be noted that all results in this paper are plotted for single-phase circuits. The corresponding

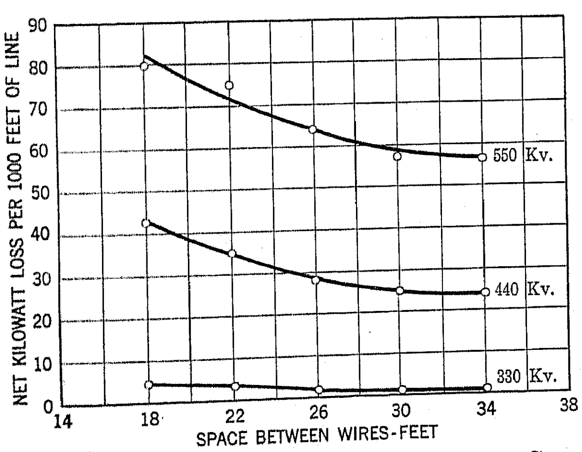

FIG. 8—NET CORONA LOSS PER 1000 FT. OF LINE CONSTANT VOLTAGE, VARIABLE SPACING 500,000-CM. CABLE

losses per 1000 feet of the normal three-phase line can be obtained from these curves by referring to a value of kilovolts between wires $\frac{2}{\sqrt{3}}$ times as great as the single-phase line voltage and by multiplying the resultant net loss in kilowatts taken from the curves by $\frac{3}{2}$ to include the loss upon all three wires.

For example, to determine the net three-phase corona loss per 1000 feet of line consisting of three 500,000-cm. cables spaced 26 feet apart at a voltage of 220 kv. between cables, the corresponding single-phase curve of Fig. 5 should be consulted for a voltage between wires of

$$\frac{220 \times 2}{\sqrt{3}} = 254 \text{ kv.}$$ The corresponding power loss is found to be 0.33 kw. This is the loss per 1000 feet of two-wire line having the same voltage to neutral as a 220-kv. three-phase line. The three-wire, three-phase line will, therefore, have a loss of $\frac{3}{2} \times 0.33 = 0.495$ kw. per 1000 feet, or 2.62 kw. per mile. A similar

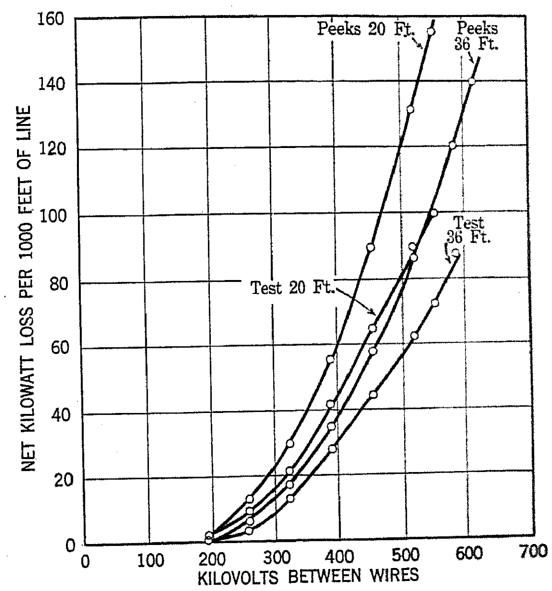

FIG. 9—NET CORONA LOSS PER 1000 FT. OF LINE COMPARISON WITH PEEK'S FORMULA 2/0 CABLE

calculation for a possible 330 kv. three-phase line having the same size of cable and the same spacing, indicates a probable loss of $\frac{13.5 \times 3}{2} = 20.25$ kw. per 1000 feet, or 107.0 kw. per mile. This would obviously be excessive and would, therefore, involve a change of design for a line to operate efficiently at such a voltage.

Comparison with Calculated Values. A complete analysis of the comparative results of tests and corresponding losses calculated for the same weather conditions, based upon Peek's formula, was not possible in the time available since the completion of the tests.

It is evident, however, from values in the tables and Figs. 9, 10 and 11, in which such comparable results are plotted, that the calculated values are consistently higher than test values *throughout the higher ranges of*

voltage. This departure of actual losses determined by the tests from the calculated losses seems to be particularly noticeable at the narrow spacings and with the smaller sizes of cable. For example, it is apparent from

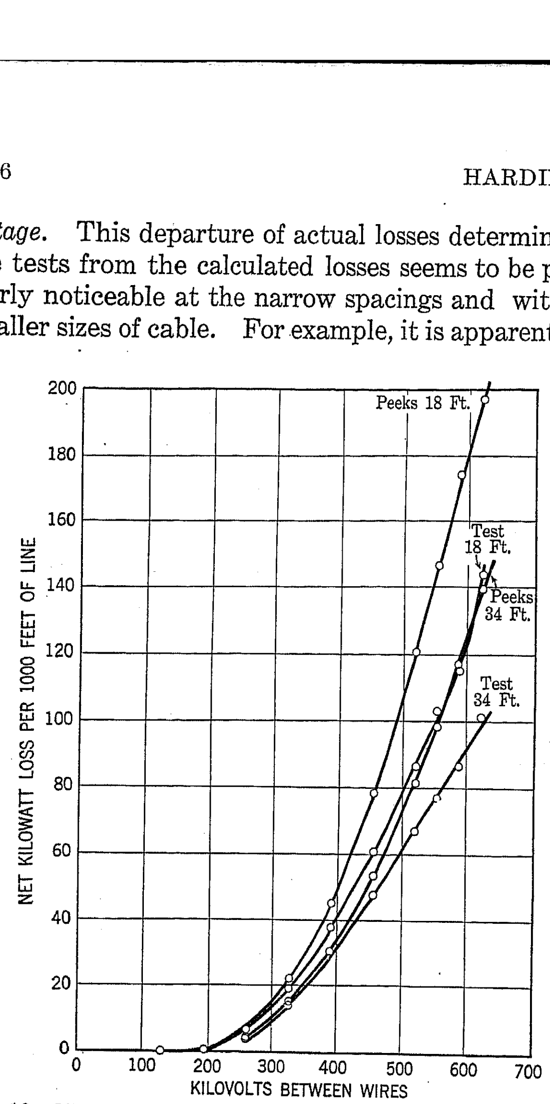

FIG. 10—NET CORONA LOSS PER 1000 FT. OF LINE COMPARISON WITH PEEK'S FORMULA 4/0 CABLE

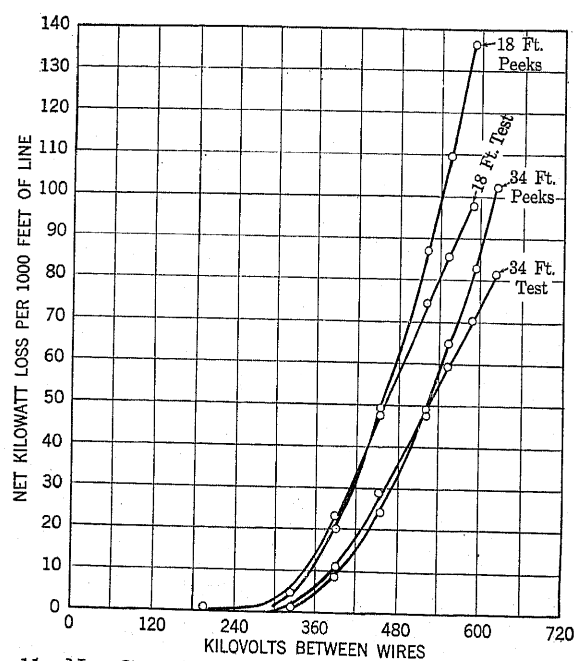

FIG. 11—NET CORONA LOSS PER 1000 FT. OF LINE COMPARISON WITH PEEK'S FORMULA 500,000-CM. CABLE

Fig. 10 that for 4/0 cable the calculated and test values are practically coincident for 18-foot spacing up to voltages not exceeding 300 kv., while the 34-foot spacing for the same cable indicated a coincidence up to 400 kv. For the 500,000-cm. cable, whose net test losses due to corona are superimposed upon the theoretical curves in Fig. 11, the calculated and test results are practically coincident up to 450 kv. for the 18-foot spacing and 520 kv. for the 34-foot spacing, the formula giving higher values of losses above and lower values below these voltages. Fig. 9 indicates a marked departure at the higher voltages of test from predicted values in the case of 2/0 cable for both narrow and wide spacings.

Test results are consistent with those reported at lower voltages in the first paper, since the theoretical calculation indicates losses less than the test values throughout the lower range of line voltages, while the former calculated values have a steeper slope upward with increased voltages than those found in the tests. In fact, the net losses throughout the higher range of line voltages, during the latter tests, seemed to follow a straight line or a modified quadratic law, rather than the parabola of the formula, thereby showing lower values of loss than those calculated.

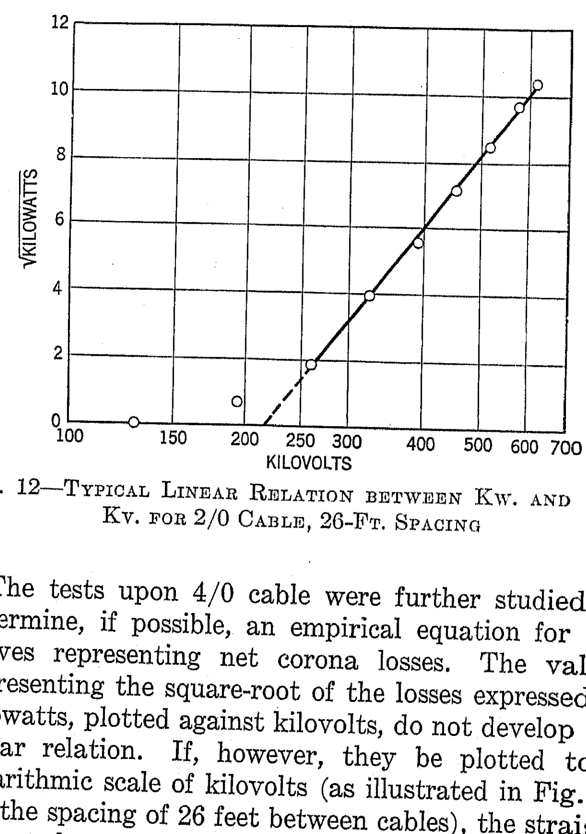

FIG. 12—TYPICAL LINEAR RELATION BETWEEN KW. AND LOG KV. FOR 2/0 CABLE, 26-FT. SPACING

The tests upon 4/0 cable were further studied to determine, if possible, an empirical equation for the curves representing net corona losses. The values representing the square-root of the losses expressed in kilowatts, plotted against kilovolts, do not develop the linear relation. If, however, they be plotted to a logarithmic scale of kilovolts (as illustrated in Fig. 12 for the spacing of 26 feet between cables), the straight line results. This indicates an equation of the form:

P (Corona loss in kw.) $= C \log_{10}^2 \text{kv.}/\text{kv.}_1$ where C is a function of the spacing (s), as indicated for both 2/0 and 4/0 cable in Fig. 13.

The voltage kv.$_1$ determined by the intercept for zero corona loss, as indicated in Fig. 12, is found to be 215 kv. for 4/0 cable or $P = C \log_{10}^2 \dfrac{\text{kv.}}{215}$.

It is rather significant that the values of C, which are

obviously proportional to the corona loss, approach a minimum value as the spacing between cables is increased. An apparent critical or unstable condition seems to exist for these two cable sizes, for spacings between 30 and 38 feet under these test conditions. It will be of interest to determine by subsequent tests whether this is due to the distortional effect upon the electrostatic field of the conductors at wide spacings

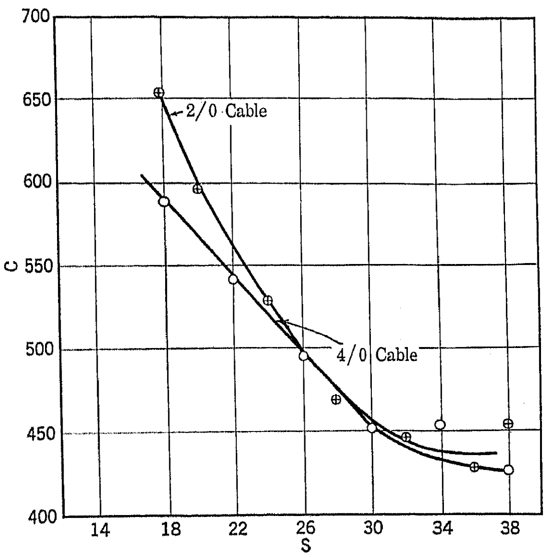

FIG. 13—RELATION BETWEEN EMPIRICAL COEFFICIENT (C) AND SPACING FOR 2/0 AND 4/0 CABLE

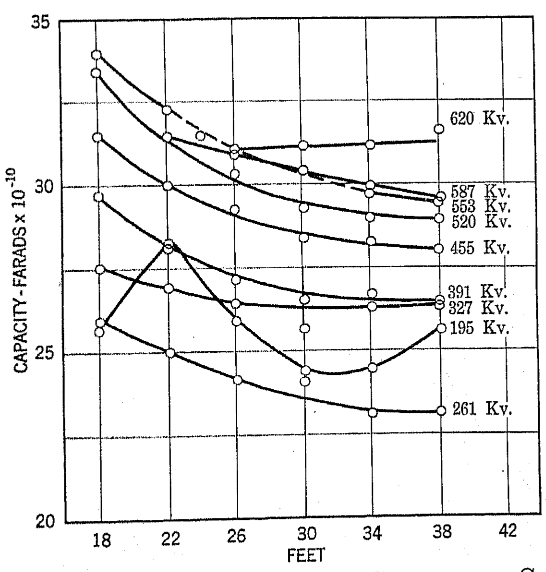

FIG. 14—RELATION OF EQUIVALENT CAPACITY OF CORONAL CONDUCTOR AND SPACING AT VARIOUS CONSTANT POTENTIALS FOR 4/0 CABLE

resulting from the proximity to the ground, or whether the "equivalent coronal conductor," if it may be called such, created by the ionization of the air surrounding the line wire, under excessive corona, becomes of such diameter or form as to produce a distinct localized minimum, or possibly a constant minimum loss independent of further increase of spacing.

Such possibilities immediately suggested three further studies, which have been undertaken in part as follows:

I. Calculation of Capacity and Corresponding Radius of Equivalent Coronal Conductor and Its Relation to Voltage between Wires.

II. Determination of Corona Losses between One Wire and Ground.

III. Photographic Reproduction of Equivalent Electrostatic Field Surrounding Model Conductors with Proportional Spacings between Wires and Ground.

The tentative results of these three investigations are briefly summarized as follows:

I. Capacity and Corresponding Radius of Equivalent Coronal Conductor.

The capacity of an equivalent conducting body of

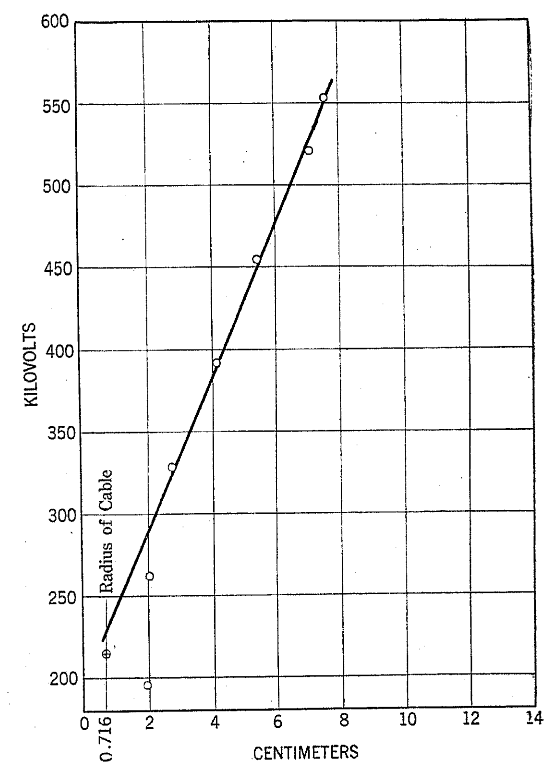

FIG. 15—RELATION OF RADIUS OF EQUIVALENT CORONAL CONDUCTOR TO VOLTAGE BETWEEN WIRES AT 18-FT. SPACING

corona or apparent corona, which has been assumed to be a cylinder, concentrically located with respect to the line wire, may be readily calculated from the test data available in the tables of the Appendix. The net corona power loss for each voltage and the corresponding current and frequency being known, the power factor was determined and recorded in column 6 of each table. The reactive or capacity component of the total current becomes known, therefore, and the equivalent capacity and radius of the enlarged hypothetical conducting coronal cylinder may be determined for any test frequency. A sample calculation of such capacity and radius is included in the Appendix as an illustration.

The relation between such calculated capacities and the spacing between two 4/0 line wires for certain

indicated constant voltages ranging from 195 kv. to 620 kv. is plotted in Fig. 14. It is particularly interesting to observe that for such wires at 620 kv., the capacity is practically constant for spacings extending

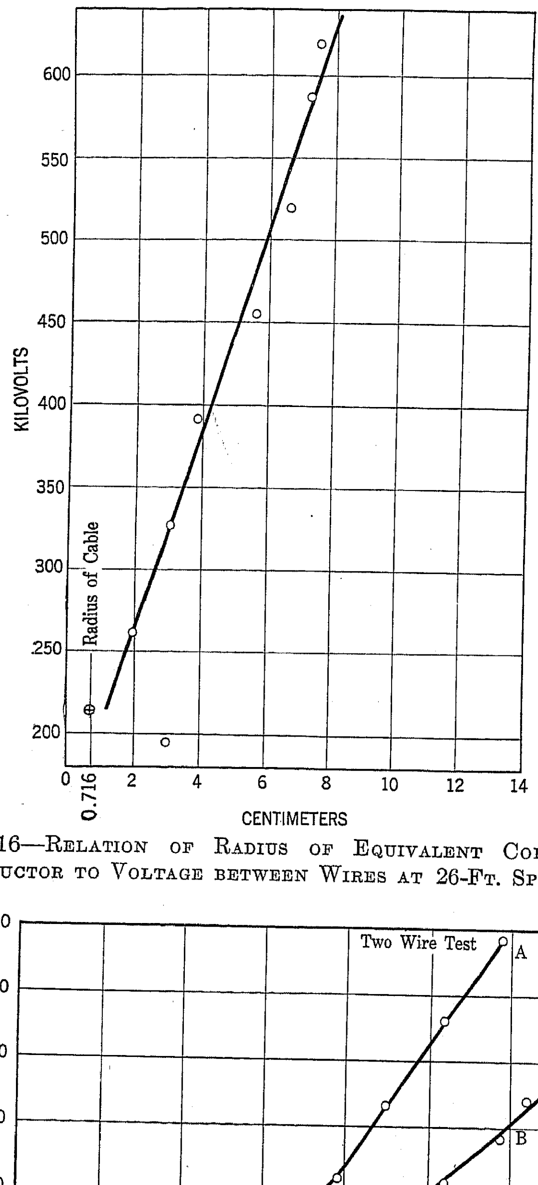

FIG. 16—RELATION OF RADIUS OF EQUIVALENT CORONAL CONDUCTOR TO VOLTAGE BETWEEN WIRES AT 26-FT. SPACING

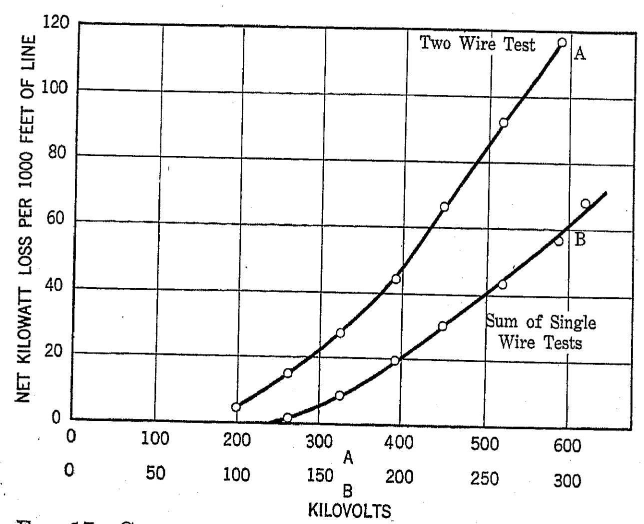

FIG. 17—COMPARISON OF CORONA LOSSES OF ONE 4/0 WIRE TO GROUND WITH LOSSES BETWEEN TWO 4/0 WIRES, 18-FT. SPACING

from 26 to 38 feet and probably beyond if the tests be extended, while at lower voltages the trend is toward smaller capacities as the spacings are increased and as the voltages for a given spacing are decreased. This condition is such as would be expected from the theory of the electrostatic circuit involved. The erratic variation of the equivalent capacity indicated by the curve for 195 kv. is also of interest, since this voltage is below the critical corona-forming voltage for such a cable. The irregularity of the curve is probably another confirmation of the well-known unstable condition surrounding such a wire when operating at a voltage approximating the critical corona potential.

If this investigation be extended to the determination of the radius of the equivalent coronal conductor, as previously indicated, the relations between such radii, expressed in centimeters, and the potentials impressed between two 4/0 wires of such a transmission line, spaced 18 and 26 feet apart, are available for further study in Figs. 15 and 16 respectively. As a basis of reference, the actual radius of the cable, which is 0.716 cm. in this case, has been plotted at a point corres-

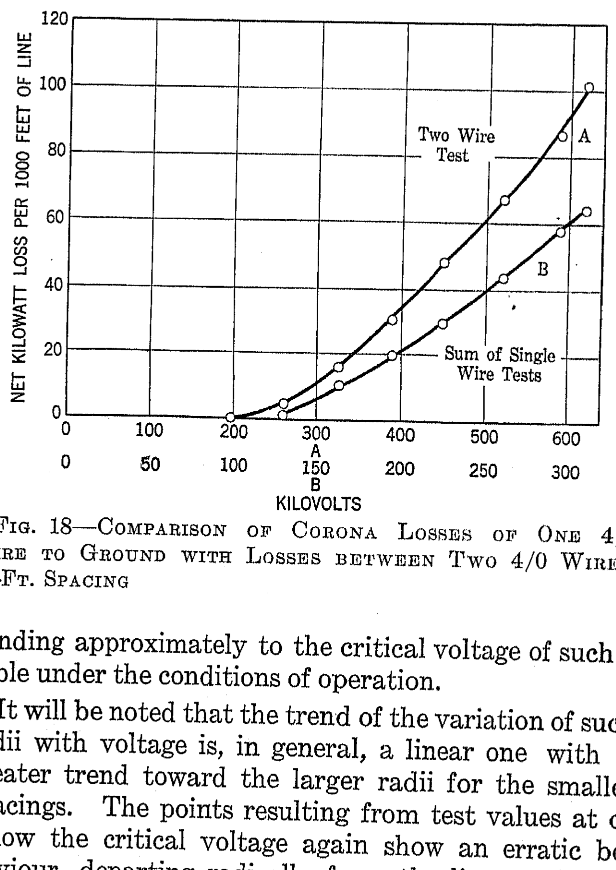

FIG. 18—COMPARISON OF CORONA LOSSES OF ONE 4/0 WIRE TO GROUND WITH LOSSES BETWEEN TWO 4/0 WIRES, 34-FT. SPACING

ponding approximately to the critical voltage of such a cable under the conditions of operation.

It will be noted that the trend of the variation of such radii with voltage is, in general, a linear one with a greater trend toward the larger radii for the smaller spacings. The points resulting from test values at or below the critical voltage again show an erratic behaviour, departing radically from the linear relation. In some of the other charts analyzed, but not reproduced in this paper, a very marked but probably purely incidental symmetry of fluctuation of such alternate points upon either side of the linear trend graph was particularly noted.

Although the practical bearing of this latter investigation may be far from obvious, it is probable that it may have a part to play in the determination of conductor diameters and spacings to be used for the higher voltages for power transmission in the future.

Corona Losses between Wires and Ground

Tests were conducted with the various sizes and spacings of wires upon the experimental transmission line with voltages increasing to a maximum of 300 kv. between one wire and ground. The other wire remained in place, at a definite spacing, but was disconnected from the high-voltage source and ungrounded.

An indication of the trend of such test data is evidenced by Tables XX and XXI in the Appendix and

Studies of Electrostatic Fields Looking at Ends of Parallel Wires at Various Spacings. All 65 Mm. Above Ground (Fig. 19-26)

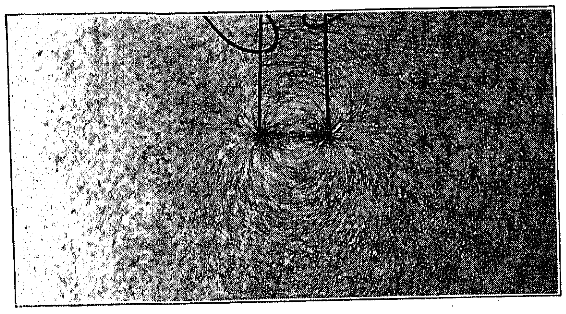

Fig. 19—Spacing, 18 Mm.

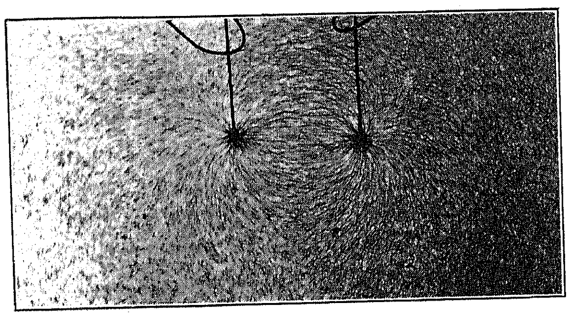

Fig. 20—Spacing, 38 Mm.

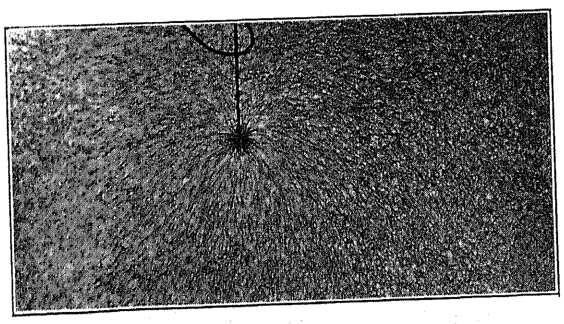

Fig. 21—One Wire and Ground

the composite curves of Figs. 17 and 18. As the spacing between wires is increased, especially if they are supported from relatively low towers, the effect of the neutral plane of the ground itself evidently becomes of importance, especially in determining proper corona eliminating designs for multi-circuit, super-voltage lines. It is to be expected for such spacings, as confirmed by these tests, that the arithmetical sum of the power losses due to corona between each wire individually and ground is very much less than the loss between wires at the same spacing. As the spacing is increased, however, this difference becomes less marked. The limiting factors in this relation at the higher voltages are yet to be determined, as they involve the relative costs of extra high towers as compared with wide rights of way for such long distance lines to be constructed in the future.

Reproduction of Electrostatic Field between Wires and Ground

The attempt which was made to apply the method of equivalent coronal conductor capacities and their radii, previously described herein, to the effect of the ground in cases involving wide spacings of wires, re-

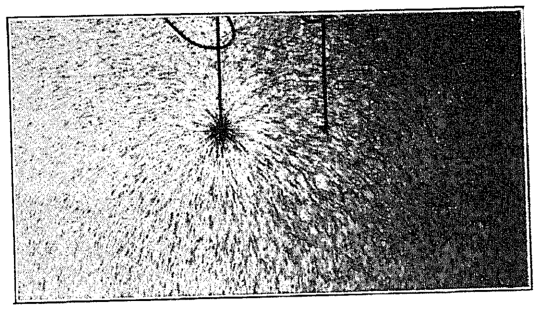

Fig. 22—Spacing, 32 Mm., Right Wire Disconnected

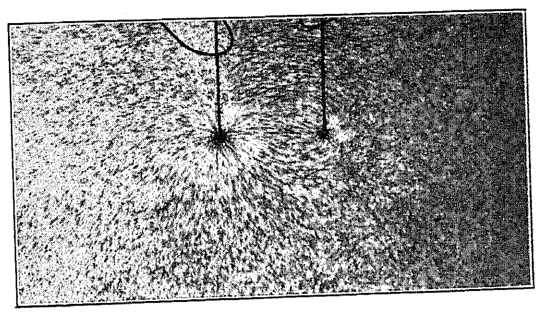

Fig. 23—Spacing, 32 Mm., Right Wire Grounded

sulted in erratic values, probably due to necessarily badly distorted resultant electrostatic fields.

The physical conception of this condition will, no doubt, be made clearer by the use of a method of photographing an equivalent model electrostatic field which has been recently originated by R. H. George, Research Assistant of the Engineering Experiment Station of Purdue University. Although this method was developed for another purpose, which will be published at an early date[4], its adaptation to this problem will be evident from inspection of Figs. 19 to 26 inclusive.

The scale of spacing in the model is proportional to the transmission line under consideration, one milli-

4. Forthcoming Bulletin, Engineering Experiment Station, Purdue University, Lafayette, Ind. "Improved Method of Visualizing and Studying The Electrostatic Field" by R. H. George, Research Assistant.

meter of the model corresponding to one foot on the actual line. In order that the effects of the same relative changes in spacing of conductors and the application of corresponding potentials between one and two wires and ground might be duplicated as closely as possible, the voltage for Figs. 19 to 26 was held constant. The captions of the illustrations will, no doubt, adequately explain the effects of ground potentials upon field distortion for wide conductor spacing.

Tests Under Abnormal Conditions. Two tests which

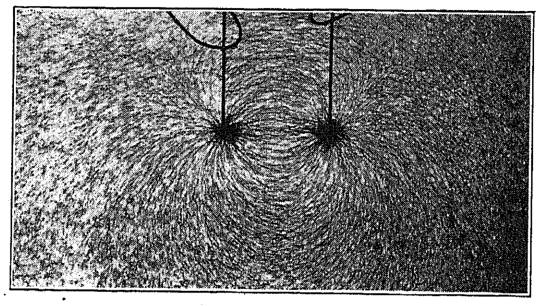

Fig. 24—Spacing 32 Mm., Potential between Wires

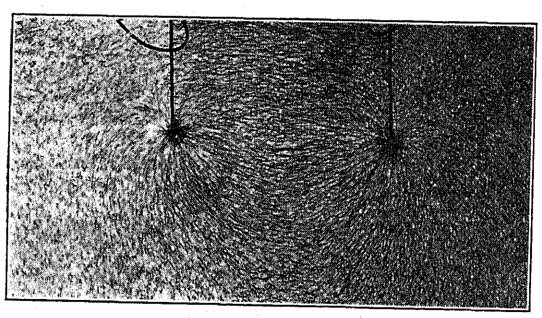

Fig. 25—Spacing, 65 Mm., Potential between Wires

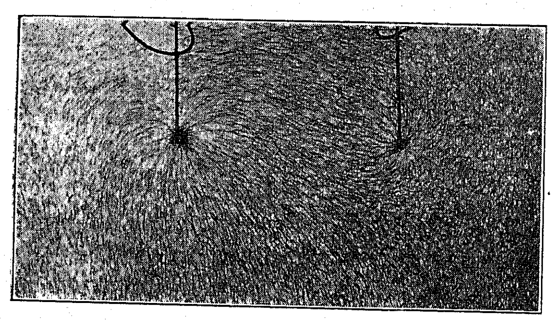

Fig. 26—Spacing, 65 Mm., Right Wire Grounded

were made under rather unusual weather conditions, seem to merit especial comment. Reference to Fig. 5 will reveal two tests upon 500,000-cm. cable at 34-foot spacing. Curve 5 in this graph represents a test during a rain storm with a temperature of + 3 deg. cent. and a barometer reading of 73.4 cm. The losses were relatively high in spite of the low temperature which would tend to produce lower losses than those of the average temperature of the other tests. Curve 6 was run upon a clear cold winter day with sleet upon the cables. The temperature was − 7.5 deg. cent. and the barometer 75.2 cm., as a result of which with the possible added effect of the enlarged conductor due to sleet formation, the loss was exceptionally low.

The tests are being continued upon other sizes of cables with varying conditions of operation, in order that a more detailed analysis may be made in a subsequent paper of actual results throughout this range of voltage.

Acknowledgment

The author desires to express his appreciation of the cooperation extended to the Engineering Experiment Station and School of Electrical Engineering of Purdue University by the following manufacturing companies, staff members and students, who provided materials and time for the design and construction of the line and for the tests reported in this paper:

The towers were furnished by the Bates Expanded Steel Truss Co., and the cables by the Aluminum Company of America. Insulators were used upon the line from the General Electric, Locke, Lapp, Westinghouse, Thomas, Ohio Brass and Jeffry Dewitt Companies.

Dr. W. E. Edington, Assistant Professor of Mathematics, Purdue University, who has devoted a portion of his time to the work of the Engineering Experiment Station, has assisted materially in the preparation of this paper. R. H. George and K. A. Oplinger, Research Assistants in the Engineering Experiment Station, operated the transformers, supervised the tests and checked all calculations. The following students of electrical engineering carried out much of the detailed construction upon the transmission line, took the readings under immediate supervision, and made calculations of the tests under the direction of the author:—

Design and Construction of Line: R. J. Rhinehart, A. Lorber, J. H. Brecheisen and H. O. Mathews.

Tests on 4/0 Cable: F. M. Holaday, P. W. Harrison, J. R. Parnin, W. F. Spaulding and W. J. Guenther.

Tests on 500,000 cm. Cable: F. C. Jones, M. S. Watson, K. O. Thorp, E. J. Archbold, R. C. Goodwin, K. T. Kwo and W. A. Sevedge.

Tests on 2/0 Cable: B. D. Holley, I. H. Hollis, W. J. Rannells, R. S. Merchant, D. Rasmussen and R. J. Morrison.

Typical Calculation of Capacity and Radius of "Equivalent Coronal Conductor"

4/0 Cable, 26 ft. Spacing, 391.5 Kv.
(Refer to Table X, Test III and Fig. 16)

$$C = \frac{I_c}{2\,\pi\,f\,E} \tag{1}$$

$$C = \frac{19.4 \times 10^{-9}}{\log_{10} \dfrac{S-R}{R}} \text{ (farads per mile, parallel conductors)} \tag{2}$$

$$I_c = I \sin\theta \text{ where } \cos\theta = \text{power factor} \tag{3}$$

From test data of Table X, $\cos\theta = 0.31$, whence $\sin\theta = 0.951$. Substituting values in (1) for gross capacity

$$C_{gross} = \frac{0.53 \times 0.951}{2\,\pi \times 60 \times 391{,}500} = 34.15 \times 10^{-10} \text{ farads}$$

C_{tare} (Feeders and Transformers)
C_{net} =

$$= \frac{6.97 \times 10^{-10} \text{ farads}}{27.18 \times 10^{-10} \text{ farads}}$$

This may be equated to (C) of Formula (2) thus:

$$27.18 \times 10^{-10} = \frac{19.4 \times 10^{-9}}{\log_{10} \dfrac{792.48 - R}{R}} \times \frac{1710}{5280}$$

whence $R = 3.83$ cm. (See Fig. 16).

Typical Calculation of Corona Loss by Peek's Formula

2/0 Cable, 20 ft. Spacing, 554 Kv.
(Refer to Table II, Test VI)

$$\text{Density Factor } (D) = \frac{3.92 \times B}{273 + T} \tag{1}$$

$$\text{Critical Voltage } (l_0) = g_0\, M_0\, r\, D\, 2.303 \log_{10} s/r \tag{2}$$

$$\text{Corona Loss } (P) = \frac{344\,f}{D} \sqrt{\frac{r}{s}}\,(e - e_0)^2\, 10^{-5}\, \frac{1.61 \times 2000}{5280} \tag{3}$$

Substituting values in (1)

$$D = \frac{3.92 \times 74.8}{273 + 14.5} = 1.02$$

$$e_0 = 21.1 \times 0.87 \times 0.566 \times 1.02 \times 2.303 \log_{10} \frac{610}{0.566} = 74 \text{ kv.} \tag{2}$$

$$P = \frac{344 \times 60}{1.02} \sqrt{\frac{0.566}{610}} \left(\frac{554}{2} - 74\right)^2 \times 10^{-5}\, \frac{1.61 \times 2000}{5280} = 155 \text{ kw.} \tag{3}$$

Discussion

F. W. Peek, Jr.: Prof. Harding has given us some curves up to 500,000 volts on conductors good for operation at 220 kv. or less. His loss measurements under some conditions show a close agreement with the quadratic law over a reasonable range of voltage for the conductors. The difference on several of the conductors is, I believe, due to the fact that sphere-gaps were used for voltage measurement. Regarding the divergence at the upper part of the curve where the arc-over voltage is approached, we have sometimes noticed a somewhat similar

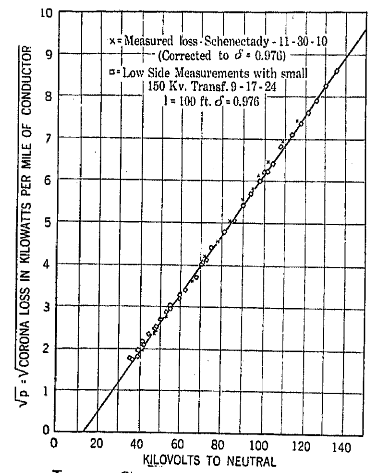

Fig. 1—Corona Loss Curve 0.066 Diameter Galvanized Iron Wire at 162 In. Spacing—60 Cycles

tendency on measurements that we have made up to one million volts. This has occurred on large conductors at spacing relatively small compared to diameter. It seems to be due to the distortion in the dielectric field that takes place because of the great amount of corona. The ratio of spacing to effective radius becomes small. The flexible corona conductor is distorted and no longer a cylinder. At the voltage when the divergence starts the corona begins to separate into huge cart

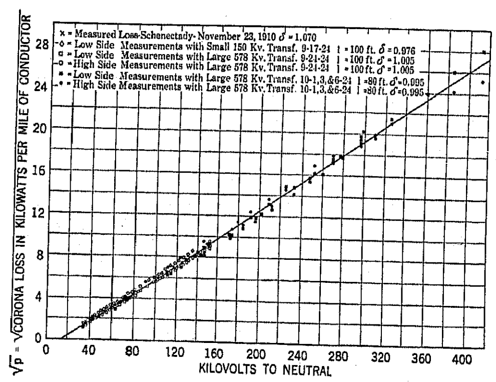

Fig. 2—Corona Loss Curve up to 800-Kv. Between Lines for 0.066 In. Diameter Galvanized Iron Wire at 162 In. Spacing 60 Cycles

wheels. These have a shielding effect preventing or lowering the loss between wheels. This does not mean that the quadratic law would not apply for calculation of the loss for million-volt conductors. Larger conductors and greater spacing would be used and the law would hold in the usual way. The tendency to diverge thus seems to apply only to extreme conditions or when spark-over is approached and distortion results.

We have never found the corona loss to vary, as Prof. Harding has, from the quadratic. Fig. 1 herewith is plotted from loss measurements made at Schenectady on a long outdoor line in 1910 and from measurements made in the Laboratory in Pittsfield on a short line in 1924. These measurements were made 14 years apart by different men with different apparatus, yet the check is exact. The curve is plotted between volts and the square root of the power because if a straight line results, it proves a quadratic. The range in voltage here is ten times the starting voltage. Measurements made on the same wire in 1924 up to over 1,000,000 volts or 60 times the critical voltage show that the quadratic law holds over this range. This seems to be a remarkably good confirmation of the quadratic law since the 1924 tests were made on a short line and check measurements were made on both high and low sides. The transformer-loss correction at 1,000,000 volts was rather large compared with the corona loss because of the short length of line. A wire with a small radius compared with the spacing was used to give a condition without distortion. Many curves similar to the above, all confirming the quadratic law, were made in 1910 up to about 250 kv.

Fig. 3 shows a similar curve for a cable like the one used by Prof. Harding. The tendency to diverge at about 500 kv. can be noted. The quadratic law is followed up to this point where distortion starts due to the large diameter of the corona. This distortion can be readily observed by visual measurements as noted above.

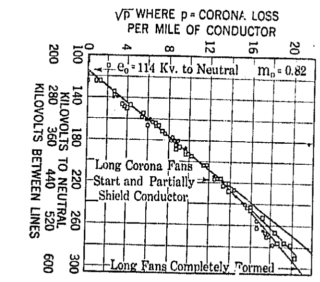

Fig. 3—Corona Loss Curve for 61 Strand, 600,000 Cir. Mil Cable at 15 ft. 9½ In. Spacing 60 Cycles, Single-Phase

$r = 0.445$ in.

$\delta - 0.964$

$p = 0.0166\,(e - 114)^2$ kw. per mile of wire.

I do not believe that Prof. Harding can be serious in his statement that 330 kv. could be used on a 500,000 cir. mil conductor. While Prof. Harding's tests are very interesting, the data cannot be applied to lines above 220 kv. because the tests were made on small conductors.

In comparing the loss between a single wire and ground with that of one of two wires, the spacing of the single wire to ground should be half the spacing of the two wires and the voltage of the single wire to ground should be half the voltage between the two wires. This would give equivalent stress.

L. P. Ferris: I should like to ask Mr. Harding whether he has taken any account of the change in wave form, which takes place with corona, in calculating the "radius of the equivalent coronal conductor?" I judge not, from the discussion on the sixth and seventh pages of his paper and the formula given in the appendix. Apparently the capacity is assumed to be directly proportional to the charging current per volt, which, of course, it would be if the wave form remained constant. It is well known that corona introduces harmonics as shown in the papers by Prof. Ryan and Mr. Wilkins. The question then naturally arises, how much of the increase in charging current can be accounted for by the increased admittance at the harmonic frequencies of a capacity fixed by the dimensions of the wires themselves and their spacings? There is apparently no doubt

that corona is accompanied by a cyclic variation of leakage or capacity or both, but it would be very desirable to have a definite picture of the mechanism of corona and its resulting distortion of wave form. We should then be able to agree on whether or not the capacity is truly increased, and if so, to what extent.

J. S. Carroll: The extraordinary increase in capacitance that Prof. Harding found has been somewhat difficult for me to understand. In some of our tests at Stanford the charging currents were about 10 per cent more than those calculated from the dimensions of the line and the line voltage as given by the voltage coil on the transformer. This bothered me for some-time until I got hold of the oscillogram of the voltage wave on the line. The oscillogram was taken from the Hendrick's coil

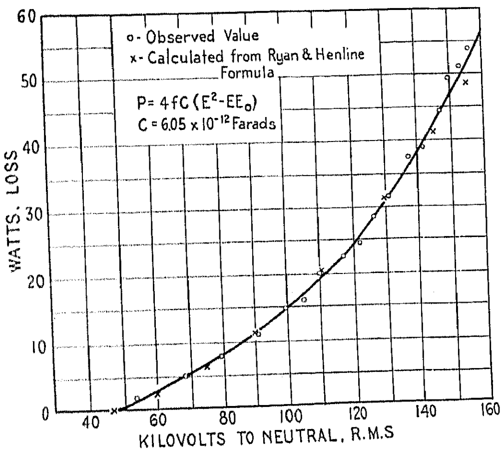

FIG. 4—SINGLE BRUSH LOSS FROM A POINT EXTENDING 3 IN. FORM A 3 IN. SPHERE

of the transformer. After the wave had been analyzed into its harmonics and these used in computing the line charging currents they were found to be within about 2 per cent of the observed values. The charging currents in the results of Prof. Harding seem to run rather high and the question of wave form, of course, has been previously brought up. These results of Prof. Harding are rather interesting from the standpoint of theory. I think there isn't much doubt that he is well above the economic range of operation, but it is interesting to know the power losses in this region.

I made some computations, using the corona-hysteresis formula that has been mentioned here, and this formula, by the way, fits the condition of the single brush as shown herewith in Fig. 4.

In these cases, until we known more about the conditions, we have to work backward, so to speak, with the formula. It would be a difficult problem to compute the exact capacitances of the arrangement we have there, so I took two points on the observed curve to determine the two unknowns, which would be the critical voltage and capacitance. These values were substituted in the formula and the power loss was calculated for various voltages with the results as shown in the curve of Fig. 4. It is interesting to note that the capacitance of this brush remained constant over a wide range of voltage.

Now, in Prof. Harding's tests. we have a line which is unquestionably being fairly well in corona, but there is some question as to whether it is in full corona. In Mr. Peek's pictures lines about this size are shown at a potential of a million volts and there are still some portions of the line that can be seen, apparently shielded by the brushes. In the use of the hysteresis formula with Prof. Harding's results we used the calculated capacitance as obtained from the dimensions of the line but the calculated values of power loss did not exactly agree with the observed values. However, when this calculated capacitance was multiplied by a constant the calculated and observed results were very close. These were only three curves out of the several of Prof. Harding's. With others tried, some fit as closely as these, others not quite so well. (See Fig. 5).

Now, this capacitance term we must think of in a little different way from the ordinary when applied to this formula. As used here it *means that capacitance which is attached to corona and not the capacitance of the conductor computed from its dimensions.* If the conductor is in full corona in every sense of the term then the field attached to the corona will be the same as that which would be attached to the conductor if no corona were present. In case of the brush formation on the conductor, if those brushes do not cover the whole field then only part of the capacitance of the line as computed from the dimensions should come in use on this formula. Of course, these curves run right into the x-axis at the critical voltage. That is because Prof. Harding's results begin well above the initial brush formation. Of course, the extreme lower part of these curves is not correct as shown by results in which lower-range instruments were used. At the early brush formation, we have a few brushes here and there, in

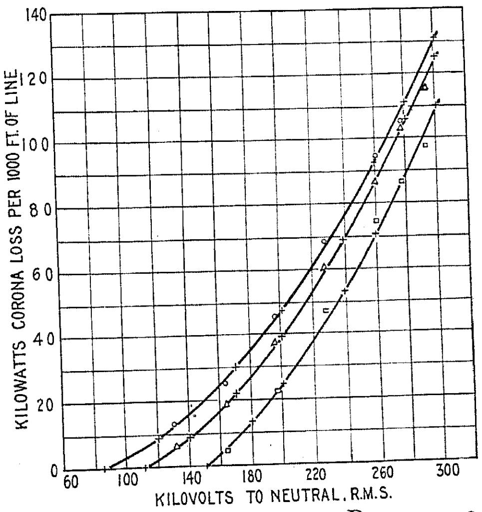

FIG. 5—CURVES OF BRUSH PATTERN IN RELATION TO C AND E_o IN EQUATION

$P = 4fc\,(E^2 - E_o\,E)$, Ryan and Henline

Using data given by Prof. C. F. Harding in his Pasadena Paper.

Curve	⊙	△	⊡	X
Conductor	2/0	4/0	500,000 cir mils.	Calculated from Henline Formula Using $K\,C$ instead of C
Diameter	0.447 in.	0.564 in.	0.904 in.	
Spacing	18 ft.	18 ft.	18 ft.	
Capacity M. F. per 1000 ft.	0.00246	0.00255	0.00275	
K	0.85	0.90	0.93	

some cases Mr. Wilkins says they are something like 100 ft. apart. It is the capacitance attached to these brushes that we want to consider, and not the full capacitance of the line, when this formula is used. The lower voltages used by Prof. Harding were the higher voltages used in most of the tests made at Stanford. What we are interested in is to find information so that we can predetermine the losses in the economic range. I have done some calculating along this line but the more calculating I do the more I see the need of experimental data and the tests actually made on the lines are extremely valuable in these respects.

Just one other word in regard to this capacitance. In the laboratory tests inside where we fixed up the rods with points

on them, and water drops just where we wanted them—in other words, where the brush formation was fixed, the corona-hysteresis formula fits the results exactly, just as it did in the case of the single brush, but when we come up to the order of a polished rod where the brush formation is not fixed, then we have trouble. I might say that in one case I tried a mathematical experiment similar to what Mr. Peek did, splitting the curve up into two component parts, you might say, with two different values of capacitance and two different critical voltages. I assumed we had a certain set of brushes at a certain critical voltage and that would have, of course, a certain capacitance; then, later on there was another set of brushes starting in with a higher critical voltage and an added capacitance. It came out very well.

C. Francis Harding: In closing the discussion of this paper, to which contributions of interest have been made by Messrs. F. W. Peek, Jr., L. P. Ferris and J. S. Carroll, it seems necessary again to emphasize the fact that the corona losses presented in the paper are actual, accurate results of tests under standard conditions of line construction and not extrapolations from empirical laboratory data. It is recognized by the author, as stated in his paper, that changes in both the design and construction of transmission lines for voltages above 220 kv. will be found necessary in order to avoid excessive corona losses, but the most practical way to determine the obstacles to be avoided in such designs is to determine the actual losses and other unknown phenomena resulting from higher voltages impressed upon present standard line construction.

The "difference on several conductors . . . . due to the fact that sphere-gaps were used for voltage measurement" suggested by Mr. Peek for the variation between values presented in the paper from theoretical calculated results has not been explained sufficiently by reference to the use of the sphere-gap, since the latter is recognized as the standard method of voltage measurement.

That the divergence between test and calculated corona losses, at the extra high voltages, may be due to distortion of the dielectric field, as suggested by Mr. Peek, is quite probable. This cause was mentioned on page 937 of the paper when, in reference to Figs. 14 and 15, it was found that the capacitance and diameter of the "equivalent coronal conductor" were not only unexpectedly large at very high voltages, but were erratic in behaviour at critical voltages and spacings. It is significant that these results have been confirmed by Mr. Peek in Fig. 3 within the range of 440 and 600 kv. between lines, although the size and spacing of conductors have not been given. The results submitted by Mr. Peek in Fig. 1 of his discussion represent values at much lower voltages, with no indication of the sizes or spacings of wires tested. The losses of Fig. 2, which are not referred to directly in his discussion and for which no cable sizes or spacings are listed, apparently indicate a considerable departure from the straight line determining the quadratic law if the curve be drawn through the points indicated as "High Side Measurements." The "Low-side Measurements" of net losses are necessarily made less accurately, although the methods of calculation and the conditions of test adopted are not indicated in his discussion. The conclusion seems to be warranted therefore, that between 440 and 600 kv. the divergence of such net losses from the calculated results may be considerable, if the conditions of line construction are such as to permit the formation of considerable corona.

With regard to the use of 500,000 cir. mil. conductor at 330 kv., no statement in the paper will be found to the effect that "330 kv. could be used on a 500,000 cir. mil. conductor" as incorrectly quoted by Mr. Peek. Losses between *two such cables* at spacings of from 30 to 34 ft. are shown in Fig. 8 of the paper to be "moderate" as compared with smaller cables and higher voltages, but the determination from test values of a loss of 107.0 kw. per mile of three-phase, three-conductor circuit of 500,000 cir. mil. cables at twenty-six foot spacing is stated on page 1185 to "*obviously be excessive and would, therefore, involve a change of design for a line to operate efficiently at such a voltage.*" Although it is probable that larger conductors will be used for voltages above 220 kv. when such lines are constructed, the possibility of increasing spacings between wires and the reduction of clearances to ground in some sparsely settled districts may be found to be a more economical means of reducing corona losses to an efficient minimum than by providing all of the adjustment by means of increased cable sizes.

No high-voltage transmission lines at present maintain the clearances between cables and ground equal to one half the spacing between the cables. It is recognized, as pointed out by Mr. Peek, that such an arrangement would provide equivalent electrical stresses. The test results of Figs. 17 and 18 were inserted in the paper in order to illustrate the saving in corona losses which may be found possible in the future by increasing spacings between cables by installing each cable or two cables of the same potential of a multiple circuit line upon individual relatively low towers, installed transversely upon the right-of-way at relatively wide spacings as compared with the height of such cables above ground.

In reply to Mr. Ferris concerning wave-form, it may be said that the calculations of capacity and the resultant "radius of the equivalent corona conductor" were made upon the basis of the sine wave having a maximum voltage established by the sphere-gap calibration. Although there is no doubt that harmonics are introduced by the corona formation upon such a line, particularly under partial and variable corona conditions, yet previous results reported to the Institute[1] by the author upon another experimental transmission line were determined from the oscillograms of both voltage and current, which seemed to indicate only very slight wave distortion at the higher power factors resulting from the very high voltages and consequent large corona losses. However, some of the seemingly erratic capacity variations at critical voltages noted in Fig. 14 may possibly be accounted for later upon the theory of distorted wave form. It is hoped that further studies may be made upon the effects of wave form upon this line.

The conclusion expressed by Mr. Carroll confirming the "need of experimental data and the tests actually made on the lines" is very pertinent, as it is believed that only the results of actual trials of extra high voltages upon lines duplicating future operating conditions with proposed new methods and designs for corona loss reduction will prove conclusively what the most economical, efficient, safe and entirely satisfactory line construction is to be for 330 kv. and above.

1. See footnote appended at bottom of page 1182.

Lightning

Does Lightning Oscillate? As a First Approximation, What is the Voltage, Current, Resistance, Energy, Power, Damping, Potential Gradient, and Rate-of-Change of Current?

BY E. E. F. CREIGHTON
Associate, A. I. E. E.
Consulting Engineer, General Electric Co., Schenectady, N. Y.

Review of the Subject.—*By the use of some new experimental data of the resistance of conducting vapors the conclusion is reached that the current in a streak of lightning oscillates. Starting with experimental value of 4500 volts per centimeter, as the average potential gradient for the electrostatic field between the thunder-cloud and earth, some astonishingly high values for the factors involved in lightning resulted. For more than a decade the average current in a lightning stroke of 10,000 amperes has been accepted. The calculations in this paper show a value as great as one-and-a-half-million amperes. Some of the other factors correspondingly large are as follows: The energy stored in the electrostatic field is 700 kilowatt-hours. The maximum power expended in the discharge is 860-billion kilowatts. The frequency for the particular stroke calculated, one mile long, is lower than former estimates,—about 50,000 cycles per second.*

Calculations were made of a bolt of lightning which struck a wooden pole protected by a No. 6 wire. The results agree with the independent calculations of the factors given above of a lightning stroke.

In a later paper the subject will be pursued further, and the equation will be recorded.

CONTENTS

THE object of this paper is to present the principal data which indicate strongly that the usual strokes of streak-lightning are oscillatory.

Significance of Oscillations

A pertinent question would be; What if lightning does oscillate? What significance has it? A few answeres will be given.

1. To the electrical engineer the protection of electrical apparatus and continuity of service are of prime importance. If lightning oscillates with a definite frequency a particular type of protective device must be used to protect against resonance. If the natural frequency of a coil corresponds to the lightning frequency the total energy of a traveling wave of electricity produced by lightning will concentrate by resonance in the coil. This local concentration of the electric charge endangers the insulation between turns of the coil.

The oscillatory type of lightning surge has an effect different from the simple high-voltage impulses which require only a lightning arrester to relieve the immediate potential stress. Furthermore, the oscillating surge differs from the abnormal currents which demand circuit breaker protection. A surge with a frequency may not possess either dangerously high voltages, which will jump through the path of the lightning arrester to ground, nor dangerous values of current, yet through resonance it is a menace to insulation.

2. Still more important is the protection of persons from electric shock, especially in a house struck by lightning. The presence of oscillations adds to the difficulty of protection.

3. Oscillations enter also into the protection of chimneys, powder magazines, oil tanks, and the like, the destruction of which causes at least a heavy financial loss.

4. To establish, in general, an understanding of the fundamentals of lightning theory and action,—in fact, to understand why lightning should strike from cloud to earth, it is necessary to know if the conditions are such as to permit oscillations. If experimental data and mathematical calculations combined with scientific speculations should prove that conditions of oscillation must exist before lightning can strike from the usual thunder-cloud to earth, then conversely oscillations are established because lightning does strike from the usual thunder-cloud to earth, as many can testify.

Where Lightning is Not Oscillatory

Oscillations are not generally accepted. The information comes to me from E. F. W. Alexanderson that

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

radio-engineers have had experiences with noises coming from "static" (an inclusive term) which lead them to conclude from their observations that the effects of lightning are consistent either with unidirectional current or otherwise, if oscillatory, with oscillations of no fixed frequency. Several eminent men of science who have taken an interest in lightning phenomena have assumed and measured direct currents induced by thunder-clouds. Furthermore, their measurements show changes of induced potential remarkably slow. De Blois[1] made measurements of induced current ten years ago, using an antenna and an ordinary bifilar oscillograph. C. T. R. Wilson[2] in making calculations of lightning current from his experimental measurements assumes a single unidirectional discharge. H. Norinder[3] made measurements of induced voltages due to thunder-clouds and again the changes of voltage were comparatively slow, even less than in a 60-cycle circuit and the current measured was unidirectional. Long before any of the foregoing observations were made Elihu Thomson, from experiments and observations, had concluded that lightning was non-oscillatory. If I understand correctly the part of the thunder-cloud considered by these eminent investigators, I am in agreement,—there are no oscillations. Later an endeavor will be made to show that the measurements made by De Blois, Wilson, and Norinder were potential changes due to the outlying parts of the thunder-cloud and not to the main streak of lightning. The large brilliant streak is the only part of the discharge with an electric resistance low enough to allow oscillations. The situation will be clarified by the statement that no proof is offered herein to cast doubt on the measurements made by these investigators. So far, none of their measurements was made near enough the main streak of lightning or otherwise with suitable instruments to record the sudden changes and high frequency oscillations of the streak itself.

Furthermore, be it understood that calculations of lightning current and oscillations, herein given, are not yet definite matters in the realm of engineering. Step by step during the past score of years a closer approach has been made toward an accurate understanding. There is yet much work to be done but the time seems opportune to record several factors which approach an engineering nature.

Scope of This Paper

Herein the results of new experimental data are presented. Also a new method of approaching the solution of the problem is given. It is not possible to present briefly the results and at the same time give mathematical justification. The merest statements of the results become voluminous without including the proofs. Therefore, it is planned to present the subject matter in readable form and, later, after the completion of the theory of formation of lightning storms, the conditions will be more propitious to show the formulas involved, to discuss their applicabilities and limitations, and state definitely the assumptions made. At present, then, comes the readable story.

However, in the lack of detailed calculations in this paper, an explanation is due those who "shake a right smart mathematical pencil." The particular group of well-established equations chosen for calculating numerical values includes those developed for "distributed" inductance and capacitance. Numerical values are mostly rounded off. Approximations are quite consistent with the knowledge of lightning and also with this first step in the presentation of the subject.

Standardized Electrostatic Field of Force

Initially there is needed a standard thunder-cloud. But pictures of thunder-clouds must first be developed before it is possible to choose one for a standard. The

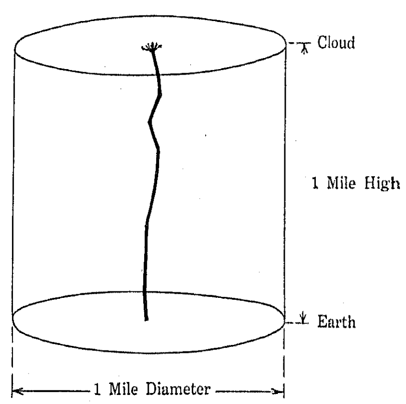

Fig. 1—Choice of Size of an Electrostatic Field of Force Due to a Thunder Cloud as a Basis of Calculation and Reference,—Designated in this Paper as Standard Field.

term "standard" in this case does not signify that every thunder-cloud has to be equal to the standard, any more than that any distance on the earth has to be equal to the standard yard, deposited in the archives at Washington. Like the standard yard, the standard thunder-cloud is a matter of reference. The standard thunder-cloud is later to be built out of the static field of force.

In the English system the standard field of force of a thunder-cloud is to be cylindrical in form one mile in diameter and about one mile high, Fig. 1. The lower surface of the field is the surface of the earth where one electric charge may be definitely located. The upper surface of the static field is that section of the thunder-cloud which may be considered the opposite plate of a condenser. But the cloud charge is not located on a definite surface like the earth. The total charge is made up of tiny charges on small drops of water distributed throughout the body of the cloud. Thus the visible thunder-cloud which produces the standard

3. *Electrical World*, February 2, 1924.

static field must be placed, at present, somewhat indefinitely about a mile above the surface of the earth.

Why choose these dimensions? Clouds do not form much above an altitude of three miles and thunder-clouds are usually much lower. Perhaps, as a guess, a kilometer is closer to the usual height of thunder-clouds. The horizontal dimension of the part of a thunder-cloud which discharges in a single stroke is estimated between a quarter of a mile and—very indefinitely—three miles. There may be larger charged volumes than the standard static field, yet it may be conceded that for the present a mile in diameter is large enough to consider,—the values of the calculated factors are sufficiently terrific.

It is well to prepare the mind for a later metamorphosis of this static field. According to the theory to be built up, the energy of the static field may not enter directly into the streak of lightning. Indeed, the electrostatic energy of this initial field of force may be turned entirely into electromagnetic energy before it is finally used up in the vivid hot streak which connects the cloud and earth. In brief, this static field is not the dynamic lightning stroke. The static field is merely a starting point.

The Capacitance of the Standard Static Field of a Cloud. The capacitance is equal to that of a condenser built of ordinary window-glass 1/8 in. thick and about 2.5 ft. square (0.3 cm. thick and 80 cm. square). Numerically the capacitance is about eleven thousandths microfarad (11.18×10^{-9} farad).

The Maximum Voltage of the Thunder-Cloud to Earth. According to the line of reasoning which follows, a thunder-cloud a mile above the earth and about to start a lightning stroke cannot have more potential above the earth than 700-million volts. The voltage of the thunder-cloud relative to the earth may be less than 700-million volts and still discharge to earth,—how much less depends upon the type of thunder-cloud and the soundness of the theories herein presented, of oscillations and of low damping resistance in the path of the discharge. It is not possible to discuss intelligently the value of the minimum potential to discharge to earth until definite pictures of the process of formation of the path of discharge are given. At present the discussion will be confined to the probable maximum value of lightning potential.

Establishment of the Probable Voltage Gradient of Thunder-Clouds

Theoretical assumptions of the main factors involved in a lightning stroke are not necessary. The discharge through the clear atmosphere is apparently like the high-voltage discharges in the atmosphere of a laboratory. After the average voltage gradient is determined, volts per centimeter or volts per foot from earth to cloud, it is only necessary to determine the approximate height of the cloud to calculate its voltage. The extremes of the possible voltage gradient will first be discussed. It is certain that the average voltage gradient from cloud to earth is not equal to the corona value of 24,000 volts per centimeter at an altitude of one mile (161,000 cm.). There can be no doubt that this critical voltage, which causes a visible discharge of electricity through the air, must exist at the point in the cloud where the lightning discharge is initiated. A visible corona must appear somewhat like a headlight to the discharge as it strikes forward. But, so far, as already indicated, no such high-voltage gradient near the earth has ever been measured.

A. B. Hendricks, in testing his two-million-volt transformer outfit, obtains an average voltage-gradient between pointed electrodes of 5000 volts per centimeter (1/6 the corona value at sea-level). The distance between sharp points was 426 centimeters (14 feet). The applied voltage was 2,120,000 volts peak value. Dividing the voltage by the spark distance gives approximately 5000 volts per centimeter for the voltage-gradient.

The voltages of spark-over of a needle gap at values up to 160,000 volts are the same for direct current as for the peak value of 60-cycle alternating current. So far as these data go, therefore, the 5000 volts per centimeter at the surface of the earth, as the average gradient, is fairly acceptable.

At the lower surface of the storm-cloud, at a mile elevation, the conditions are different in several respects from those at the surface of the earth. Not only are there charged raindrops, humidity at the dew-point, but also the elevation itself will change the potential gradient. The test of spark-over voltage between sharp points in normal, dry air would lower the potential gradient from 5000 volts per centimeter average at the Pittsfield elevation to 4290 volts per centimeter average at one mile elevation. A higher humidity at the cloud might raise the gradient above 4290 volts per centimeter. The presence of charged raindrops free to move under the electrostatic force would have an unknown effect. Furthermore, if there is a local discharge at the surface of the cloud the conditions are no longer static. There may be a resultant oscillation or at least an impulse. The possible significance of a local discharge in the cloud is the production of ultra-violet light which ionizes the air in the neighborhood, making it more conducting. Also if there is a local oscillation, the spark voltage in the neighborhood is lowered as so well pictured by President Ryan in his May address in New York. These factors of humidity, charged raindrops, local discharges, ultra-violet light produce uncertainties in the average voltage gradient in the cloud, which would be disturbing if it were necessary to get an exact value. But it is not. Some of the factors of lightning are not known and it will be shown in this theory that one factor is incorrectly estimated by over 10,000 per cent. Therefore, it is quibbling to hestitate at a guess which apparently involves at most only a relatively few per cent error.

H. Norinder estimated a voltage gradient near the earth as great as 4000 volts per centimeter. It must be evident if the voltage gradient near the earth was 4000 volts per centimeter, and we picture the cloud ready to begin a brush discharge, that is to say about 24,000 volts per centimeter at the lower surface of the cloud, the *average* potential gradient between cloud and earth must have been greater than 4000 volts by some unknown value. Having now in a rough way found the probable values in the neighborhood of 4000 and 5000 volts per centimeter, an intermediate value of 4500 volts per centimeter will be arbitrarily chosen as a probable maximum for a tentative working value.

An average voltage gradient of 4500 volts per centimeter and a height of one mile (161,000 centimeters) give the maximum possible voltage of the standard static field, stated above, of 700-million volts.

The Maximum Voltage Induced by Lightning On a Transmission Line

Since the potential gradient near the surface of the earth must be less than the average potential gradient to the cloud, the maximum potential that can be *induced* on transmission wires must be less than the product of the maximum potential gradient of 4500 volts per centimeter and the height of the line expressed in centimeters. For transmission wires strung at 33 to 44 feet above the surface of the earth the maximum possible induced potential from lightning will be five- to six-million volts.

To avoid a possible misconception, distinction may be pointed out between induced charges and the instantaneous voltage of a bolt of lightning. The voltage just in front of the lightning bolt as it bores its way through the atmosphere to earth is approximately 30,000 volts for every centimeter. By this line of reasoning, a power line that is struck by lightning may possibly reach a voltage instantaneously of six times the maximum induced value, numerically 30-million to 36-million volts,—but not more.

Returning again to speculations on the induced values of potential on a line, there is a special significance in the possibility of reaching five- to six-million volts. Will transmission circuits ever reach a high enough insulation to prevent all accidental short-circuit arcs around insulators? It has been frequently observed by transmission engineers that each step in raising the power voltage of the line so improved the insulation of the line that fewer lightning discharges cause flashovers on the insulators. Speculations have been made regarding the possible number of flashovers on the new 220,000-volt line with one-and-a-half-million volts (impulse) arc-over of the insulators. What would take place if such lines had been constructed in lightning-infested districts? If the maximum induced voltage of six-million volts is established, then as frequently as it happens every transmission circuit subjected to this maximum will arc-over the insulators momentarily at least.

The energy stored in the electrostatic field is about 700 kilowatt-hours which, if it could be gathered for use, would, at 10 cents, bring \$70. In less practical units there are 3×10^9 joules.

Power of a Discharge

The power expended by the discharge of a standard electrostatic field, although it is only a part of the total energy of the thunder-cloud, is astounding,—860-billion kilowatts (860×10^{12} watts).

Contemplating this possible display of power indicates we must give up the habit of speaking of dynamic power in lightning arrester work as indicating generator power and not lightning power. There is more dynamic in lightning than there is in our so-called misnamed dynamic power.

Is it possible that such power exists? The use of a potential gradient of 4500 volts per centimeter substituted in established equations indicates it does. The value of 4500 volts per centimeter cannot be much in error because 4000 volts per centimeter has been measured.

R. A. Millikan uses heavy discharges in the laboratory to strip the outside electrons off the atoms of the first chemical group, leaving nothing but the helium nucleus. The proof of the condition of the atoms he finds in the spectrum. Lightning with its terrific power will do as much to the nitrogen atoms of the atmosphere. How much more will it do to the oxygen atoms? This speculation will be given a special significance later.

Lightning current of a standard electrostatic field may reach a million amperes r. m. s. or 1.45-million amperes peak value.

Lightning currents have been measured by the magnetization of pieces of basalt placed in the neighborhood of the bolt of lightning. In a few tests magnetic forces in the basalt were left which indicated currents as high as 20,000 amperes. Elsewhere, by assuming the duration of a lightning stroke to be 28 millionths of a second, Wilson was able to calculate as much as 140,000 amperes. With these figures in mind it was startling to calculate that the standard thunder-cloud would give a current of a million amperes. This high current is calculated on the assumption that the resistance in the path of the stroke is not sufficient to prevent oscillation.

What is the resistance of the path? How may we determine if the discharge is damped sufficiently to prevent oscillations? Measurements in our laboratory were made on the current of arcs ranging from 1000 amperes to 34,000 amperes. The resistivity of the vapor (.0084 ohm per centimeter cube) derived from these tests was used to calculate the size, that is to say the diameter, of a streak of lightning which would just give a resistance that would damp out oscillations.

The diameter of such a lightning discharge would be less than ½ inch (a centimeter in diameter). When a discharge reaches a diameter of a foot, as apparently some of them do, the resistance in the path of the discharge must be less than 1/1000 the critical damping resistance. Thereby the conclusion is reached that lightning is oscillatory. Properly taken photographs of lightning will give the data to make the foregoing conclusions more convincing.

The lowest frequency that the discharge streak of a standard electrostatic field may have is, in round numbers, 50,000 cycles per second for a discharge a mile long (more accurately, 43,600 cycles per second). There is a special significance to frequencies of this order of magnitude. The natural frequencies of many transformer coils are of this order of magnitude. Resonance between the impressed and natural frequencies means destruction of insulation.

There is no known reason why the standard lightning stroke cannot oscillate in segments and thereby exhibit a higher frequency.

It is well-known also that lightning discharges shorter than a mile take place which might give a higher fundamental frequency than 50,000 cycles per second. Discharges three miles long have been photographed.

Damping of the Oscillations. There are several factors of vital interest in the question, How is the lightning current damped? What sort of law does it follow from its peak current to its zero value?

In an early paragraph the statement was made that lightning currents of 20,000 amperes peak value had been measured by the magnetization of basalt. In a later paragraph the results of calculations gave a peak current in a standard lightning cloud of the order of magnitude of a million-and-a-half amperes. As matters stand the experimental measurement has a firmer basis for truth than the theoretical calculations. In other words, every theoretical calculation must square itself with experimental measurements. An analysis of this difference between 20,000 amperes (measured) and 1,450,000 amperes (calculated) will show that both values may be correct even in the same lightning stroke. In order to measure the magnetic force of a lightning stroke F. Pockels assumes necessarily that the discharge is non-oscillatory—that is to say, the discharge is a direct current which rises to a maximum value and immediately turns and decreases to zero. In order to bring these widely diverging values of 20,000 and 1,450,000 into harmony it is necessary only to prove that the million amperes is the first alternation of an oscillation which continues to oscillate, magnetizing and demagnetizing the basalt until the last oscillation is reached. Then it is necessary to muster the factors which show that the lightning stroke does not follow the usual gradual disappearance of a current that takes place in our familiar discharges of condensers through inductance and low resistance as measured in the laboratory. Fig. 2 shows this usual type of decrease of current of oscillation to a very low value. In the familiar laboratory circuit the resistance has a nearly constant value. To be sure, in the lightning stroke the resistance of the earth may, in some isolated cases, be high enough to predominate and cause quick damping of the oscillations, but where the earth conduction is fairly good, most of the damping occurs in the resistance of the lightning streak itself. It is well-known that the resistance of an arc increases rapidly as the current in the arc decreases. Therefore, the oscillations in a lightning discharge will decrease step

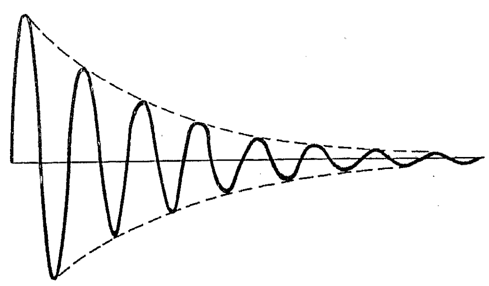

Fig. 2

by step in its peak value until the current arrives at some such value as 10,000 or 20,000 amperes, after which the resistance in the path of the stroke increases so rapidly that the oscillations are damped out and this last high value of current comes down to zero without overshooting in the other direction of current, as shown in Fig. 3.

If this theory is correct the measurements of current made by Pockels were of the final alternation of the lightning stroke. The point at issue at present simply

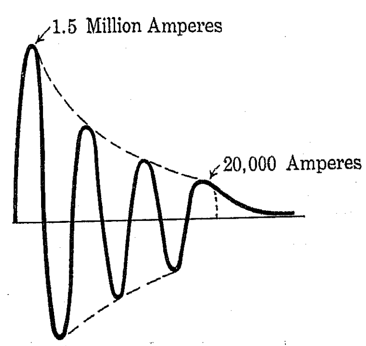

Fig. 3

is that the million ampere theory must square itself with incontrovertible experimental measurements. Has this not been made possible in the above explanation? If so, the truth of oscillations of lightning is a little more firmly established and we can pass on to the next step.

Time-Rate-of-Change of Lightning Current is of the Order of 400-Billion Amperes per Second

At the offset to clarify the position of the rate-of-change of current, it should be noted that we have

already dealt with an important factor, namely the rate-of-change of potential or potential gradient. But the potential gradient is a space change in the voltage, namely the voltage per centimeter of altitude in the atmosphere. There is another factor in the voltage change, namely the time-rate-of-change of voltage, especially in the unmade path of the advancing discharge. This factor of time-rate-of-change of voltage is pointed out at present for clarification purposes only. Later we may deal with the question of how long it takes a lightning charge to bore its way through the atmosphere from the cloud to the earth, or vice versa according to the authority. At present we are concerned with what takes place from the instant that the path is initially established in the hot streak to earth. The current must necessarily start from zero. It must rise according to some law, or combination of laws, to its peak value, possibly of the order of a million amperes. If the discharge is "standard" the current should rise to its peak value in about one two-hundred-thousandths of a second (.0000058 second). If, first, the tentative assumption is made that the current rises along a straight line from zero to one-million amperes, the rate-of-change of current will be two hundred and fifty billion (250×10^9) amperes per second (1,450,000 amperes divided by .0000058 second).

If, more correctly, it is assumed that the rise of current from zero to a peak value, instead of following a straight line, follows the more usual familiar sine curve, then the rate-of-change of current will be greater,—400-billion (400×10^9) amperes per second. This is the result for a cloud a mile high, a mile in diameter, and discharging at a peak current of 1.45-million amperes.

Experimental Confirmation of Rate-of-Change of Lightning Current

By an entirely different angle of approach, quite independently of the calculation on the standard lightning stroke, a reasonable check on the above results is obtained. In investigations of lightning on transmission lines my old associate, John A. Clay, Resident Manager and Engineer of the Western Colorado Power Co., at Durango, Colorado, has given me data of a direct stroke from which I can make tentative calculations of the rate-of-change of current. The details of this occurrence will be given in the A. I. E. E. Journal at some later date. At present I am privileged to use the data for calculations.

A wooden pole has an iron ring around its top and a No. 6 iron wire passes down the pole from the iron ring to the earth, ending in three widely spaced turns around the base. The pole was struck by lightning. In spite of the protection of the No. 6 wire in parallel with the wooden pole the potential induced along the pole was sufficient to cause a discharge along the wood in a parallel path to the protecting wire but on the opposite side of the pole. The discharge was severe enough to strip off the sap-wood for nearly the full length of the pole. Although the assumption may not be absolutely rigid, it seems reasonable to assume that the high voltage from the top to the bottom of the pole was due to a well-known law, namely the product of the inductance of the No. 6 wire on the pole and the rate-of-change of current. There are but three factors: voltage drop, inductance, and rate-of-change of current. The approximate inductance of the vertical straight wire can be obtained by simple mathematical calculations. We are seeking for a value of the rate-of-change of current, therefore we shall perforce have to assume how much voltage was required to ionize a path in the wood and establish a discharge which split and cast off the surface of the pole. In choosing this voltage a good deal of taste and discrimination may be used. However, the choice of voltage must be within a limited range set by the knowledge of spark potentials. Without attempting a thorough discussion, the first tentative assumptions will be two values: First, as the upper value, the corona voltage gradient not of 30,000 volts per centimeter but 24,000 (corrected for an altitude of 6000 feet); and second, as the lower limit, the average voltage gradient for a gap between points, 4000 volts per centimeter.

Assuming 24,000 volts per centimeter for a pole 33 feet (1000 cm.) high gives the absolute upper limit of rate-of-change of current as 960-billion (960×10^9) amperes per second. Incidentally the instantaneous voltage from top to bottom of the pole might have been 24-million volts for the maximum possible value, but it is far from probable that the maximum value was reached.

Of course, the splitting of the pole may take place gradually from end to end as might be done with an axe or other tool. In such a case it would seem that the electricity at the point of advancement has still a potential gradient of 24,000 volts per centimeter, but the average potential gradient from the top to the bottom of the pole may be something less. As a minimum it seems reasonable to assume the average potential gradient obtained by Hendricks for a fourteen-foot discharge between sharp points, namely 4000 volts per centimeter (corrected for altitude). Using the average voltage gradient at 4000 volts per centimeter, the rate-of-change of current in the direct stroke to the pole must have had at least the minimum value of 160-billion (160×10^9) amperes per second. Incidentally the absolute minimum voltage from top to bottom of the pole is now set at 4-million volts.

One of the joys of this speculative work is to attack an unknown factor from two independent standpoints and have the results agree. The gods occasionally supply such a gift; it is unseemly to look into the matter too critically. Yet perhaps some little devil of chance has falsely slipped the decimal point to make the two calculations agree. If later these results prove to be illusions it will only go to show that illusions in an engineer's experience are naturally short-lived.

Considerations of the Results

As matters stand, calculations show that the rate-of-change of current in the lightning stroke to the pole must have been between 160-billion and 960-billion amperes per second, according to which extreme of the potential gradient is chosen as able to split the pole. The previously calculated standard electrostatic field gave a rate-of-change intermediate, namely 400-billion amperes per second. This rate corresponds to an average gradient down the pole of 10,000 volts per centimeter. Thereby the total voltage from the pole-top to ground would have been 10-million volts (10,000 volts per cm. × 1000 cm. height). This remarkable agreement lends confidence to the earlier calculations of current of over a million amperes in the lightning stroke as reasonable and approximately correct.

The Colorado thunder-cloud cannot have forced on it the dimensions of a standard electrostatic field one mile in diameter and one mile high without engendering valid objections. The static field of that stroke was what it was and nobody knows. It may have been exactly equal to the adopted standard. The real point is that it could not have been greatly different in its equivalence.

No one saw the stroke on the pole. Even if witnessed, the dimensions and height of the cloud would remain unknown. Therefore it would be impossible to use these factors to calculate the current in the stroke and yet through the mathematical trick just employed it is learned that the current must have been of the order of magnitude of a million amperes.

The simplest illustration of this result is to show what the current could not have been. For example, let it be assumed that the lightning current in the stroke was 10,000 amperes, the value we were given and believed in, for the average lightning stroke, during more than a decade past. If this assumption is not true then its use in the equations will give unreasonable values. It does. The substitution of 10,000 amperes gives a frequency of the lightning stroke greater than six-million cycles per second,—a value quite impossible to accept. As a comparison, the frequency of 6⅓ million cycles corresponds to a quarter-wave length of line oscillations of 1200 centimeters,—a length equal to about the height of pole. This statement is only an analogy and does not prove anything. But the equation says very definitely that if the six-million cycles per second for the lightning stroke is not acceptable there is an alternative, namely to increase the diameter of the cloud. But to bring the frequency of oscillation of the lightning streak down to the value of the standard lightning stroke (43,600 cycles per second) and limit the current to 10,000 amperes would require an enormous cloud 146 miles in diameter—an absurd size for a thunder-cloud. Although the range of size of thunder-clouds is broad, nevertheless, there is a limit to the latitude allowed in the choice of the dimensions. As to altitude, clouds seldom form above three miles. Thunder-clouds are usually much lower. As to horizontal dimensions, the rain that falls during any brief time gives a rough estimate of the plan of the cloud. The usual thunder-cloud is comparatively small, a few miles across at most. Any result which requires a thunder-cloud of reasonable dimension is acceptable. To get reasonable results by the well-established equations demands a lightning current of the order of a million amperes.

Summary of the Factors

1. The maximum value that the *average voltage gradient* between cloud and earth may have is probably about 4500 volts per centimeter.
2. The maximum voltage of a thunder-cloud a mile high would therefore be about 700-million volts.
3. The current of a lightning stroke from a cloud a mile high has an r. m. s. value of about one-million amperes.
4. The lowest frequency of a lightning stroke a mile (161,000 cm. or 1.6 km.) long is about 50-thousand cycles per second. Strokes of greater or less length do not vary in frequency inversely as the length,—as in transmission circuits, but otherwise.
5. The energy in the electrostatic field is 700 kilowatt hours.
6. The power of the stroke is 860-billion kilowatts.
7. The rate-of-change of current in a lightning stroke is of the order of 400-billion (400×10^9) amperes per second.
8. The damping resistance decreases as the area of cross-section of the vivid streak increases. It is only the very thin discharges or discharges having high earth resistance that do not oscillate. If we can properly interpret our photographs of lightning strokes the diameter of the discharges in general is large enough to permit free oscillations. It will be left until later to produce data indicating that although lightning has an oscillation it may not have a fixed frequency even during the oscillations of a stroke.

Conclusions

The most pertinent questions are: What facts have been used and what assumptions have been made?

Some of the experimental facts used are:

1. The average potential gradient to produce a discharge in the normal atmosphere is about 4500 volts per centimeter. This gradient multiplied by the height of thunder-cloud gives the potential of the cloud.
2. The specific resistance (.008 ohm per centimeter cube) of arc vapors has been measured in the laboratory with currents up to 30,000 amperes.

Mathematical factors:

3. Very low specific resistance is proof positive that the resistance of the vivid streak is negligible initially and therefore that a simple equation may be

used (current = voltage of the cloud ÷ surge impedance. The surge impedance is $\sqrt{\frac{L}{C}}$).

The combination of these three factors,—average potential gradient, low specific resistance, and a simple well-established equation—gives a current in a lightning streak about a mile long of over a million amperes.

Assumptions involved:

1. That a streak of lightning is a straight conductor, the inductance of which may be calculated with close approximation by the established equations.
2. That the electrostatic field of the cloud is a capacitance that may be calculated with approximation by the formula for parallel plate condensers.
3. That the plate of the condenser as formed by the cloud has an equivalence at some depth in the cloud not known but a depth small as compared to the mile of height.

Since, so far, only a part of the thunder-cloud was considered, namely its lower surface, it may appear to the reader that the assumption was first made that the resistance was high in the path of the displacement current of the static field and subsequently that the resistance was low when the discharge gathered in the static field. Later it will be shown that as soon as the bolt strikes, the static field changes its location in the cloud from the lower surface of the cloud to the branches of the streaks in the cloud in which the electricity gathers.

As already indicated, it is not possible to bring this part of the speculative work to any great degree of completion in this paper, as it is dependent on the other parts to follow. Very considerable modifications will have to be made in the details of our standard thunder-cloud, as herein given, after an understanding of the formation of the lightning stroke is set forth. A complete understanding is not yet available in the records of human knowledge. It is only, however, by setting up pictures hypothetically of the various phenomena involved in the several kinds of lightning storms that rapid advance can be made. These theories are targets at which all observers can shoot. There is a rule to this game. Each step in the theory must square itself with the available experimental data and also with the preceding and following steps. At this point the matter must stand for the present.

Discussion

For discussion of this paper see page 1217.

Lightning and Other Transients on Transmission Lines

BY F. W. PEEK, Jr.
Member, A. I. E. E.
General Electric Co., Pittsfield, Mass.

Review of the Subject.—*A great many uncoordinated researches and observations have been made of lightning on transmission lines both in the field and in the laboratory. It is the purpose of this paper to coordinate this work with a view of determining the various types and order of magnitude of predatory voltages to which transmission lines are subject. No claim is made for exact results. If it were possible to obtain such results, they could apply only to specific cases. A knowledge of the general types of disturbances and their order of magnitude should be of great value in determining the best means of providing against them. Failures of apparatus can be provided against in a number of ways, for instance, by excessive insulation; by less insulation but a design to prevent local high stresses; by prevention of high lightning voltages by placing the line under ground; by greatly limiting the possible voltage by a ground wire; by limiting the time of application of the high voltage by arresters; or by combinations of the above. Obviously, the matter of design and economics is also of importance in considering the problem of protection.*

The technical part of the discussion will not be limited to cloud lightning, but will cover other disturbances.

Recent work of the author with his lightning generator and model transmission lines with and without ground wire will be included.

Voltage of a Lightning Flash

There has always been speculation as to the voltage of a lightning stroke, and various estimates have been made in more or less complicated or indirect ways. Recent laboratory tests have shown that up to about 2,000,000 volts maximum, 150,000 volts is required for every foot of spark.[1] If this rule held for great distances, the voltage of lightning could be calculated, since the length of the lightning flash as well as the height of cloud, etc., can be estimated. It had been generally concluded, however, that the voltage of the stroke was very much less than would be indicated by the length of the flash, or that when the flash-over started, it in some way continued to great distances at relatively low voltages.

In a lecture before the Franklin Institute the author described an experiment which seems to offer an almost direct means of measuring lightning voltages.[2] The means is quite simple. When a lightning flash occurs within a certain distance of a transmission line, a certain percentage of the voltage of the bolt is induced on the line. The voltage of the bolt cannot be measured, but its distance from the line and height of cloud can be estimated. The actual voltage induced on the line can be measured by gaps or estimated from insulator flashovers. The author has measured lightning voltages on transmission lines in Colorado as high as 500,000; insulator flashovers by lightning have occasionally indicated voltages as high as 1,500,000 or more.

A model was made to scale representing cloud and transmission line for a certain observed condition. By means of the lightning generator it was found that when a flash occurred from this model cloud 1 per cent of its voltage was induced on the model line. But we know by observation that the voltage induced on an actual line, under similar conditions, is sometimes of the order of 1,000,000. If this is 1 per cent of the voltage of an actual lightning flash, the voltage of the flash must be 100,000,000 volts. (See Fig. 1). This gives a voltage of 100,000 per every foot of spark, (330 kv/m.) which, considering the possible error, indicates that the needle gap spark curve may hold even at these extreme voltages. While the field produced by the charge is fairly uniform, it is probable that at the instant before spark-

over a needle-like streamer forms and breakdown then corresponds to the needle gap distance. Needle gap spark-over requires less than 20 per cent of the 30 kv./cm. required for a uniform field. The sparking distance should usually correspond to a continuous voltage because there is generally no large transient until after the spark starts.

It thus appears by approximately direct measurement that the order of voltage of a severe lightning stroke to ground may be about 100,000,000. The lightning voltage during a storm will, of course, vary over a very

1. F. W. Peek, Jr., Tests at 1,000,000 Volts, *Electrical World* December 31, 1921.

Presented at the Pacific Coast Convention, Pasadena, Cal., October 13-17, 1924.

wide range, sometimes much higher but generally lower than the value above. The author has observed that during a severe thunderstorm there may be many induced strokes at very low voltages, a less number at moderate voltages and so on to very few at the extreme voltages.

It will be noted that the above conditions require a gradient of 100 kv./ft. (330 kv./m.) in the most dense part of the dielectric field where the flash occurs, and a

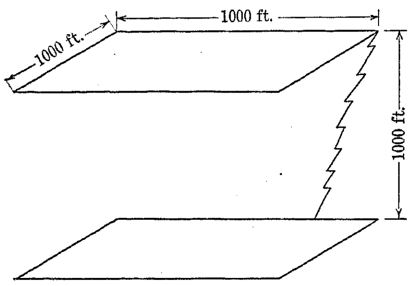

Fig. 2—"Cloud" Assumed for Calculation of Waves Shown in Fig. 3

gradient of less than half of this value a short distance from the flash. (See Fig. 4.)

Norinder has recently measured voltage gradients during a lightning storm which confirm the values given above.[3] To quote from his article in the *Electrical World*—"field intensities of the order of 100 kv. to 150 kv. per meter (30 to 45 kv./ft.) are common during thunderstorms at about the height of an ordinary transmission line. Pressures of 200 kv. per meter (60 kv./ft.) have also been recorded. A close study of the records shows that in the regions near the lightning path field intensities of the order of 300 kv. to 400 kv. per meter (90 to 120 per ft.) may exist." De Blois observed corona brushes of considerable dimensions. This also is an indication of gradients of the above order.

Nature of a Lightning Discharge

The experimental evidence seems to show that for the most part lightning discharges are impulses of very steep wave front, although some discharges are of impulses of slanting wave front and some are oscillatory. Oscillographic measurements made by De Blois on discharges from antennas showed that 60 per cent of the discharges were of steep wave front.[4] Similar studies recently made by Norinder indicate impulses of slanting wave front. However, it is not possible to tell from oscillographic records just how steep such waves are because of the relative slowness of the apparatus in responding. Other observations, however, indicate the order of the steepness of the wave front. When an impulse voltage is measured by a needle-gap and a sphere-gap, the sphere indicates approximately the true value of the voltage while the needle indicates a much lower value.[5] The ratio of these voltages indicates the steepness of the wave front. From observations on transmission lines the author has found impulses corresponding to single half cycle of 200-kv. sine waves and also impulses of very much greater steepness with an impulse ratio of two.

It is of interest to make certain assumptions as to size of cloud and length of discharge and calculate the wave to see if the above observations seem reasonable. Although such a check is quite rough, it should give good indications as to whether steep wave front impulses are likely to occur.

Assume that a cloud 1000 ft. (305 m.) square and 1000 ft. (305 m.) high, uniformly charged, discharges to earth. (See Fig. 2). The capacity of such a cloud is approximately 27×10^{-10} farads and the inductance of the path is 0.000488 henrys. If the resistance of the discharge path is 1000 ohms, the discharge is an impulse and non-oscillatory. The time is conveniently measured in microseconds. See Fig. 3, which is quite in agreement with observations. Fig. 3 also shows that the wave is practically an impulse with a resistance of 500 ohms for the discharge path, and that it is a damped oscillation for 100 ohms resistance. It is certain that

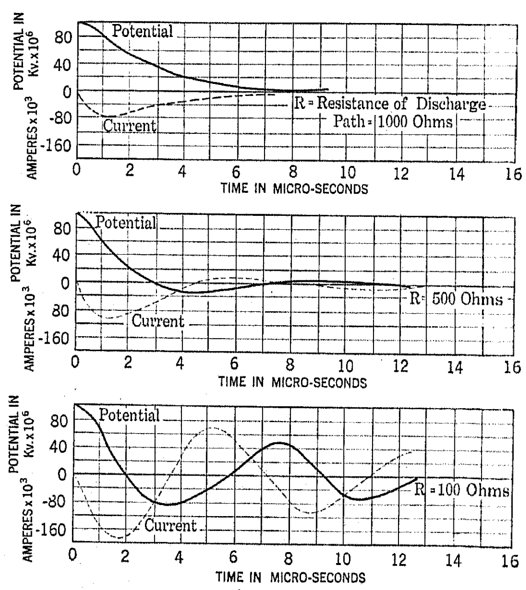

Fig. 3—Transients for "Cloud" Discharge to Earth (See Fig. 2)

$C = 27 \times 10^{-3}$ Microfarads
$L = 0.488 \times 10^{-3}$ Henrys

the cloud condenser is not as simple as the example taken and the probabilities are that there are local flashes in the cloud before the final flash occurs.

At 100,000,000 volts the maximum current would be 78,000 amperes. The stored energy would be 13,500 kw/sec.

LIGHTNING ON TRANSMISSION LINES

Most lightning disturbances on transmission lines occur by electrostatic induction and not by direct stroke. A charged cloud causes an electrostatic field to earth. Part of the field will terminate on a transmission line within its area. The line is said to have a "bound charge." If the voltage between earth and cloud becomes high enough, a lightning flash will occur. Although this flash may be a mile away from the line, the charge on the line is released and the insulated line increases from earth potential to some value above with polarity opposite to that of the cloud. The effect is of a voltage suddenly applied between line and ground. The field that extended between line and cloud now extends between line and ground. The voltage wave travels over the line at the velocity of light. If the line insulators are strong enough or have a high enough impulse ratio, the impulse may travel to the powerhouse to break down apparatus or to be harmlessly discharged to ground over the arrester if it has low resistance and low impulse ratio. As this lightning wave travels over the line, it becomes gradually dissipated by losses. The voltage that the line assumes at the instant of discharge is that of the equipotential surface at the point in which the line is located. This is a certain percentage of the potential of the cloud above earth, or, in fact, a certain percentage of the voltage of the lightning bolt. In studies in Colorado, as already stated, the author has actually measured induced lightning voltages on transmission lines as high as 500,000 volts. Insulator flashovers have occurred that indicate induced voltages as high as 1,500,000 volts, although the greater percentage of voltages induced on transmission lines are very much lower than this. These figures as already shown afford a means of estimating the voltage of a lightning flash.

Lightning Voltage vs. Height of Line. Fig. 4 shows the lines of force from a charged cloud. Transmission lines of equal height are shown, one right under the cloud and others some distance away. It will be noted that for the line under the cloud the gradient is 100 kv/ft. (330 kv/m.) but that it is much less a short distance away. The gradient is high immediately under the cloud. It will also be noticed that the voltage for any line will vary approximately as the height of the line because the field over the relatively short distances is approximately uniform. No attempt is made, because of the scale, to show the flux terminating upon the line. When a discharge takes place from cloud to ground, the line takes the potential of the equipotential surface in which it is located. The induced lightning voltage on a transmission line thus varies approximately as the height of the line. It is also approximately equal to the height of the line times the voltage gradient. Note that the voltage decreases very rapidly with increasing distance from the cloud.

Maximum Possible Induced Lightning Voltage on a Transmission Line. It was shown above that the maximum possible voltage gradient during a lightning storm was about 100 kv./ft. (330 kv./m.). This gradient would determine the voltage induced on the line if it were directly under a cloud charged to a voltage sufficient to discharge it to earth or to the line. Generally this condition will exist only in cases of direct stroke and gradients for very severe storms will be of the order of 50 kv./ft. (165 kv./m.) while for the majority of storms, gradients will be much lower than this. Low gradients will also exist for cloud to cloud discharges, which are generally in the majority.

It is of interest to tabulate height of tower vs. theoretical maximum voltage at values for very severe storms. The voltages in Table I were found by multiplying the height of tower by the gradient caused by the cloud. In the second column, the maximum voltage was found by using a gradient of 100 kv/ft. As previously stated, this is the gradient necessary to cause the lightning flash, and can only apply to the line when it is directly under the storm center. The voltages in the third column were found by using a gradient of 50 kv/ft. Such a gradient occurs when the line is about 1000 ft. from the storm center. It is a severe condition and does not usually occur. In column 4, a gradient of 100 kv/ft. was used, while a gradient of 50 kv/ft. was used in columns 5 and 6. All these conditions are severe and unusual. The voltages are for the instant that the flash occurs, and before possible insulator arc-overs can take place. These figures are, of course, not exact, but probably give the order of the voltage that might occur on a badly exposed line in a very severe storm directly over the line. Data obtained in Colorado for 24 miles of a badly exposed line on a high mountain ridge showed only one or two direct strokes in a season of fifty severe storms. Of the many lightning impulses induced on the line very few exceeded 50 kv. during a storm.

Referring to Table I, note that the ground wire practically cuts the voltage values in half. The ground wire will be very completely considered in a later section. The lightning spark-over voltages for insulators and bushings are given in the last column.[6] It will be noted that a 220-kv. line is generally free from lightning voltages high enough to cause insulator flashovers.

Propagation of Lightning on Transmission Lines. A laboratory study was made of the propagation of lightning on transmission lines.[7] These tests show that the voltage decreases in value and becomes less steep as the lightning impulse travels along a line. On striking an end, it increases in voltage and steepness of wave front as it is reflected. When an impulse strikes an inductance or choke coil, part is reflected but the voltage on the far side may increase to several times the in-

TABLE I
LIGHTNING VOLTAGES ON TRANSMISSION LINES

Height of Tower Ft.	No Ground Wire		Ground Wire			Lightning Flash-over Voltage of Line		
	Theoretical Highest	Probably Usual Highest	Direct Stroke to Ground Wire (One Wire)	Usual Highest (One Ground Wire)	Usual Highest (Three Ground Wire)	200 Kv. Line	154 Kv. Line	110 Kv. Line
75	7500	3750	3750	1875	900	..	..	..
50	5000	2500	2500	1250	625	1800	..	..
40	4000	2000	2000	1000	500	1800	1400	900
30	3000	1500	1500	750	375	1800	1400	900
20	2000	1000	1000	500	250	..	..	..

For a grounded line, the voltage above ground just before the discharge would be zero. For an isolated system the line would not assume the above voltage before the discharge as there would be leakage over the insulators and arresters and much "static." There would also be a reduction of the static voltage by the section of the line not under the clouds.

coming wave. This is not the case if the choke coil is shunted by resistance. A large choke coil without resistance may be a source of danger.

The corona loss in a line helps to lower the voltage of the wave. This was noted by measuring the voltage as the wave traveled along the line.

High Frequency and Oscillations Due to Secondary Discharge, Switching and Arcing Grounds. When an insulator is arced-over or a break occurs to ground, an oscillation takes place. In 1907 and 1908 the author conducted some tests in the mountains of Colorado for E. E. F. Creighton and J. A. Clay.[8] A 24-mile idle line was available. The lightning was permitted to discharge to ground through a large gap in series with a small auxiliary gap in a dark box. A rapidly revolving photographic film on a steel disk recorded the discharge. Many of these discharges were photographed. In all cases, following the first impulse, a very highly damped oscillation took place at the natural period of the line or about 1900 cycles. Fig. 5 gives an example of one of the many records taken. A few of the records are given in Table II.

TABLE II

5d	7.5	0.0020	1850	20	

The duration values given in Table II are a measure of the duration of the secondary oscillations and not of the lightning stroke. The "duration" measurements by De Blois are of the same order 0.006 seconds, while measurements by Norinder are of the order of 0.05 seconds. This instrument did not record the first impulse but the oscillation following the arc-over. Other observations indicate that in general there is the very steep impulse, followed, when breakdown occurs, by a highly damped oscillatory discharge of the line at its natural period. This oscillation is of comparatively low frequency.

8. E. E. F. Creighton, Measurements of Lightning, TRANS. A. I. E. E., Vol. XXVII, p. 669, 1908.

When there is an arcing ground, especially on a non-grounded delta system, oscillations occur. As far as can be observed, these oscillations are damped and have the effect of lightning impulses.[9] They rarely reach double voltage on a transmission line but may reach higher values when confined by inductance coils and may build up high local voltages in transformers. Although large numbers of tests have been made by producing arcs on power systems, undamped oscillations have not been observed. Fortunately, the severe oscillations produced by arcs on non-grounded systems are disappearing with the adoption of the grounded neutral system. With the grounded neutral systems the oscillations of arcing grounds are no longer a problem.

Disturbances due to switching are of the same nature as impulses or damped oscillations.

The reason that oscillations are highly damped seems apparent. Corona loss increases as the square of the excess voltage above the starting voltage and directly

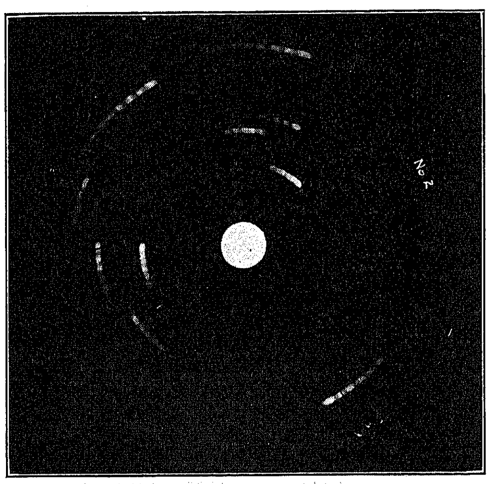

FIG. 5—LIGHTNING DISCHARGE FROM TRANSMISSION LINE PHOTOGRAPHED ON REVOLVING FILM

as the frequency. A simple calculation shows that it would require thousands of kilowatts at high frequency to supply the high-frequency loss on a comparatively short line at voltages considerably below the high-frequency flashover voltage of a line insulator. Furthermore, with arcs to ground or between lines the oscillations could not be isolated to short sections of a line. This also applies to damped oscillations of high train frequency.

High-frequency low-voltage undamped oscillations can exist and do exist locally on transmission lines. Such oscillations have been observed at towers where there were incipient arcs due to loose connections on the insulators or to faulty units in a string. The energy of such oscillations is necessarily low, since it is caused by the discharge of the very small capacity of the insulator. Probably the principal harm that these oscillations can cause is disturbances in carrier current systems.

A full size 220-kv. tower with insulators with and without grading rings was set up in the laboratory to try to obtain high-frequency voltages by arcs. The short section of line was excited at 60 cycles. To simulate a line, the high-voltage condensers from the impulse generator were inserted between the short line and ground. The dampening of such an arrangement should be much less than on a transmission line of similar capacity. In considering available energy it must be remembered that breakdown is caused by voltage. A large condenser with low losses in a short line can maintain the voltage more readily than the capacity of a long leaky line. Arcs made on the condensers failed to cause the insulators to arc-over. Loose contacts were made on insulator strings and varied to cause incipient arcs as well as arcs of considerable length. There was no measurable increase in voltage. A frequency meter showed a frequency of about four million cycles and very low voltage for local insulator arcs. Corona discharges five feet in diameter at a million volts failed to cause any measurable increase in voltage. Arc-over at normal voltage was readily caused by dirt.

TABLE III
ACTUAL DIMENSIONS OF MODEL LINES

Dimension of Cloud: 5 ft. by 7½ ft. (152 cm. by 229 cm.) Horizontal plate with rounded edges

Height of Cloud above Ground: 43½ in. (112 cm.) unless otherwise stated

Height of Line	Size of Conductor	Spacing
	Diameter	
12 in. (30.5 cm.)	0.040 in. (0.102 cm.)	3 in. (7.6 cm.)
6 in. (15.2 cm.)	0.020 in. (0.051 cm.)	1½ in. (3.8 cm.)
3 in. (7.6 cm.)	0.010 in. (0.025 cm.)	¾ in. (1.9 cm.)
1½ in. (3.9 cm.)	0.005 in. (0.012 cm.)	⅜ in. (0.9 cm.)

Ground Wire: Same size as line wire and, unless otherwise stated, conductor spacing from nearest conductor.

Lightning Generator Constants: Resistance 5000 ohms. Cap = 1.31×10^{-3} mf. $L = 2.88 \times 10^{-2}$ mh.

It is, of course, possible to apply persistent oscillations or damped oscillations of high train frequency to a short section of transmission line by means of a powerful oscillator. The effects of such voltages are quite characteristic and unlike anything that has been observed on a practical line. (See page 708). Insulators are not punctured and shattered, but cracked by excessive heating. At some sharp point on the line large corona losses cause great hot streamers. The ionization persists from cycle to cycle or train to train. If this point is removed or covered with porcelain, a similar arc starts at some other place where the gradient is high. These hot streamers or "electric needles" cause arc-over at about half of 60-cycle arc-over voltage.[10] To produce the thermal effect and to reduce the insulator

9. G. Faccioli, Electric Line Oscillations, TRANS. A. I. E. E., Vol. XXX, p. 337, 1911. W. W. Lewis, Switching Operations, *G. E. Review*, Oct. 1913. F. E. Terman, Measurement of Transients, TRANS. A. I. E. E., Vol. XLII, p. 462, 1923.

10. F. W. Peek, Jr., Dielectric Phenomena in High Voltage Engineering, McGraw-Hill.

flashover voltage, the oscillations must persist for a relatively long time. Although high-voltage persistent oscillations or oscillations of high train frequency do not occur on transmission lines, they are of interest in an academic way and make a spectacular demonstration.

The arc-over voltage is always higher for the types of oscillatory voltages that occur on transmission lines than it is for 60-cycle voltages.

Oscillation may cause high local internal voltages to build up in transformers.[11]

The Ground Wire

Quite an extensive laboratory study has been made on the protective value of the ground wire. This investigation was made on a model in which size of conductor, conductor spacing, height of line, etc., were all reduced to scale.[12] The results show quite conclusively that under favorable conditions the ground wire offers a very high degree of protection for both induced and direct strokes. Under such conditions and practical conductor arrangements it is possible to reduce induced lightning voltages to one-third of the value of those induced on unprotected lines. Under these conditions the ground wire also offers almost complete protection against direct strokes. When it is possible to obtain the value of protection mentioned above, the higher voltage lines will be practically immune from insulator flashovers due to lightning.

Some very interesting theoretical studies of the ground wire have been made.[13] Methods of making the calculations are also found in text books.[14] In general, the experimental work checks the theoretical work. There have been many conflicting reports from operating companies as to the protective value of the ground wire. Probably approximately half of the reports are in favor and half against the ground wire. The reason for this seems to be apparent from this investigation. The ground wire gives the high value of protection mentioned if the ground is good and the reactance of the ground connection is low. In a dry country, with poor grounds, its protective value against induced strokes would be low. On the other hand, in a damp country its protective value should be high. Its protective value would be low if grounds were made infrequently, since there would then be a considerable length of wire or reactance between the ground wire and the ground connection.

Complete data are given in the tables for the various factors affecting the ground wire. These will be discussed in detail.

Induced Strokes. The arrangement for studying induced strokes on transmission lines is shown in Fig. 6. The plate represents the position of the cloud which causes a steady electrostatic field to ground in the vicinity of the transmission line. The complete cloud includes the condenser of the lightning generator. This field is in reality a 60-cycle a-c. field but at the instant

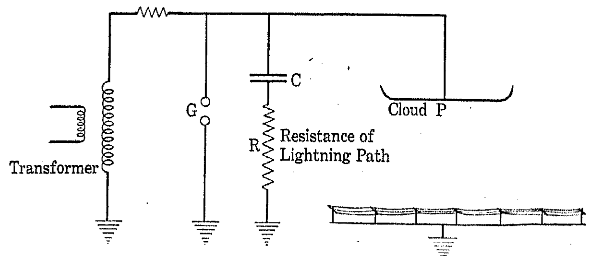

Fig. 6—Connections Used in Studying Induced Voltages on Transmission Lines

of discharge of the clouds to earth is in effect a steady field. Due to this field, all points in the intervening space have a definite potential. The space in the vicinity of the line has a certain percentage of the lightning potential above earth. When the condensers discharge, the charge on the transmission line is released and the line assumes the potential of the equi-potential surface in which it is located. See Fig. 4. The voltage of the cloud P and of the transmission line can be accurately measured; the voltage of the cloud to ground by spheres and the voltage of the lines to ground by small needle-gaps mounted to give minimum capacity. The ratio of the conductor diameter to spacing, etc., was selected to correspond to practical conditions. Tests were made with the transmission line grounded through high resistance to represent the grounded neutral system and also without grounds. The results

were practically the same. The model cloud and line are shown in Figs. 7 and 8.

The actual height of cloud is not important. It can be readily shown mathematically that since the field is practically uniform between the line and earth the induced voltages depend only on the voltage gradient in this part of the field. A given voltage gradient may be caused by a high cloud and high-cloud voltage or a low cloud with low-cloud voltage. Any condition may thus be simulated by a fixed cloud distance and varying voltage.

$s = 1\frac{1}{2}$ in.

By reducing the line spacing, size of conductor and height to scale, the capacity and inductance *per unit length* remain practically the same as for the full size line. The only factor that does not correspond is the resistance. It is relatively higher. However, it is not believed that this materially affects the results. It might also be well to point out that with equal voltage gradients the induced voltage will be much lower in the model than on an actual line. This follows because the voltage is approximately equal to the height of line times the gradient.

The length of the artificial cloud has no particular meaning except that it is long enough to produce a practically uniform field.

It will be noted from Table IV that the protective

value of the ground wire is quite high and the same for all cloud heights as theory would indicate. With one ground wire the voltage is practically cut in half. This also conforms with theory. The last column in Table IV is called the protective ratio. A ratio of 0.43 means that the induced voltage on the line with a ground wire is 0.43 of that on a line without a ground wire.

Ground Wire Arrangement. Table V shows the effect of various ground wire arrangements in limiting the lightning voltage. This table gives sufficient data to estimate the value of any practical arrangement.

TABLE VI
COMPARISON OF INDUCED LIGHTNING VOLTAGES ON GROUNDED AND NON-GROUNDED NEUTRAL SYSTEMS

Line Arrangement	Height of Line		Voltage Induced on Line		Protective Ratio of Ground Wire
	Actual of Model	To Scale	Actual of Model	To Scale	
No ground wire.	6in. (15.3cm.)	30 ft. (9.2 m.)	29.8	1788	..
Ground wire above center line..........	" "	" "	14.4	864	0.48
No ground wire power lines grounded through resistance ("neutral grounded")...	" "	" "	33.1	1986	..
Ground wire "neutral grounded"...	" "	" "	14.7	882	0.45

Under favorable conditions one ground wire reduces the voltage to one-half; two to one-third and three to one-fourth. The effectiveness of the ground wire increases as the distance between it and the line wire is decreased. The protective ratios given above are for a spacing equal to the conductor spacing which closely approximates the practical condition.

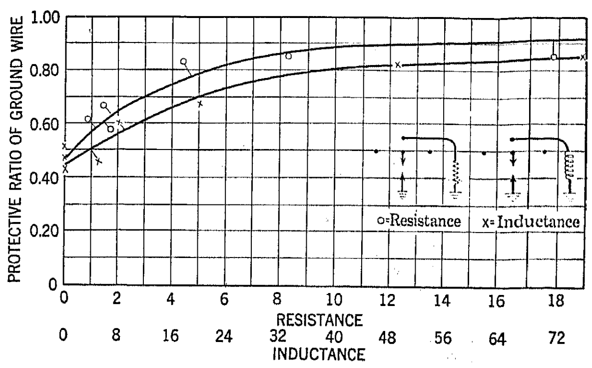

FIG. 9—EFFECT OF RESISTANCE AND INDUCTANCE UPON THE PROTECTION OFFERED BY AN OVERHEAD GROUND WIRE

Comparative Value of Ground wire on Grounded and Non-Grounded Neutral Systems. Table VI shows that the ground wire is equally effective on grounded and non-grounded neutral systems. It is interesting that the induced voltage is generally slightly higher on grounded neutral systems.

Variation of Induced Voltages and Effectiveness of Ground Wires for Lines of Different Heights. Table VII shows that by doubling the height of the line the

lightning voltage *induced on the line is approximately doubled.* The protective ratio of the ground wire is not changed with change in the height of line. Table VIII shows that the protective ratio is independent of cloud voltage.

Effect of Type of Discharge on The Value of the Ground Wire. So far, the results discussed have been for voltages induced by cloud to cloud or cloud to ground discharge with a steady field between cloud and line at the instant previous to discharge. A quite different type of discharge might occur. There might be a cloud at near ground potential directly above the line, while above this cloud there might be another at a very high potential. See Fig. 10. A discharge between these clouds could in turn cause an impulsive discharge between cloud and ground. This would induce a voltage on the line. A model of this arrangement was made with the results as given in Table IX. The protective value of the ground wire is the same as for the other types of discharge.

Relative Values of the Ground Wire Where the Soil is Conducting and Non-Conducting. The Effect of Inductance or Resistance in Series. Tests were made to determine the relative value of the ground wire when used in countries with dry and damp soil. A long box with a metal bottom was filled with 6 in. of sand. The 6 in. line was placed upon the top of the sand. Referring to Table X, the first two tests were made with a metal plate on the surface of the sand as a conducting ground. The next three tests were made with the sand ground and with the "water level" below the surface at a distance equal to the height of the line. By comparing tests 1 and 3, it is seen *that under equal conditions the induced voltage is higher in dry countries.* This follows because the flux extends from cloud to water level.

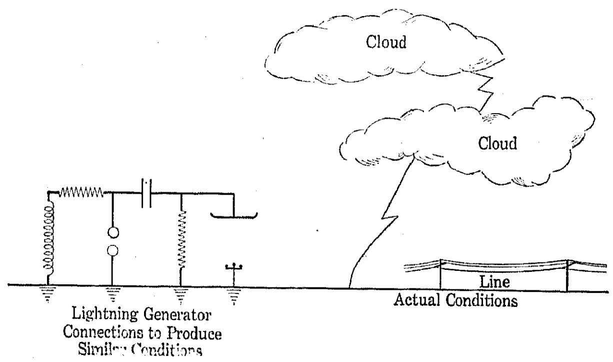

FIG. 10—IMPULSIVE DISCHARGE (DISCHARGE TAKES PLACE FROM UPPER TO LOWER CLOUD THEN FROM LOWER CLOUD TO GROUND)

The effect is that of increasing the height of line. Test 4 shows that the ground wire is effective providing connections are made to water level. Test 5 shows that it is not effective with a poor ground connection.

The ground wire reduces the voltage by reducing the initial charge or the flux terminating on the line and by

*Length in feet.

increasing the capacity to ground. This capacity has in series with it, however, the inductance and resistance of the ground connections. If the lightning discharge took place without time, the initial instantaneous voltage would be the same with or without the ground wire. The tests so far have shown that there is sufficient delay so that the inductance does not produce an appreciable effect with short wire connections. Inductance was added to the ground wire connection with the result shown in Fig. 9. Tests were also made with long ground connections and with series reactance. They show that the protective value of the ground wire could be greatly reduced in practise by resistance in the ground connection or by considerable distance between grounds causing high inductance. Thus, in a long span the induced voltage would be highest in the center of the span and minimum at the tower.

The actual values of resistance and inductance used, as well as length of ground connections, are given in Table XI. These values do not apply directly to a practical line, since the voltage and the energy on the actual line would be much higher. It is difficult to correct these to equivalent conditions for an actual line. It is safe to say that the values should be much smaller than those indicated to make an effective ground wire. They emphasize the importance of short low resistance low reactance ground connections. Fortunately, the modern steel tower affords a low inductance path to ground.

Electromagnetic Induction. The voltages measured in the line wires protected by ground wires are made up of the electrostatic induction and electromagnetic induction due to the induced current in the ground wire. The electromagnetic induction was found to be negligible. High impulse currents from the lightning generator were sent through the ground wire. The voltage induced on the line was 400 volts per ft. per 1000 amperes.

Direct Strokes. The ground wire, if favorably installed, is undoubtedly of great value in case of direct strokes. In the experimental work on direct strokes, the voltage was increased so that the discharge would take place almost directly over the ground wire. It will be seen by referring to Table XII that the ground wire offers good protection from direct strokes. There seems to be greater chance for an unprotected line to be struck in a dry country than in a wet country. In these tests the connection used was that in Fig. 6.

TABLE XII
PROTECTIVE VALUE OF GROUND WIRE FOR DIRECT STROKES

Tests were also made with the impulsive discharge of Fig. 10. It is interesting that this type of discharge was early recognized by Lodge. It is more difficult to predict where this type of discharge will strike than for the steady discharge. In these tests about 2 per cent of the hits struck under the ground wire to the line. The data will be found in Table XII. It appears that the ground wire will give almost complete protection against direct strokes on the line.

These tests indicate why direct strokes are so rare in practise. With everything deliberately arranged for the spark to take place to the line projecting above a "plain", it very frequently took place elsewhere. In practise the chances of a direct stroke would be very small, first, because the cloud arrangement would not be deliberate and, second, because the chances would be lessened by trees, hills, etc. The same would apply to high induced strokes because they necessitate a very high-voltage cloud near the line. Here, too, hills and valleys would be helpful.

Insulating to Withstand Lightning Voltages
Lightning Breakdown Voltage of Apparatus

Transient voltages are more likely to cause concentration of stress in apparatus containing inductance and capacity than normal frequency voltages. In designing inductive apparatus to withstand lightning voltages, the problem is greater than merely putting enough insulation between line and ground to withstand the highest probable lightning voltage as in the case of the insulator string. This has been recognized in the use of heavy end turn insulation in transformers. However, it is not always possible or economical to insulate local turns or coils to withstand the full voltage of a lightning impulse. It is obviously of great importance to design apparatus so that transients do not concentrate on a few turns but divide evenly over the total insulation. This has been done by shields.

Fig. 11—Lightning Striking the Overhead Ground Wire of a Transmission Line During Study of Direct Strokes and Induced Lightning Voltages on a Three-Phase Line during a Lightning Storm

Shields have a preventative action like the ground wire. Two good examples will be mentioned here. The ring insulator shield is used at high voltages to distribute the normal frequency stress more uniformly. By its use, the operating stress is reduced to about 25 per cent of the stress on a non-shielded string. The maximum lightning stress is also reduced to 25 per cent of that for a non-shielded string.

There is great danger of concentration of stress in transformers. At the first instant that lightning strikes a tranformer, the coils act as if they are open circuited; only the capacities function and the transformer is in effect a string of capacities or insulators with capacities to ground to cause unbalance. By placing a proper shield on the line end the effect of the capacities to line is to neutralize the capacity to ground and there is no voltage concentration. The transformer shield differs from the insulator shield in that the insulator shield controls the stress at both normal and transient operation, whereas the transformer shield operates only for transients.

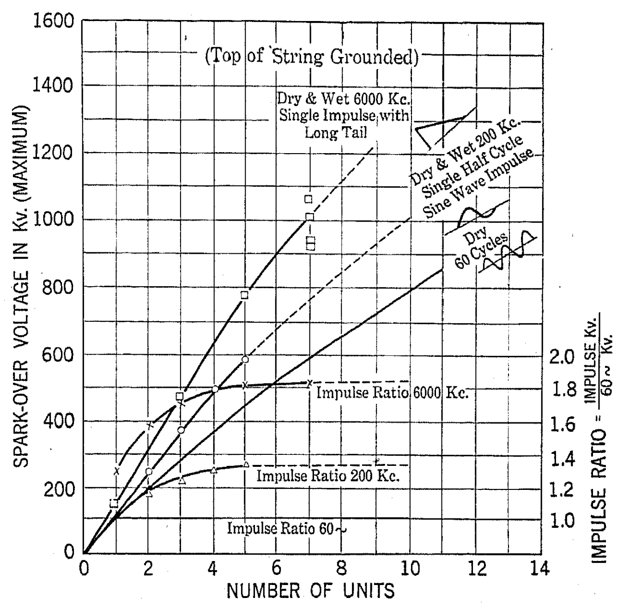

Fig. 12—Comparison of 60-Cycle and Lightning Flash-over Voltage on Suspension Insulators

The general principle of shielding is to place the coil between shields so that the electrostatic field established by the transient causes each turn to take the same relative stress as it does at normal frequency. An oscillation is thus not possible. The shield is of equal value in preventing high voltages from building up locally on the apparatus by high-frequency oscillations on the line. If even voltage distribution is obtained the problem is simplified.

For lightning strokes, switching surges and other high-voltage transients that occur on transmission lines, the breakdown voltage is much higher than for 60 cycles. The range of these surge voltages is given for line insulators in Fig. 12. The highest values represent steep wave front lightning voltages. For such voltages the wet and dry arc-over values are the same.

The steeper the wave front or the higher the frequency the higher is the breakdown voltage.

Persistent oscillations cause breakdown at decreasing voltages with increasing frequency, if the ionization persists from cycle to cycle. Hot electric needles are formed which reduce the spark-over voltage. However, as already stated, because of excessive losses, such oscillations cannot reach high values on transmission lines. This also applies to damped oscillations of high train frequency. Where the train frequency is over about 1000 cycles the breakdown voltage begins to decrease below the 60-cycle value with increasing train frequency. On transmission lines a damped train of oscillations may occur for each half cycle. The train frequency is then 120 per second. The breakdown and spark-over voltages are higher than for the 60-cycle. The breakdown voltage for the oscillation of the "Tesla Coil" excited at 60 cycles is also higher than the 60-cycle breakdown voltage.

Oscillations on a line can only follow after an arc occurs. Thus the original break must always occur in

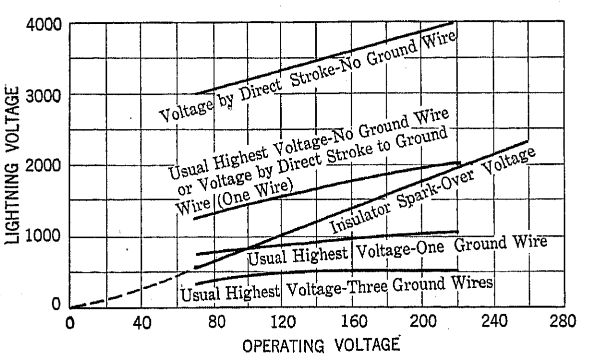

Fig. 13—Comparison of Insulator Arc-Over Voltage with Maximum Lightning Voltage for Severe Storm Directly Over Line

some other way as by lightning or by dirt or faulty construction. It is important to prevent the initial failure. Failures by dirt have been too frequently attributed to high frequency.

The lightning breakdown voltage of liquid and solid insulations is often five or more times the 60-cycle value when the stress is equally distributed.

The lightning flashover voltage of insulators is plotted with operating voltage in Fig. 13. On this same figure are plotted curves of the probable highest lightning voltage for lines with and without ground wires. A direct stroke on a line without a ground wire causes voltages much higher than the insulator arc-over voltage. The second curve down represents the usual highest voltage on a line without a ground wire. It happens that this same curve corresponds to the voltage by a direct stroke on a line with one ground wire. This curve crosses the insulator spark-over voltage curves for an operating voltage of 220 kv. This indicates that a 220-kv. line without a ground wire is not likely to have insulator trouble from lightning except in case of direct stroke. It further indicates that a 220-kv. line with a favorably installed ground wire is not likely to have trouble from lightning under any circumstance. The next curve gives the usual highest voltage for a line with one ground wire. Under usual conditions very little trouble should be expected for lines insulated for over 100 kv. operation. The lowest curve shows that three ground wires reduce the probability of lightning trouble to still lower operating voltages. The probability of trouble with direct strokes would be reduced in proportion.

The values of voltages taken in the above curves are for the most severe storms directly over exposed lines. Such conditions might not occur during a year or several years. It is a well established fact that during any storm there are likely to be many low-voltage induced impulses, a less number of moderate voltage impulses and frequently none at high voltage.

Lightning Arresters

The methods for guarding against lightning so far discussed have been preventative, such as the ground wire; better distribution of stress by the shield and by extra insulation. The remaining method is the arrester.

The object of the arrester is to permit transient or other excess voltages above a given value to discharge to earth and to suppress the dynamic arc and prevent oscillations. Since the transient currents are likely to be very high an efficient arrester must have low resistance. An arrester must also have low time lag, otherwise the transient voltage may rise to high values before the discharge occurs. A good arrester is of unquestionable value at the low and moderate operating voltages. The question of the extent of its use to take care of the unusual conditions at the very high voltages is an economic one.

Because arresters have gaps they cannot prevent low-voltage oscillations from building up high voltages in transformers. However, there is very little to be feared from such trouble in modern apparatus with shields. Where special cases require it, such oscillations are readily absorbed by placing a resistance in series with a condenser without a gap across the line.

Conclusions

Voltage and Energy of a Lightning Flash. The voltage of a severe lightning flash is probably of the order of 100,000,000. The current may be 78,000 amperes and the stored energy 13,500 kw./sec. The discharge is usually non-oscillatory and often takes place in a few microseconds.

Voltage Disturbances on Transmission Lines. Most lightning disturbances on transmission lines are steep wave front impulses that occur by electrostatic induction. There may also be impulses of slanting wave front and damped oscillations. The lightning arc-over of insulators is always higher than for 60 cycles and is not greatly affected by moisture.

The usual induced voltage is probably below 1000 kv. The voltage increases almost directly with the height of the line. The maximum possible voltage can be estimated by multiplying the maximum gradient of 100 kv./ft. by the height of the line in feet.

A lightning wave travels over the line and is dissipated to a considerable extent by corona loss. When it strikes an inductance or the end of the line it increases in value and is reflected. If the inductance is not shunted by resistance, high values of voltage may be built up. When breakdown occurs there is a damped oscillation at the comparatively low frequency of the natural period of the line or some section of the line.

Switching surges and other high-voltage disturbances that occur on transmission lines are damped oscillations. Such disturbances always require a higher voltage to cause insulator flashover than 60 cycles.

Persistent or continuous undamped oscillations at high voltage cannot exist on transmission lines because of the enormous losses. This also applies to damped oscillations of high train frequency.

A high-frequency oscillation requires an arc. It is, therefore, a secondary disturbance following a breakdown caused by lightning, dirt or some defect. Oscillations are not serious on grounded neutral systems.

The Ground Wire. A single ground wire when properly installed under favorable conditions reduces the induced lightning voltage to 48 per cent of that without a ground wire; for two ground wires the reduction is to 34 per cent while for three ground wires it is to 24 per cent.

The reduction is the same for isolated and grounded neutral systems.

The ground wire is apparently not effective in a dry country unless grounds can be made in conducting soil. Induced lightning voltages are higher in a dry country than in a wet country.

The effectiveness of a ground wire decreases as the resistance or inductance of the ground connection increases.

The ground wire is also a good protection against direct strokes.

Insulating to Withstand Lightning Voltages—Lightning Breakdown of Apparatus. Insulating inductive apparatus to withstand lightning voltages is a greater problem than simply adding insulation. Shields to prevent localization of stress are important and function in a manner somewhat similar to the ground wire.

A plot of the lightning strength of insulators and the probable highest lightning voltage for different operating voltages is given in Fig. 13. The indications are that a 220-kv. line with a ground wire should be almost free from lightning troubles. It cannot be said that there is any definite voltage where immunity begins, since the unusual may always happen. The danger becomes less and less with increasing operating voltage.

The extent to which protection should be used is a combined engineering and economic problem. The technical problem, which has been the subject of this discussion, is to determine the strength of apparatus, and the voltages to which it is likely to be subjected. With these factors known, the economic problem is to balance the cost of insurance against the value of better service and reduced liability of trouble.

Discussion

LIGHTNING AND OTHER TRANSIENTS ON TRANSMISSION LINES (Peek) LIGHTNING (Creighton)

Pasadena, Cal., October 14, 1924

F. W. Peek, Jr.: In some respects Mr. Creighton's conclusions are not as far from my own as might appear at first glance. The effect on transmission lines is determined wholly by the gradient. The fact that he has very high energy values is due to the high voltages or high cloud heights that he has assumed.

Mr. Creighton finds lightning oscillatory because of the very low value of resistance that he takes for the spark or bolt. In this I cannot agree with him. The specific resistance that he has taken was for a short very high-current dynamic arc. Such resistance is low because it is determined by the metallic vapor from the electrodes—in other words, a huge arc-light.

The conduction of a lightning spark is determined by the ionization of the gases of the air and not by metallic vapor. The specific resistance in gas conduction is very much higher than in metallic-vapor conduction—in fact they are not of the same order. Even in sparking-over an insulator string at 60 cycles, the initial break is gas conduction and it takes an appreciable time before the metallic vapors come into the arc. This initial spark can generally be seen in insulator flash-over photographs as a bright line independent of the rest of the arc. If specific resistance corresponding to gas conduction is taken it will be found that the discharge will be either non-oscillatory or very highly damped.

J. B. Whitehead: Since the time of Franklin there has been no question as to the electrical nature of lightning, but not until recently have we been able even to approach a reasonable certainty as to the particular forms of discharge and the values of electrical quantities occurring in lightning strokes. Even now our knowledge is very approximate, and the conclusions we have drawn are likely to be upset at any time. Messrs. Peek and Creighton compute the values of voltage, current and energy of a lightning discharge, from the known values of spark discharge in the air, and the assumption that a thunder-cloud and the earth constitute a parallel-plate condenser. The experimental evidence on which the conclusions are based, are the laws of spark discharge as we know them from direct tests, observations of potential gradients at the surface of the earth during lightning storms, and now, in Mr. Peek's case, experiments with laboratory models of transmission lines and cloud, and in Mr. Creighton's case, deductions from values of resistance of high-voltage electric arcs. The conclusions in each case are in approximate agreement as to the probable gradient at the surface of the earth at the time of the discharge. Mr. Creighton's estimated value of the voltage of the cloud is seven times that of Mr. Peek's, which leads to a corresponding difference in the values of current and energy. The two papers differ particularly in their estimate of the form of the discharge; Peek holding that usually the discharge consists of a single pulse, with occasional heavily damped oscillatory discharges. Creighton, on the other hand, concludes that the lowest frequency of a lightning stroke is about 50,000 cycles per second. Peek's conclusion is in conformity with

that of a number of others who have worked in this field, and Creighton is making a radical departure from a considerable mass of expert opinion, when he assumes that the discharge is always oscillatory. He bases his conclusions entirely on the low value of the resistance of a high-power arc, assuming that the discharge path of the charged condenser formed by cloud and earth is such an arc. I do not think that he has made out a good case for this. There appears to be two serious objections to his view. The first is the assumption that all of the resistance of the discharge lies in the spark or arc itself. In the passage of the spark, electric charge is drawn from wide areas of both earth and cloud. As is well known, the earth may have considerable values of resistance. Our knowledge of the effective resistance to the passage of charge through the mass of a cloud is not very definite, but I believe that in this case it would be found that this resistance is considerably higher than that of the surface of the earth. For example, the heavily ionized air between two corona-forming lines unquestionably has a very high resistance. The second objection is the assumption that the specific conductivity of the lightning streak is the same as that of the vapor of a sustained high-current arc. In the latter case the electrodes between which the arc is formed are vaporized, and it is this vapor which constitutes the conducting medium of the arc. No such source of conducting ions is present in the lightning streak.

It is probable that lightning discharges take a wide variety of forms. It would appear, however, from these two papers, that the evidence that we now have is quite good as to the unidirectional pulse as the commonest type of discharge, that such oscillations as do occur are very heavily damped, and that there is little or no evidence of a prevailing type of oscillatory discharge of relatively high frequency.

H. Michener: The portion of Mr. Peek's paper which deals with the ground wire is of particular interest to me as the value of the ground wire has been discussed at great length by various members of the Edison organization. Our present 220,000-volt lines have always been equipped with the ground wire with the exception of about 60 mi. of one line. The operation of this 60-mi. section, without ground wire, has been the same as that of the 60 mi. of line parallel to this and which has a ground wire. These two 60-mi. parallel sections are located in the San Joaquin Valley.

In planning for a new line from Los Angeles to Big Creek it was necessary for us to decide for or against the ground wire. This line will be located in the mountains and the foothills nearly all of the way and 75 per cent of the footings will be in rock. We have interpreted the results of the experiments that Mr. Peek has reported in his paper to mean that a ground wire on a line in a location such as this will give only 2 per cent more protection for the line than it would have without any ground wire. On this basis we have decided to build the line without a ground wire, but to design the towers so they will carry a ground wire safely in case we should ever want to install one.

H. T. Plumb: There is not enough caution thrown out similar to that of Mr. Peek about seeing that the ground wires and lightning arresters are properly grounded. In this Western country where there is not much soil, and where that soil oftentimes is thoroughly dried out, it is difficult to get ground connections and I want to suggest something which I have been advocating and using for several years. That is, making a coupling with the earth, not through conductance, but through capacitance; connecting to something that is extensive and that is a good conductor, and let it make the connection to ground by capacitance. I believe that will very materially add to the protective value of many lightning arresters which are not now properly grounded.

J. Slepian: The very interesting quantitative results which Mr. Creighton obtains, although admittedly somewhat speculative in nature, have a very great practical value for those engaged in combating the effects of these atmospheric disturbances upon power systems. It is very gratifying to find a general agreement as to the magnitudes of the voltages which may be induced on transmission lines, and to find that there is a logical relation between these magnitudes and the dielectric properties of air.

Mr. Creighton has not limited himself to the study of induced surges on systems, but has estimated the quantities in the lightning stroke itself, voltage, current, power, frequency, etc. These quantities depend on the capacity, inductance and resistance of the discharge path. The first two factors are geometrical in nature and may be calculated with considerable confidence. The resistance of the broken-down air making up the lightning stroke is a much less certain quantity. Mr. Creighton, by taking the results on the conductivity of heavy-current arcs in the laboratory makes it seem very plausible that resistance in the lightning path is small compared to the reactive ohms in the lightning circuit, and so neglects it in calculating current and power. The current and power so obtained are appalling. The practical conclusion to draw is that against the direct stroke to a power system we are helpless. Our puny lightning arresters are futile, discharging their hundreds or even thousands of amperes from the stroke involving millions of amperes.

We are better situated, however, with respect to the induced surges. Here the currents involved are well within the capacity of modern arresters. And since, fortunately, direct strokes are rare, while induced surges are frequent, we may feel confident that these arresters are really rendering an effective service.

By assuming that the resistance in the lightning stroke is small, Mr. Creighton arrives at another conclusion which at first sight would seem to be of very great importance for induced strokes. This is the oscillatory character of the lightning discharge. A remote stroke then, might induce on a system a surge of such low voltage that it would not discharge through the arresters, and yet which on account of its oscillatory nature, might develop a dangerous resonance in the vitals of a transformer. I wish to show that this apparent danger is actually non-existent.

I need merely to point out, that developing a resonance is a a cumulative phenomenon and therefore takes place only for wave trains which are sustained or only slightly damped. The first cycle of the train starts the resonant system oscillating; the second cycle finds itself in phase with this oscillation and increases it further; the third cycle likewise finds itself in phase and feeds still more energy into the resonant system. Thus the resonance builds up, and the energy stored in it will amount to many times the amount supplied by the first cycle. Things are otherwise if the wave train is strongly damped. The second cycle in the train, because of its smaller intensity, adds only a little to the energy supplied by the first cycle; the third cycle still less, and so on. Thus the total energy supplied to the resonant system by the damped train is little more than that supplied by the first cycle, and a cumulative resonance does not exist.

Now, I shall show that a lightning stroke is always of this strongly damped character. Where is the damping resistance? In the radiation! The column of highly conducting air, stretching up one mile high is the most effective antenna one could find for radiating the 50,000-cycle energy from Mr. Creighton's cloud. It is, in fact, as all lightning strokes must be, granting low ohmic resistance in their paths, an open oscillator oscillating at its own natural period. Such oscillations are always strongly damped by their own radiation. Textbooks on radio telegraphy show that in such natural oscillations, the second cycle is only about 30 per cent of the amplitude of the first; the third cycle will then be less than 10 per cent of the first, so that practically, we may say that the train is limited to two cycles. Hence a cumulative resonance is impossible.

It must not be thought that the radiation resistance which causes this great damping will seriously affect the calculations of Mr. Creighton. Very considerable resistance may be added to an oscillating circuit without affecting the maximum current very greatly. For example, the maximum current in a critically damped circuit is equal 1/2.718 times the maximum current in that same circuit with resistance reduced to zero.

John B. Taylor (by letter): "Does lightning oscillate?" The question is not a new one in our discussions. Sixteen years ago (see TRANS. A. I. E. E., Vol. XXVII, p. 684, 783 and 795, 1908) Mr. Creighton was assuming oscillations in lightning flashes with frequencies of 1,000,000 cycles, and I was characterizing such a figure as unreasonable for a mile-long stroke because the velocity of propagation in space is wholly insufficient to move a charge back and forth over a mile in a millionth of a second. This objection related only to the estimated figure for frequency, irrespective of low or high resistance in the discharge circuit which determines whether the discharge oscillates or not.

Mr. Creighton, in his present paper, defends the idea that the typical cloud discharge is oscillatory and now calculates or estimates 50,000 cycles per second for the one-mile-long discharge between earth and a cloud one mile in diameter. The capacity of the cloud to earth is given as 1/100 micro-farad which, in round figures, requires an inductance of 1 millihenry to give the oscillation frequency of 50,000 cycles. This value of inductance seems much too low for a straight-away conductor a mile in length well separated from any return circuit. A value of inductance two or three times as great appears more reasonable.

However, this point does not appear so important as the omission of anything in the picture to indicate what becomes of the moving charge or current at the two ends of the mile-long flash. His argument for the presence of oscillations is that the flash itself has a definite diameter greater than ½ in. and approaching 1 ft., and that the resistance of a flash of such size is low enough to permit the discharge to persist in oscillations. But the charge and discharge must move in the cloud from the main flash to the edges. This will add perhaps a mile to the length of the discharge path, increasing the inductance, and properly further affecting the estimates of frequency. It is hard to picture a thunder cloud with moisture particles or drops in such contact as to provide an extended conducting path of low resistance. A suitable picture of the cloud itself seems quite as essential to the theory as a picture of the main flash.

Mr. Peek straddles the question by saying that *some* lightning discharges are oscillatory. He does not tell just what class of experimental evidence is taken to justify his conclusion that oscillations at times occur. For his cloud of assumed dimensions (1000 ft. square, 1000 ft. elevation, a smaller and lower cloud than Mr. Creighton's) he figures that there will be oscillations with frequency of about 140,000 cycles if the resistance of the discharge path is below 1000 ohms.

Messrs. Creighton and Peek both make reference to experimental work on the other side of the Atlantic by Mr. H. Norinder who reported in *Electrical World*, Feb. 2, 1924. Mr. Norinder made experimental observations of induction from natural lightning flashes, and, with a cathode-ray oscillograph, secured evidence that none of a number of lightning flashes studied were oscillatory. As the cathode-ray is not subject to the mass and natural period limitations of the vibrator in the more familiar oscillograph, it serves well for studying electrical oscillations at frequencies of a million or more cycles. Mr. Peek must have overlooked this fact when reading the Norinder article for he states immediately following the mention of Norinder's work:

"....it is not possible to tell from oscillographic records just how steep such waves are because of the relative slowness of the apparatus in responding."

Mr. Creighton disposes of Norinder's conclusions by making a distinction between oscillations in the cloud and in the flash, and promises to discuss this at a later date.

From these two papers and from the Norinder article, it appears that Mr. Creighton holds a brief for there being oscillations in a lightning discharge, basing his case on assumptions as to dimensions and physical characteristics.

Mr. Peek says there may or may not be oscillations but invites the question: "What is the evidence?"

Mr. Norinder gives experimental evidence that oscillations are absent in lightning flashes.

E. R. Stauffacher: Mr. Michener has told you that we were somewhat reluctant to give up the idea of using an overhead grounded wire on the new Big Creek line, but it was finally decided that the possibility of the ground wire breaking and coming in contact with the conductors outweighed the protection which the ground wire would afford. I should like to ask Mr. Peek one question regarding the value of overhead grounded wire as applied to the location of this wire with reference to the conductors and the structure of the tower.

The Big Creek transmission towers are constructed approximately as shown in Fig. 1 herewith with overhead grounded wire fastened at point A. Can we assume that the values given by

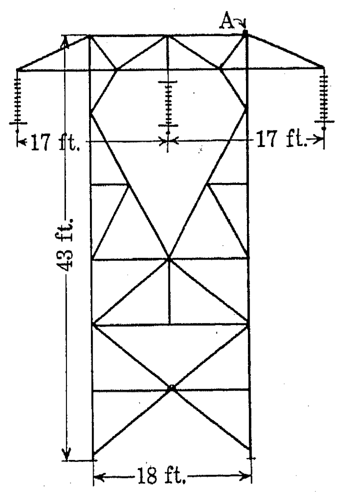

FIG. 1—STANDARD BIG CREEK TOWER SHOWING LOCATION OF OVERHEAD GROUNDED WIRE WITH RELATION TO CONDUCTORS

Mr. Peek for the protective value of overhead grounded wire apply to transmission lines having the conductors in horizontal configuration, separated a distance of from 17 ft. to 22 ft. to the same extent as if the conductors were placed in vertical configuration for example, and spaced closely together? If this distance between conductors were 11 ft. instead of 22 ft., can we assume that these values given, that is, the protective values of the ground wire, will be the same in both cases?

It has been the practise of the Southern California Edison Company during the past year to use an extensive system of grounding at the major substations, and we are now beginning that practise at our minor substations. We feel that one ground wire to a ground well did not give us sufficient protection and we are now adopting the policy of connecting everything together, thus approaching a condition of the station building and equipment sitting on a copper mat.

As regards lightning arresters, the ground leads are brought to pipes driven immediately along the row of arresters. From these pipes connections are made at several points to the network of underground conductors. Mr. Plumb's remarks regarding the use of some metal object, such as the framework of a building, or a fence around a substation, leads me to ask Mr. Peek this question: Suppose the grounded wire on an overhead transmission line

is connected to steel towers that are set in rock, which is an insulator, do we or do we not have a good ground for the dissipation of external discharges and thereby gain advantage of the protective value of an overhead grounded wire?

W. A. Hillebrand: Referring to Mr. Peek's paper, and the discussion of lightning phenomena, and also to Mr. Norinder's referred to therein, if you have a bound charge, after the lightning discharge breaks, that bound charge, presumably, will proceed to travel in opposite directions. If, for instance, the discharge should be six miles long the frequency would be in the order of 30,000 cycles per second. Now, this charge is passed from a highly charged region, that is, where the dielectric is charged, into a region where the dielectric is not charged, so correspondingly it will be absorbed in the dielectric and the energy will be dissipated. As shown by Dr. Whitehead, these damping losses are absorbed in the dielectric region, as the charge passes, and it is reasonable to assume that energy will be returned and oscillate at this frequency through the circuit.

What bearing has the ground wire on this? To a man with radio experience a ground wire is very similar to a counterpoise used in high-power radio transmitting stations for the purpose of reducing the ground resistance, increasing the current, the energy of oscillation, and the voltage is developed directly proportional thereto. Now, if there is anything in the possibility of developing an oscillation, as a result of a traveling wave, then anything that tends to reduce the rate of damping will increase the vigor of that oscillation and the voltage developed in direct proportion thereto.

One of the most complete ground wire systems that I have ever seen had three ground wires on top of a steel tower and three conductors directly below it. This vertical distance between was roughly six feet; the voltage of the circuit is 33,000 volts; the length of the system is about 100 miles, there were about 18 miles of steel towers carrying this combination. Now, as a result of their troubles, due to lightning, on that 33,000 kv. circuit, they would not consider an insulator with less than a normal 66-kv. rating that measures, roughly, 13 x 12 inches, having a 60-cycle flash over of about 200,000 volts. Now, is it possible that you have two compensating effects that counteract one another? The undoubted shielding effect of the ground wire system, also this other effect reducing the ground resistance, increase the oscillation that may result from a closely coupled counterpoise, and of the vigor of that coupling, the closeness of it, there is ample evidence from a number of sources.

Now, it is possible that the nature of the ground itself has something to do with the intensity of lightning disturbances and of their frequency. According to the fundamental electrostatic law the tube of force terminates in the cloud at one end and the charge in the ground at the other. This charge within the earth is drawn up as an amperage current in the earth. There is presumably only a certain amount of energy for the accumulation of the charge. If the ground resistance is high, is it possible that that in itself is a limiting factor? The ground resistance is low in a well watered valley, or on the surface of a subterranean water system and there you will get characteristic thunderstorms of greater violence than elsewhere.

If general corona is allowed to develop the energy is probably immediately or quickly dissipated. On the other hand, both experience and theory tell us that if that energy is allowed to break loose at a single point, at a clamp, or some other point, you will get a streamer that may run to a great length. It is disputed whether or not this thing does exist. There are many evidences that point unquestionably to the fact that we have something of that kind.

The experiment that Mr. Peek shows so beautifully of artificial lightning splitting blocks of wood, has been performed by natural lightning for many years. Over a year ago, in Northern California, I saw a pine tree, four or five feet in diameter, an old tree the center of which was partially rotted out, struck by lightning and it broke off about half way up the trunk and the flash continued down, cork-screwing down the tree. I don't know how many kilowatt-hours, but probably not more than half a dozen, would be required to shatter that tree. The interesting thing which Mr. Peek did in his experiment, was to dissipate the energy where he wanted to. If he wanted to burn up No. 6 iron wire weather-proofed, he subjected the antenna lead to a stroke of lightning and the wire evaporated leaving the weather-proof covering intact. When he wanted to split a stick of wood, his conductor was large enough and the energy was dissipated in the wood. That was what happened in that tree; this current of an unknown number of amperes split the tree to pieces, came down to the bark and where it entered the ground there was no sign of any disturbance whatsoever. I looked around the roots of the tree to see if there was any evidence, but apparently the conductivity at that portion of the circuit was too high.

R. P. Jackson (by letter): In the exceedingly interesting discussion of the possible limits of lightning discharges from cloud to ground, it does not appear that any consideration was given to the fact that the upper plate of the conductor, that is the cloud, is not a metal plate of comparatively low resistance, but is a great group of small segregated, conducting particles. The assumption that the earth resistance is negligibly low is probably quite correct. The resistance of the main path of the arc might readily be within the range indicated. In the cloud itself, however, the arc or current path must branch into a multitude of filaments ultimately reaching each individual droplet. What the resistance of this umbrella or mushroom-shaped portion of the spark path is, is difficult to surmise. It is probable that even if the discharge would otherwise be oscillatory, there is a powerful damping action due to the inability of successive alternations to spread out to the whole cloud and a rapidly increasing resistance is thereby interposed. The effect therefore may be quite different from that of an ordinary discharge through a reasonably fixed resistance and although the initial wave front may be steep it would appear as though the damping action of the cloud resistance would be very great.

F. W. Peek, Jr: Mr. Michener and Mr. Stauffacher have both asked regarding the ground wire. As I understand it, in considering a new line, the question came up as to whether a ground wire should be used or not. It was decided that a ground wire should not be used, not because the ground wire when properly and favorably installed, would not give good protection, but because, under the conditions of this line it could not be well grounded, and, therefore, would not materially effect the lightning induced on the line. I think that was a correct conclusion because if the ground wire cannot be well grounded it gives very little protection. The factor of protection, to a great extent, depends upon the resistance.

In the tests that I made, the ground wire was, in most cases, approximately at a distance from the conductor equal to the spacing between adjacent conductors. My data is applicable to Mr. Stauffacher's line. There is one interesting point that I would like to make clear. When the conductors are arranged in a horizontal plane the voltage induced on each conductor will be about the same so there will be practically no lightning voltage between them. The lightning voltage will be between conductors and ground. When the conductors are in a vertical plane, there will be considerable voltage between conductors, as well as between conductors and ground.

One interesting fact about the ground wire is that one ground wire will protect any number of other conductors. If one conductor is protected and other conductors are placed, they will receive protection without reducing the protection on the first conductor.

Answering Mr. Hillebrand, a number of years ago in Colorado we made experiments on a 25-mi. idle line. In these tests the voltage between line and ground was measured by gaps while

the nature of the discharge was determined by means of a rapidly revolving photographic film. The gaps indicated that the first discharge was a steep wave front followed by the oscillation of the line at its natural period, which, in this case, was about 1800 cycles, or at very low frequency. With the longer lines, the frequency would, of course, be much lower than this. The effect is thus that of a steep-wave-front impulse which may be dangerous, followed by a more or less harmless low-frequency oscillation.

The ground wire tends to increase the damping, just as a short-circuited turn in a transformer would. The actual resistance of the ground itself is very low, because of the great cross-section. It is, in fact, much lower than the resistance of the ground wire. The ground resistance is high where it is part of the ground-wire circuit. This follows because of the small contact area where the ground connection is made.

E. E. F. Creighton: In formulating a closure on the several interesting points brought out in the discussions of my paper it seems pertinent to state my attitude of mind. As a developer of electrical protective devices I am endeavoring to learn the severest conditions to which the protective devices will be subjected. If there are oscillations a certain type of protection should be provided. If finally it should be proved by measurements that lightning is never oscillatory it will simplify the design of electrical protective apparatus. Meanwhile continuity of electrical service is too important to permit us to assume no oscillations when possibly they exist. The cathode-ray oscillograph, properly applied, will tell the tale and put an end to our speculations.

My speculative paper is founded primarily on some new experimental evidence of low resistance of sparks. By the term sparks is meant the accepted designation of conduction by gases and is to be distinguished from conduction by metallic vapors. I think the metallic vapor was driven from the conducting stream in which currents as high as 30,000 amperes were recorded by the oscillograph. Mr. Peek differs with me in my assumption that the lightning streak has the same low value of specific resistance as I measured in these tests. I cannot be absolutely positive that metallic vapor was not present in the three-foot length of arc. Unfortunately these tests could not be included in my brief paper. Metallic vapor travels about 2000 ft. per second. The driving forces in the arc and spark were great enough, I think, to give greater velocities to the metallic vapor which should have driven it bodily out of the conducting stream.

Be that as it may, the latest researches by physicists, Dr. Millikan for example, have shown that the outer layer of electrons on such atoms as nitrogen and oxygen may be torn loose under extremely heavy current densities. These free electrons in great numbers might supply high conductivity in the spark stream. Getting electrons free from gases, like nitrogen and oxygen, requires more agitation of the atoms and bombardment than from metallic vapors. Under low-current densities nitrogen and oxygen in a spark have admittedly lower conductivities than metallic vapors. It seems to me, however, there is great risk of being wrong to assume that under the intense forces of a lightning discharge the ionization of nitrogen and oxygen is not appreciably greater than when measured at lower current densities. The electrons exist in great numbers in the gas atoms. It is a matter of experience that the electrons under bombardment can be separated from the atoms and thereby become conductors of electricity. The degree of conductivity is the question debated.

In Dr. Whitehead's discussion I wish to correct a misunderstanding. He says, "Creighton is making a radical departure from a considerable mass of expert opinion when he assumes that the discharge is always oscillatory." I do not assume the discharge is always oscillatory. I agreed with these experts (second page of my paper) that they are right. I think many lightning discharges are non-oscillatory and the cloud part (the blue brush and weak spark portion) of every discharge must necessarily be non-oscillatory. The resistance of the path, or in other words wide-spread dissipation of the energy, is too great to permit oscillations,—according to the accepted mathematical theory. I discussed this matter of location of resistance at the time De Blois published his paper. In brief, the situation may be stated as follows: If we mentally replace the highly conducting streak, say a mile high, by a metallic conductor the top of the conductor will act as one plate of a condenser and the earth as the other. The electromagnetic energy will be stored up around the conductor. Since the oscillating current (assuming it exists will be greatest near the earth, the electromagnetic energy will be greatest there. According to this understanding the lightning bolt should fade away, beginning at the top and rapidly extending downward. The main streak of the lightning stroke is indeed a vertical antenna and it radiates a part of its energy as has been pointed out by Dr. Slepian.

Radiation of "wireless waves" by the lightning is admittedly a factor too important to neglect. Aside from the heavy drain on the energy in the lightning bolt by electromagnetic waves there is also the further drain of energy in the form of heat and light, both at relatively high frequencies. To offset these losses and thereby to keep up the possible oscillations there are sources of supply of energy which may be drawn on after the first cycle of natural oscillation. One source of energy is in the thundercloud itself. We know definitely by measurement that the energy in some thunderclouds is not given up immediately and thereby exhausted during the first stroke. Correspondingly, therefore, we may infer that the energy is not all given up by the cloud to the bolt during the first part of the stroke. This speculation is appropos to a continuation of the oscillation.

Furthermore, there is another source of energy which may be designated as "burning the atmosphere." It requires a great expenditure of energy to disrupt the atmosphere during the initial formation of the lightning bolt. Why should this energy not be returned in part, on recombination of the elemental parts,—just as for example in the combining of carbon and oxygen.

The million cycles per second as a natural frequency of lightning, that Mr. Taylor mentions in his discussion, was derived from some measurements made in Colorado about eighteen years ago in conjunction with Clay and Peek. The frequency was obtained not from lightning, but from resultant oscillation in the power transmission circuit. It is admitted that these oscillations may have been local in the circuit and not due to the lightning bolt.

In closing, I wish to point out again the characteristic attitude herein that we should look to the worst effects of lightning, with the understanding that protection successful against the worst will make all the lesser effects negligible.

Transmission at 220 Kv.
on the Southern California Edison System
A SYMPOSIUM

Review of the Subject.—*The object of this composite paper is the presentation of a fairly complete description of this 220-kv. system and its operation, together with an account of some work which is being done in preparation for a third line to Big Creek.*

The first section is descriptive of the system and the flashover troubles, giving a detailed account of the bird theory for the cause of flashovers and of the evidence substantiating that theory, also of the measures being taken to prevent the birds from causing flashovers.

The balanced relay protection for the lines and the relay installations to control a flashover or other accidental ground in case the balanced relays are not allowed to function, together with some information obtained from a study of flashovers are contained in the second section.

Section three is devoted to a study which is being made to determine the mechanical and electrical characteristics which will give a most economical third line from Big Creek to Los Angeles. Both aluminum and copper conductors of various large sizes and working at various tensions are considered, and tower locations on ten miles of profile were made.

Section four reports that vibration, particularly in the longer spans, has apparently caused some failures of ground wires and possibly of conductors. Frequencies of 13 to 30 cycles per second and amplitudes up to one inch have been recorded. The vibrations are believed to be due to air currents, but no means of preventing them has been discovered.

In order to minimize the effects of vibration, it is proposed to reduce the weight of the dead-end clamps so that the shocks will be transmitted to the tower connections instead of being absorbed at the outer end of the clamps as at present. A new light weight dead-end clamp has been designed and is being tested under service conditions.

In section five it is concluded that for a high voltage line of large capacity the high cost per mile and heavy tonnage to be transported during construction require careful location work to strike the most economical balance between a straight line and one most easily accessible for construction and maintenance. Right-of-way cost must also be given consideration, together with many other factors which make up the total cost.

The complexity of the problem and the large amount of money involved with consequent opportunity for saving, warrant unusual methods of reconnaissance and survey, and purchasing right of way.

Section 1—Description of System and Operating Experiences

BY H. MICHENER

Associate, A. I. E. E.

Southern California Edison Co., Los Angeles, Cal.

THE single line diagram (Fig. 1) shows the 220,000-volt system of the Southern California Edison Company. The lines from Big Creek No. 1 through Big Creek No. 3 to Eagle Rock are 243 miles long. The taps to Laguna Bell start about three miles from Eagle Rock and are 26 miles long. From 1913 to 1923 the lines from Big Creek to Eagle Rock operated at 150,000 volts. Since May 1923 the system as shown has been operating at 220,000 volts.

Fig. 2 shows the anchor tower with dead-end insulators.

Fig. 3 shows the standard tower with suspension insulators and with a 10-foot extension under it. On account of the increase in the legal minimum clearance from conductor to ground, it was necessary, when reconstructing for 220,000 volts, to install five, ten or fifteen-foot extensions of this type under 2150 towers out of a total of 3340. The greater number of these was raised with the lines energized. Fig. 4 shows one being raised.

The conductors on the lines from Big Creek to Eagle Rock are of 605,000 cm. aluminum with 78,500-cm. steel core. The insulators have 12 units in a suspension string and thirteen units in each of the two parallel dead-end strings which are three units and two units more respectively, than when operating at 150,000 volts.

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

Figs. 5 and 6 show the two types of towers for the branch lines to Laguna Bell. These are new lines designed for 220,000 volts. The conductors are 666,600-cm. aluminum with 85,400-cm. steel core. The insulators have 13 units in a suspension string and 15 units in each of the two parallel dead end strings which are the numbers that would have been put on the old lines if the tower dimensions had permitted.

The shield rings are made of cast aluminum, with the exception of those at the top of the suspension strings. Copper or iron shield rings would be less damaged by an arc and would constitute less fire hazard. When flashovers occur, the aluminum of the shield ring melts and actually burns while falling to the ground. This sets fire to any inflammable material with which it comes in contact. Several bad grass fires were started in this way and it was necessary to clear the grass away from the towers. Flashovers had caused fires before the aluminum shield rings were installed but to a less extent in proportion to the number of flashovers. As a laboratory check on the belief that the aluminum actually burns, *i. e.*, combines with the oxygen of the air with sufficient rapidity to cause heat and fire, arcs were established between small wires of various kinds of metal. The copper and the iron wires melted, the molten metal became a dull red before reaching the floor and did not set fire to the shavings which had been sprinkled on the floor. When the arc was established between the aluminum wires there was a shower of sparks which remained white hot and burning for an appreciable length of time after reaching the floor and which immediately set fire to the shavings.

Practically the only operating troubles ever experi-

enced on the Big Creek lines have been insulator flashovers. During the ten years of operation at 150 kv. they occurred at the rate of about 16 per year. After the line was energized at 220 kv., the number of flashovers increased materially and were for the various months from May, 1923 to June, 1924 inclusive, as follows: 6, 5, 12, 14, 9, 10, 8, 1, 4, 3, 3, 0, 0, 1. When August, 1923 passed with its 14 flashovers, it was necessary to abandon the policy of trying one preventative at a time in search for the one which would stop the flashovers and, instead, to try at once all the possible preventative measures that could be conceived. This work was started early in September and, together with the more systematically planned work of the immediately preceding months, began to bear fruit in decreased numbers of flashovers.

Two or three years ago one of the men in charge of the lines saw a bird, just as it was leaving the tower, drop a stream of stringy excrement which extended from the tower member above the insulator to a point as low or lower than the conductor. The observer was apprehensive of a flashover until the stream had fallen clear of the tower without coming in contact or within arcing distance of the conductor. The bird was reported to have been an eagle.

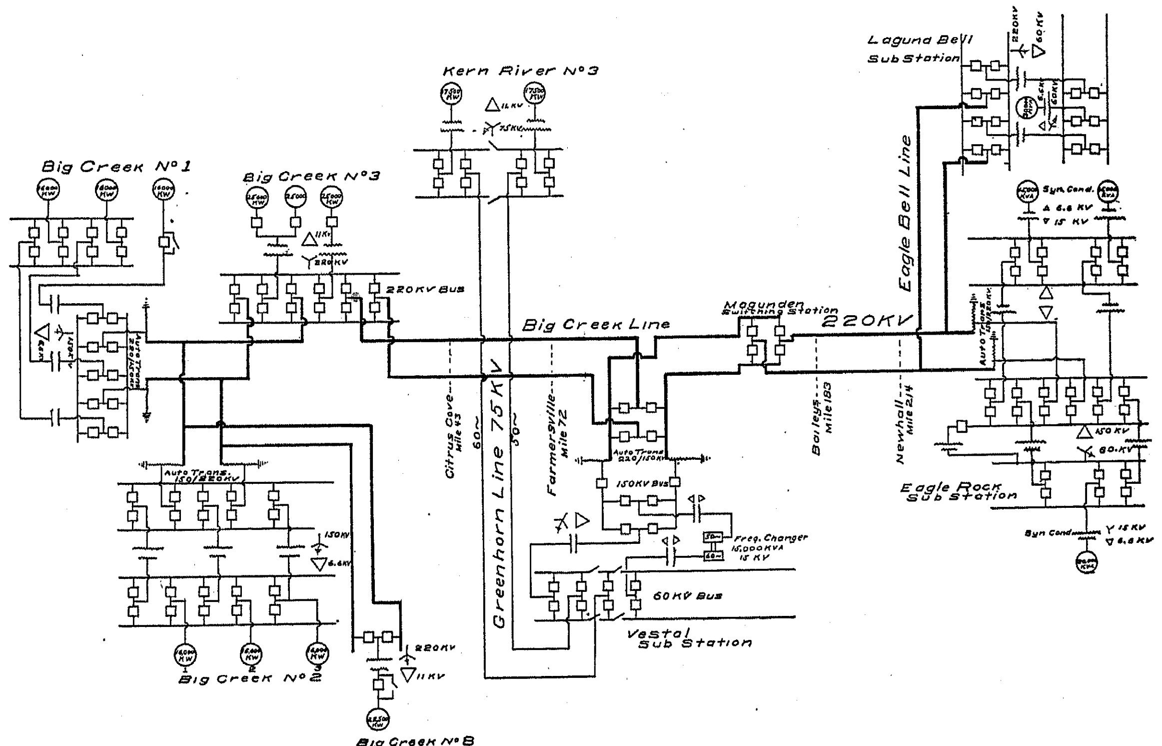

FIG. 1—SINGLE LINE DIAGRAM OF THE 220,000-VOLT SYSTEM OF THE SOUTHERN CALIFORNIA EDISON CO.

A large part of the work done in the effort to prevent flashovers was predicated on the belief that they were caused by the semi-liquid excrement of large birds, hawks and eagles, at the time it fell over the string of insulators or through the air close to them, thus short-circuiting a considerable portion of the air along the insulator string.

The bird theory of flashovers was given consideration several years ago, soon after the lines began to operate at 150 kv., but no evidence to support it could be obtained. The idea in mind at that time was that the accumulation of bird dirt on the insulators would be the only way that the birds could be responsible for flashovers. Some of the strings which fastened over were found to be clean so the bird theory was discarded as a cause of any considerable number of the flashovers. The flashovers occurred so infrequently in those days that the number of observations from which to draw conclusions was small. It took five years after operation began to accumulate as many flashovers as occurred during the first year of 220-kv. operation.

At nearly all the towers where flashovers have occurred during the last two years, direct evidence that a bird was the cause has been found. To facilitate the description of this evidence assume a particular case. The direction of the line is north and south. Three or four feet east of the point of support of the insulators a streak of bird excrement and a spot burned by the arc were found to coincide on the crossarm member. Burned spots were found extending from this point along the crossarm member to a point eight or ten feet on the west side of the insulator.

On the east side of the shield ring a spot of bird excrement and a burn from the arc were found to coincide and burns from the arc extended around the ring to the west side.

The conclusions drawn are that the bird was sitting on the tower some distance to the east side of the point of support of the insulator string and the wind was blowing toward the west with sufficient force to cause

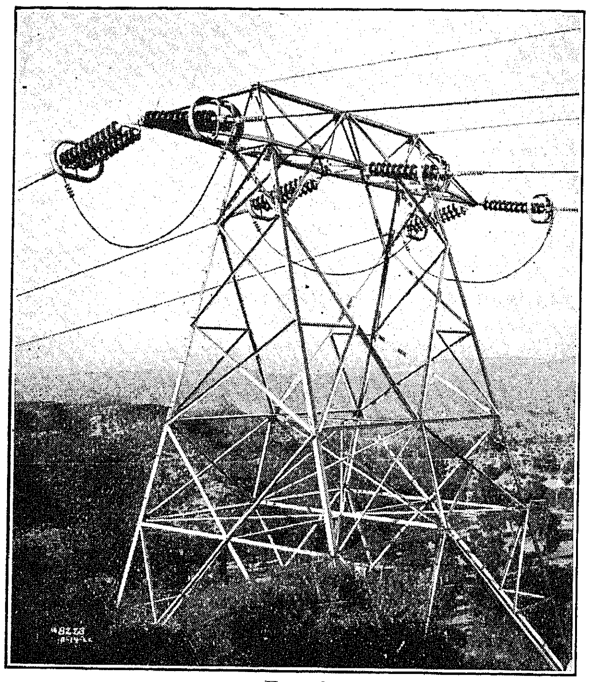

Fig. 2

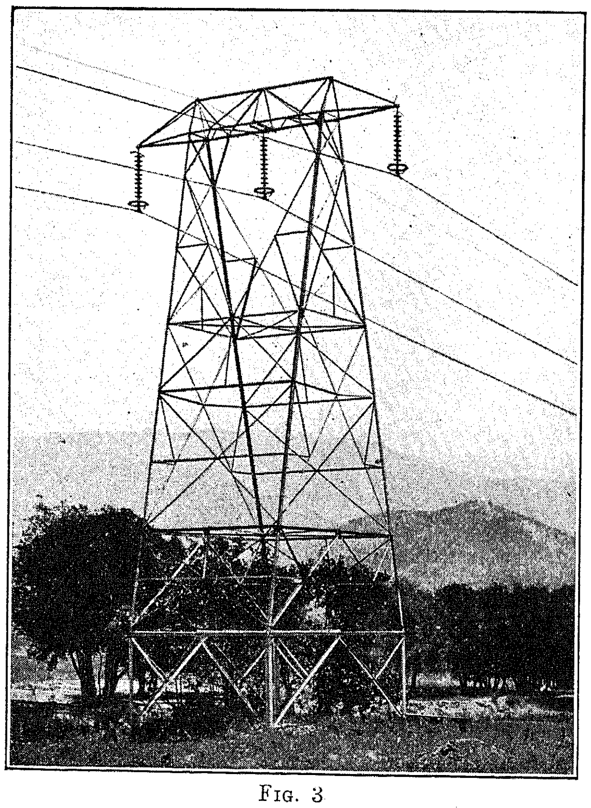

Fig. 3

the stream of excrement to strike the shield ring and start the arc. The wind then blew the arc across the insulator string, the top traveling along the tower and the bottom around the shield ring.

The above is a special case and is subject to many modifications according to the position of the bird and the direction and strength of the wind. It is not necessary that the stream of excrement actually strike the energized parts. In the case of a dead-end tower the arc is started between the jumper loop and the crossarm members.

The greater number of flashovers has occurred on the sections of the lines where there have been the most

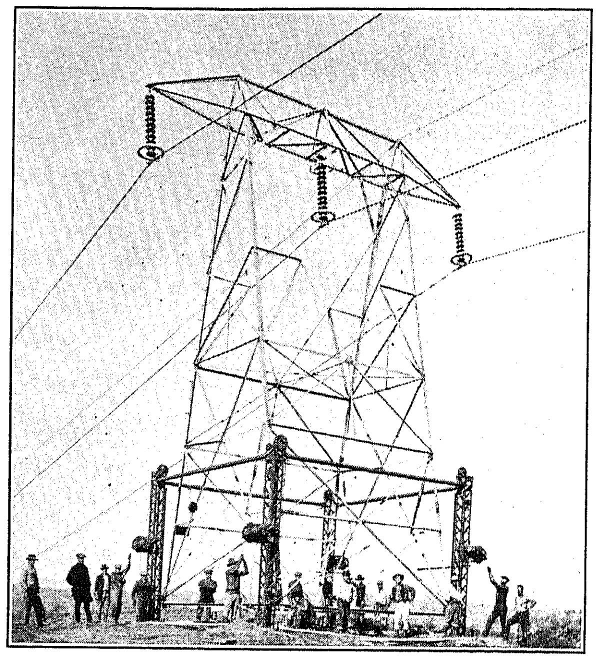

Fig. 4

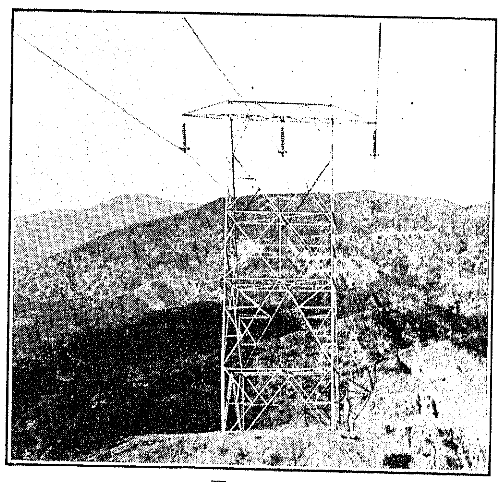

Fig. 5

birds as indicated by the greater amount of bird dirt on the insulators when cleaned a few months ago. Also the insulators on the center conductors have had more than seventy-five per cent of the flashovers during the last four years. These insulators were much more dirty from birds than those on the outside conductors.

F. W. Peek, Jr., in his high voltage laboratory, set up an 11-unit string of insulators, mounted a $\frac{3}{8}$ in. tube,

with cork in the bottom, on the tower near the top of the insulator string. Then by putting one or two ounces of a starch-salt solution in the tube and pulling the cork out by a string, flashover occurred at normal voltage when the stream flowed down over the insulators and also when it fell through the air near the insulators but touched neither the insulators nor the energized parts at the bottom of the insulators.

The first attempt to prevent the birds from causing flashovers consisted of placing guards made of steel strips in an inverted V on the favorite roosting places of the birds over the center string of insulators. Also wires were stretched about four inches above the horizontal members of the crossarm for a distance of four or five feet on each side of the center. Above each outside string of insulators a single spike was placed so that it interferred with a large bird perching there (See Fig. 7). These guards were put on the greater part of the line about two months after 200-kv. operation began but the flashovers instead of decreasing in number, increased very appreciably. The indications were that the birds, having been forced out of their accustomed places, were perching on the top shield ring of the center insulator string and thus causing more trouble than before. The upper shield rings were then removed. At the same time one more unit was added to the suspension strings making twelve units per string, and the insulators were all cleaned and meggered, and the defective units replaced. This work was done during September, October and November with a very little running into December and January.

The flashovers continued at the rate enumerated above. This was due partly to the persistence of the

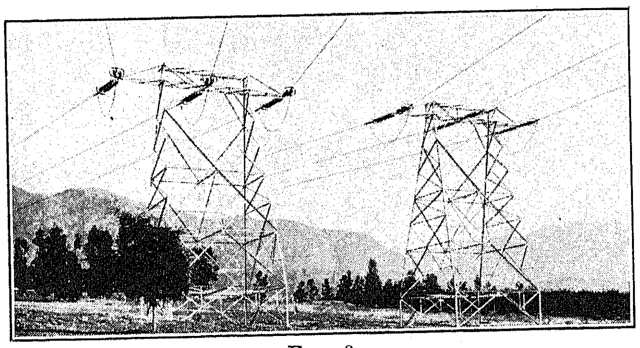

Fig. 6

birds in crowding into their old perching places and partly to the fact that no bird guards were placed on the dead-end towers. The proportion of flashovers occurring on dead-end towers increased after bird guards were placed on the suspension towers.

Because the flashovers were continuing, though at a diminished rate, 60 miles of line were equipped with galvanized iron pans in the crossarm above the center strings of insulators. They were about 4 by 8 ft. with the center above the insulators. They were installed in Feb. 1924, and no flashovers have occurred in this section since then. However, only four flashovers have occurred on the whole line during that period.

It is believed that guards which will not allow any large bird to perch above the conductors will eliminate nearly all flashovers which cannot be traced to other mechanical interferences or to external lightning.

There is a possibility that flashovers may be caused by an accumulation of any kind of dirt on the insulators in combination with dew or fog. Laboratory

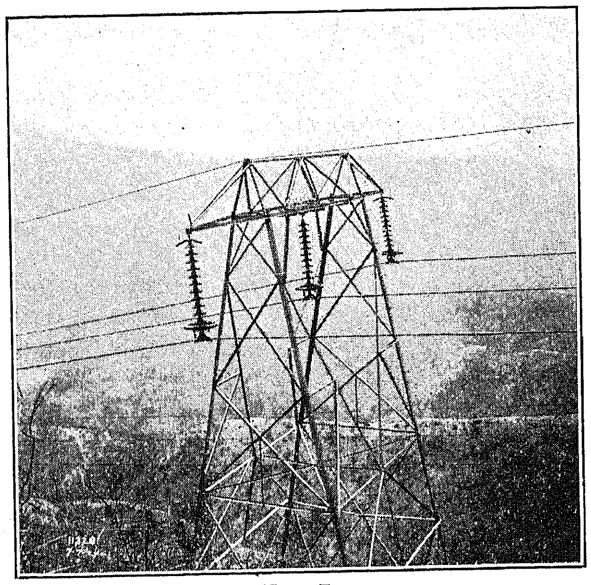

Fig. 7

tests have shown that this condition can occur. Mr. Peek has been able, by a combination of dirt and dew, to flashover a 9-unit string at about 20 per cent its dry flashover voltage. This condition is difficult to obtain but the fact that it can be indicates that the insulators should be kept clean, especially in regions where soluble salts, such as alkali and sea salt are deposited on the insulators.

Section 2—Automatic Protection—Balanced Relays and Flashover Control

BY. E. R. STAUFFACHER

Associate, A. I. E. E.

Southern California Edison Co., Los Angeles, Cal.

Throughout the history of the Big Creek transmission line there have been flashovers which would occur occasionally at no particular interval and at no particular season of the year or time of day. This was the case when operating at both 150 kv. and 220 kv. These flashovers would occur in the proximity of an insulator string, would result in grounding one of the wires and would cause an interruption to the service. The operators became expert in handling these flashovers with the original installation of two units in each Big Creek No. 1 and Big Creek No. 2 and the synchronous condensers in Eagle Rock and the interruption resulting from a flashover was very short. When

the system became more complicated by the addition of the frequency changer and the Kern River No. 3 connection at Vestal, with more generating stations at Big Creek, the manual control of flashovers did not give such good results. The procedure under manual operation was as follows:

The ground current resulting from a flashover was indicated in the power houses and the substations by means of ground ammeters and bell alarms. The operators at the power houses then immediately began to reduce the exciter fields manually until the transmission voltage was lowered sufficiently for the flashover arc to break and thereby free the line from this ground or short circuit. After this the generator field was restored to normal, thus building up the transmission voltage again. At the receiving stations the practise was to open the field on the synchronous machines upon the occurrence of a flashover, thus allowing these machines to operate as induction motors until the flashover was cleared by lowering the voltage at the generating end. When the voltage was up to normal, the frequency changer and the synchronous condenser fields were again closed. As a result of the successful use of balanced relays on some of the important trunk lines of the 60-kv. transmission network, similar relays were adopted for the 220-kv. system, and at the same time it was decided to install equipment which automatically would accomplish the function of lowering the voltage of the generators and opening the fields of the synchronous apparatus at the substations in a manner quite similar to the method heretofore followed manually.

The single line diagram, Fig. 1, shows the 220-kv. Big Creek circuits are operated in parallel through busses at each of the power houses and substations and at Magunden. When a flashover occurs in any one of the four sections the proper functioning of the balanced relays will cause switches to be opened automatically to isolate the section of transmission line upon which the flashover occurs, with no disturbance to the rest of the system and with no interruption to service. The only indications that a flashover has occurred are the tripping out of the switches and a drop in voltage for a period of two to five seconds.

At each sectionalizing point the balanced relays installed are connected to bushing-type current transformers in the oil circuit breaker terminals. Upon the occurrence of unbalance in the current flowing in the two lines, these balanced relays close their contacts, trip out the proper switches and thus disconnect the section of line in which the trouble has occurred. At some of the stations the relay system is more complicated than at others. At Vestal, for example, it was necessary to balance the sum of the currents flowing in two oil circuit breakers and one auto-transformer connected to one line against the same for the other line. This is accomplished by means of paralleling the current transformers in the apparatus concerned. Due to the possibility of a dangerous rise in voltage should some automatic operation separate the generating end from the receiving end of the transmission line, the tripping connections of the oil circuit breakers were so arranged that after the circuit breakers of one line are operated, those of the second line would immediately become non-automatic. With such connections, the removal of one line from service for any purpose renders the remaining line non-automatic and leaves the service exposed to the risk of a comparatively long interruption with only manual protection. To provide against such a contingency automatic flashover control equipment operating on the generator voltage was installed.

A master relay connected in series with the second-

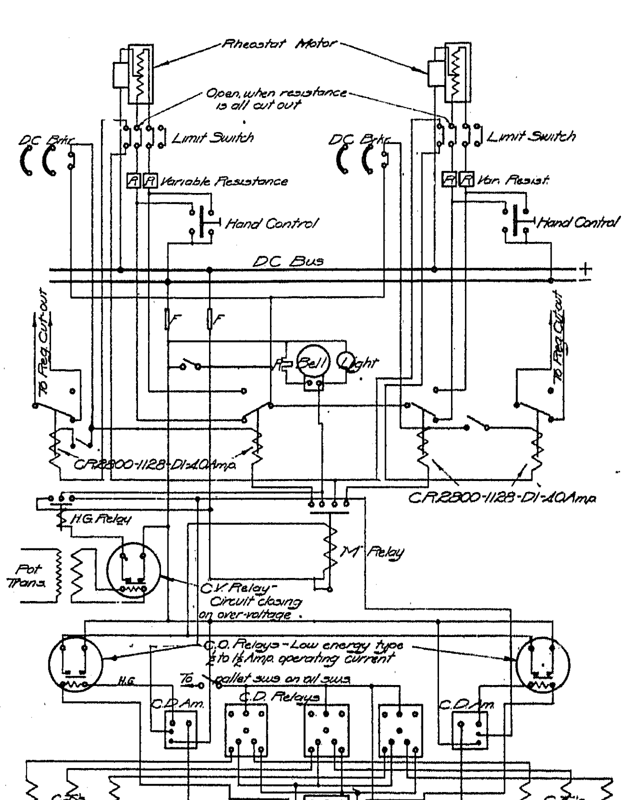

FIG. 8

aries of the current transformers in the grounded neutral of the power transformers is so arranged that when the ground current passes through this relay, due to a flashover, the relay contacts will close and operate a number of auxiliary relays. These auxiliary relays will cause the motor-driven rheostats to cut in resistance in the field of the exciters at the various generating plants until the voltage is lowered sufficiently to break the arc, thus eliminating the flashover from the line. The master relay is then returned to its original position, which, by means of the auxiliary relays, will cause the motor-driven rheostats to go back to their original position, thus bringing the voltage back to normal. Simultaneously with the lowering of the voltage at the various generating plants, the ground currents at the

terminal substations and at Vestal operate relays which automatically lock open the master circuits of the field regulators of the condensers and frequency changers, thus introducing the maximum resistance in the exciter

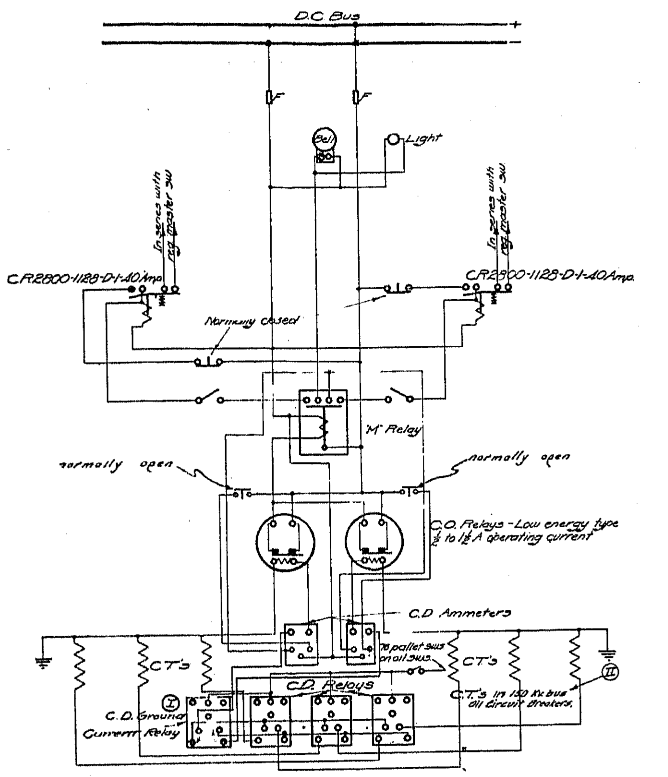

Fig. 9

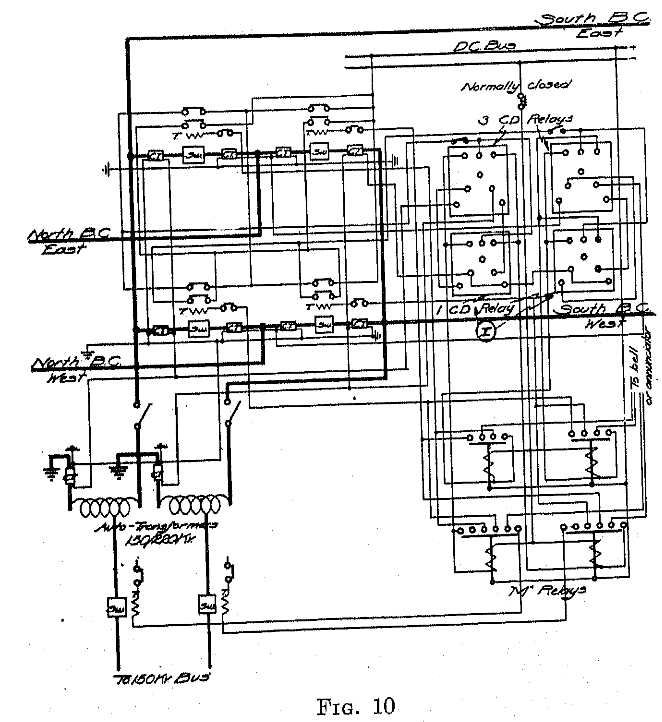

Fig. 10

field. When the arc is broken and the condensers and frequency changers are returned almost to synchronous speed, the master relay is released by a push button, thus allowing the regulator to bring the excitation of the condensers and the frequency changer back to normal.

The time required to handle the flashovers, when two lines are in parallel and the balanced relays operative, is from two to five seconds. When line conditions are such that the balanced relays cannot operate, about 30 seconds is required to handle the flashover, either by the manual method or by means of the automatic suppressor. Of this time 10 seconds is required to bring the voltage down to the value where the arc will break and approximately 20 seconds is consumed

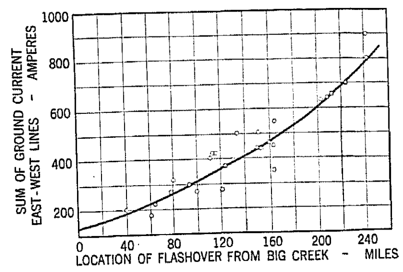

Fig. 11—Ground Current—Eagle Rock 220-Kv. Flashovers East-West Lines. (East-Line Short Circuits)

in restoring the voltage to normal. However, a rheostat in series with each of the motor circuits is so connected that it will permit varying the above time interval in lowering and raising the voltage as experience dictates. The use of these rheostats makes it possible to calibrate all equipment at generating plants, so the voltage can be lowered simultaneously throughout the Big Creek generating system regardless of the characteristics of the individual generators. Figs. 8, 9 and 10 give detailed wiring diagrams and explanation of the connections for the balanced relays and the

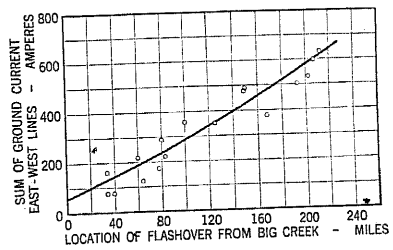

Fig. 12—Ground Current—Eagle Rock 220-Kv. Flashovers East-West Lines. (West-Line Short Circuits)

automatic flashover control for Big Creek No. 1, for Eagle Rock, and for the balanced relays only at Vestal. The connections at the other stations are similar with only slight differences where local conditions demand. Knife switches are included in the connections so that any part of the equipment can be rendered non-automatic at will.

Careful studies of the flashovers have been made with reference particularly to location, time, duration weather at point of flashover, voltage, ground current, and kv-a. connected at each of the stations, damage

done by the flashover, and relay operation. Cases in which the trouble was cleared by the relays caused less damage than others.

A study of the ground currents at the time of a flashover shows that these currents vary roughly with the distance between the flashover and the major generating plants or major substations. Curves indicating this are given in Figs. 11 and 12. In the curves the locations are given in terms of miles from Big Creek and it will be noted that as the distance from Big Creek increases, the amount of ground current flowing from Eagle Rock also increases. This is undoubtedly due to the decrease in ground circuit resistance, as the distance between Eagle Rock and the point of flashover is decreased.

Since the time of placing the balanced relays in operation (August, 1923), the performance has been very satisfactory. A comparatively short time has elapsed since the entire 220-kv. line has been placed under automatic protection and there has been no opportunity to study the clearing of flashover in the section south of Magunden. There have been a number of operations on the two sections between Big Creek No. 3 and Vestal and from Vestal to Magunden. At the time of the greater number of these relay operations there was no interruption to service. The relays were first set for a current unbalance of 350 amperes. On the first two cases of trouble following the installation of the relays, those on the end of the section in trouble toward Big Creek operated properly but those on the end toward Eagle Rock did not operate, because there was not sufficient energy supplied from the Eagle Rock end to cause as great unbalance as 350 amperes. After the second occurrence, the relay setting was lowered so that only 300 amperes unbalance was necessary to cause the relay contacts to close. Since that time the relay operations have been satisfactory in all cases, clearing the trouble from two to five seconds, and giving since installation 13 perfect operations out of 15 opportunities.

Section 3A—Economic Studies of Transmission Line Design with Particular Reference to the Mechanical Features

BY C. B. CARLSON

Non-Member

Southern California Edison Co., Los Angeles, Cal.

The concrete example of the studies for a new 220-kv. line to the Big Creek water power plants will be used in presenting methods for arriving at the economic conditions of design for this article. The method used was as follows:

Ten miles of actual profiles of an existing transmission line which traverses practically the same route as that to be followed by the new line were taken and so chosen as to represent three miles of level profile; three miles of rolling profile and four miles of mountainous profile. On these profiles were plotted the actual tower locations for the following various materials and conditions.

Tension—between 12,000 lb. and 24,000 lb. on steel reinforced aluminum cable having aluminum of 666,600, 1,000,000, 1,250,000 and 1,500,000-circular mil sizes. Copper cables of equal conductivity to the size of aluminum mentioned above were tried with several working stress values. There were naturally several heights, strengths and spacings of towers and also numbers of extensions required to meet the conditions of the various sizes of wires and unit stress variations.

The spacing of the conductors was fixed at 22 ft., because of the requirement to have six feet of clearance to ground under maximum conditions of swing.

A sufficient number of points was plotted for each condition to permit of the drawing of a curve. The span and the tension which would give the most economical cost were then taken from these curves and referred to the calculations for electrical conductivity economy, the different phases of which are discussed in another part of this paper. The electrical and mechanical studies are interdependent and were conducted in close cooperation.

In the case of the aluminum cable, it was found for the amount of current to be carried about a million circular mils of aluminum were necessary. The economical tension was about 12,000 lb. and by insisting that a factor of safety in the steel core be such that the maximum working load be 10 per cent less than the elastic limit of the steel core, a cable with the following characteristics was determined on: 1,033,500-cm. steel reinforced cable with either 7 or 19 strands of steel of equal cross sectional area and 54 strands of aluminum.

The same set of economical studies was made with reference to the use of copper conductor. The different tension and tower locations were plotted on the same profiles as were used for the aluminum cable. One of the electrical requirements in the use of the copper was that the outside diameter of the cable be not less than 1.1 inches, so investigation was made on a recently manufactured cable which had two layers of copper stranded on a flexible tube. By plotting total values of cost for completed line for the various tensions, tower locations and tower heights, curves were drawn between the points and the minimum condition was determined, and the point where a rise in cost started was also determined which gave a little range in conditions to permit them to be fitted to the varying profile of an actual line.

A certain limitation was imposed in the use of tension values which was fixed as a maximum, the use of two strings of high strength insulators having a predetermined maximum tension value. This tension, used in its maximum proved economical for both the aluminum and for the copper. To date, however, there has been no definite decision as to which of the materials for cable will be used, hence no definite conclusions can be

stated, but for the copper cable the following sizes were determined:

One of 650,000 circular mils stranded on flexible copper tube having an outside diameter of 1.1 inches. Also a stranded copper cable with 800,000 cir. mils having an outside diameter of 1.03 inches. Of the two sizes the 650,000-cir. mil cable used at a maximum tension value of 12,000 lb. was found to be the more economical. The tower design was based on using a steel of high elastic limit, which material has been found to represent a saving in the cost of the line.

Specially designed attachment details were developed and tested. The principal point which was especially considered was a form of attachment to the cable which would minimize the effect of vibration. Tests are now being conducted on the attachment to determine this effect.

It will be noted that a tremendous amount of calculating is necessary to arrive at the minimum values, but it seems that changes in tension, heights of towers, and spacing of towers impose so many variables that no system better than the curve plotting method will satisfy.

Section 3B—Economic Studies of Transmission Line Design with Particular Reference to the Electrical Features

BY W. D. SHAW
Associate, A. I. E. E.
Southern California Edison Co., Los Angeles, Cal.

Initial Conditions

Length of line was to be 275 miles. This was determined by the fact that the present Big Creek lines from Big Creek to Eagle Rock Substation are 243 miles in length and the lines from Eagle Rock to Laguna Bell Substation are 26 miles or a total length of 269 miles. Assuming that the future lines would terminate at Laguna Bell or in the same neighborhood, the round figure of 275 miles was used.

The spacing of conductors was to be 22 ft. using a flat constructure and was determined by the studies on tower design as outlined elsewhere in this paper.

The voltage was to be 220,000 volts at the generating end and 200,000 volts at the receiving end; this was determined by the voltage of the present Big Creek lines. The power factor of the load is 80 per cent lagging.

Line Characteristics

With the above conditions fixed, the first step was to determine the auxiliary line constants for different size cables, varying from 600,000 to 1,600,000 circular mils, the lower limit being just below the size of the original Big Creek line. Due to corona, it would not be desirable to use a cable with as small a diameter as the present line.

The constants of the line alone were calculated by the usual hyperbolic method, then the constants of the line in combination with the sending and receiving transformers were found by the method outlined by R. D. Evans and H. K. Sels in the *Electric Journal* of August, 1921. The capacity of the transformers was sufficient to deliver 150,000 kw. at the receiving end.

The final results are shown in Table I.

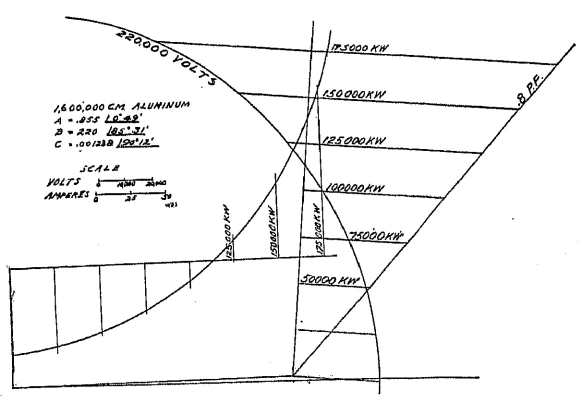

Fig. 13

The 650,000-cir. mil copper is of special design wound over a hollow copper tube which gives it a larger diameter than the ordinary stranded copper cable of the same cir. mil cross section.

With the constants determined, the graphical method as outlined in C. H. Holladay's paper in the A. I. E. E. Journal for November, 1922, was used to determine

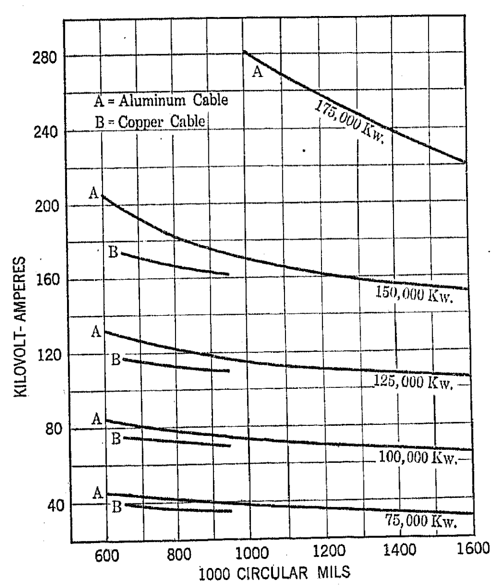

Fig. 14

the condenser kv-a. necessary and the line and transformer losses under different conditions of load. Fig. 13 gives the diagram for the 1,600,000-cir. mil aluminum cable and Fig. 14 gives the condenser kv-a. necessary for different sizes of aluminum and copper cables under various loads. In order to determine the most economical conductor, it is necessary to find the one

TABLE I
AUXILIARY CONSTANTS

Circular Mils....	600,000	650,000	800,000	950,000	1,000,000	1,600,000
Material....	Aluminum	Copper	Copper	Copper	Aluminum	Aluminum
Diameter..	0.96 in.	1.1176 in.	1.031 in.	1.123 in.	1.24 in.	1.544 in.
A.........	0.858 / 1deg.18min.	0.857 / 1deg. 7min.	0.859 / 0deg.46min.	0.857 / 0deg.49min.	0.857 / 1deg. 8min.	0.855 / 0deg.49min.
B.........	236 /80deg.14min.	229 /83deg.37min.	232 /85deg. 5min.	229 /85deg.22min.	227 /83deg.32min.	220 /85deg.31min.

for which the sum of the variable costs are at a minimum under any stated condition.

These variable costs were determined and put in the form of annual cost per kilowatt year delivered. The different items making up the variable costs consisted of the annual depreciation and interest on the condensers, cable and towers, together with the annual cost

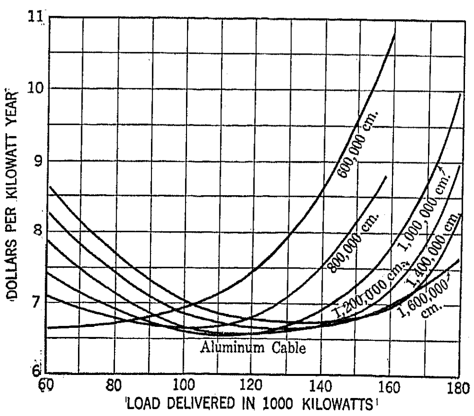

FIG. 15

of energy wasted in the transmission circuit which includes the transformers and condensers, as well as the line itself.

The cost of energy lost was determined by the cost of reproducing it by steam at the same load center, taking into consideration the annual load factor. The

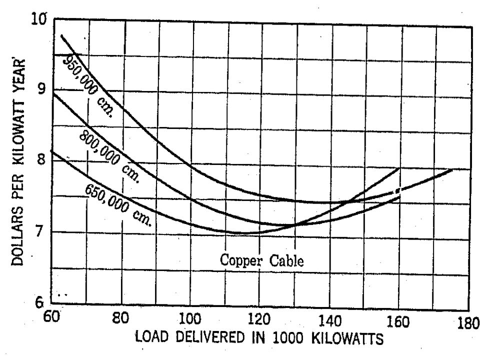

FIG. 16

variation in cost of towers, due to the use of different size conductors was determined by the economical study of tower design given in another part of this paper.

Fig. 15 gives the comparative variable costs per kilowatt year for different loads and different sizes of aluminum conductor. Fig. 16 gives the same thing for copper conductors.

An analysis of the curves shows that 150,000 kw. is the maximum economical load, since the annual costs start to increase either before or at that point even on as large a cable as 1,600,000 cir. mils. There are several sizes of conductors where the cost curve is comparatively flat between 100,000 kw. and 150,000 kw. delivered.

The curves also show that there is no clear-cut decision available as to the correct size of cable. Before the final decision is made consideration must be given to several factors. For instance, the prices upon which the curves are based are those of the early spring of 1924 and are subject to revision, the total initial cost may be a deciding factor and the load conditions under which the line will operate also affects the answer.

Section 4—Vibration of Conductors and Overhead Ground Wires

BY J. M. GAYLORD
Member, A. I. E. E.
Southern California Edison Co., Los Angeles, Cal.

Among the problems connected with the 220-kv. lines, that of the vibration of conductors and ground wires has claimed its share of attention. On account of the larger diameter of the conductors this phenomenon is clearly visible, and exaggerated reports are frequently received that the conductors are jumping up and down 6 in. or more. There have also been complaints of the rattling of towers, even on still nights. In one instance a conductor failed at the outer end of a dead-end clamp and the appearance of the broken strands indicated that vibration might have caused the break. A second conductor was discovered with 28 aluminum strands out of a total of 54 broken at the end of a dead-end clamp. Numerous cases of broken ground wires have been found, the strands breaking at the point of attachment to the towers. In a few cases ground wires have fallen but a larger number of broken strands has been discovered by inspection and repaired before complete failure of the cable. These troubles led to an investigation of the vibration problem as it appears in the spans of the Big Creek and Eagle Bell lines. While this investigation has not yet led to definite conclusions as to the cause of vibration and method of preventing it, the information obtained is presented here as a part of the operating record.

The motion of the conductors is always in an approximately vertical plane and no horizontal displacement of the conductor has been observed. It is comparatively easy to secure records of the amplitude, frequency and duration of the vibrations. This is done by means of the recorders shown in Fig. 17.

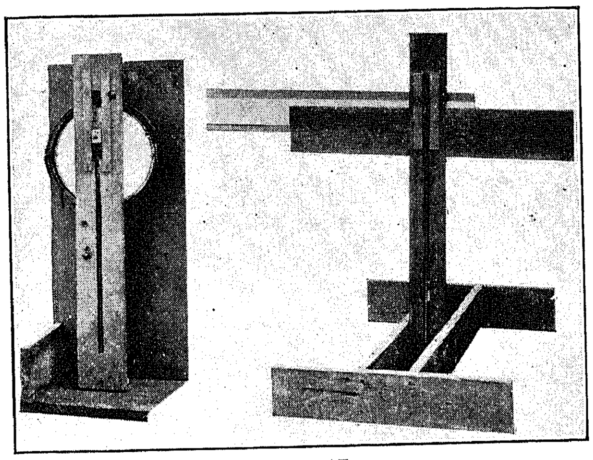

FIG. 17

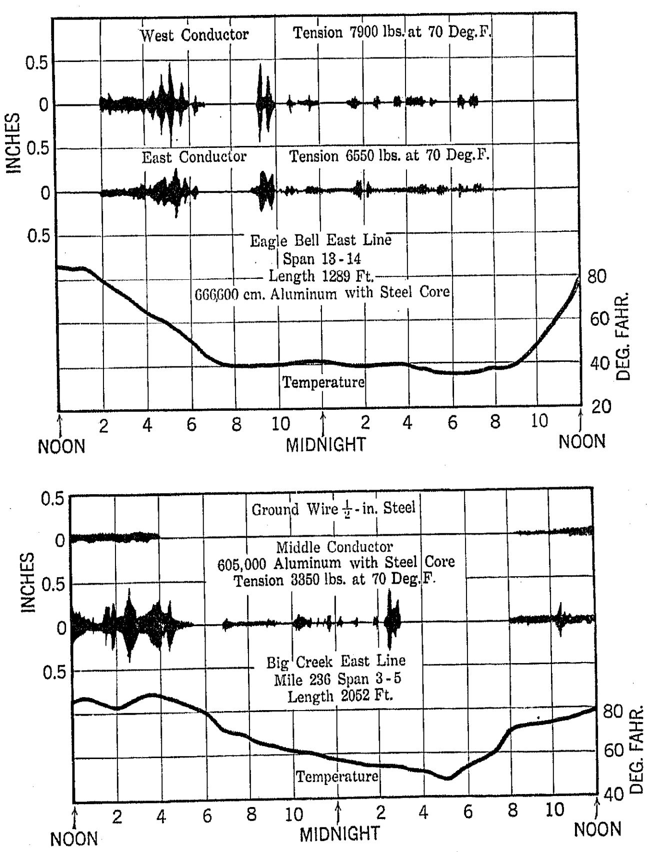

FIG. 18

The motion is transmitted to the recorder by means of a paraffined string thrown over the conductor and attached to the sliding block, which carries the pencil. A spiral spring below the sliding block keeps the string taut. For the frequency records the paper is moved horizontally by hand, the motion being timed with a stop watch. The 24-hr. duration records are obtained by applying a similar device to the circular record chart of a Bristol mechanical recorder. Simultaneous records of vibration and temperature were taken to determine a possible relation between these conditions. These records fail to show any such relation and appear to establish the fact that vibration is generally independent of temperature. A great many spans apparently never vibrate while some are particularly subject to vibration; the longer spans being particularly susceptible. Vibrations are intermittent and the records show that they start and stop at irregular intervals throughout the day. Fig. 18 shows typical records of amplitude and duration. These graphs were transcribed from the original records

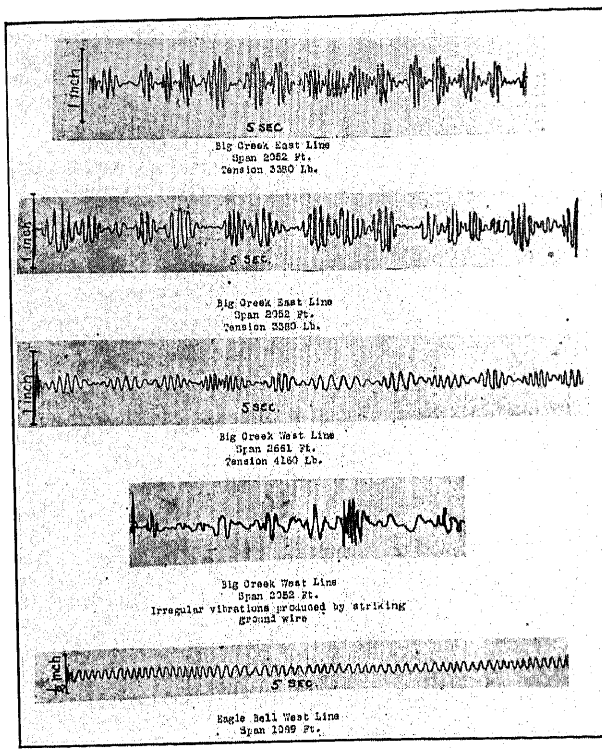

FIG. 19

to eliminate the effect of the stretch of the string which makes an irregular line on the circular chart and obscures the meaning of the record.

Spans subject to vibration were observed under various conditions, such as the sudden changes of temperature, lines dead, lines being energized, lines being dropped, etc., and it appears that vibration is not effected by any of these changes. Apparently this is a purely mechanical phenomenon and might have been encountered on lines of any voltage just as well as on the 220-kv. system.

In span 13-14 of the Eagle Bell line vibration is especially prevalent and it was at this point that one conductor failed. When temporary repairs were made, this conductor was left with considerably less tension than the others. Simultaneous records were taken

of the tight and loose conductors in this span and both were found to vibrate during approximately the same periods throughout the day, although the amplitude and frequency were less in the loose conductor. Apparently conditions other than tension and temperature produce the vibrations. There appears to be no difference between center and outside conductors on the tower as far as vibration is concerned. Several simultaneous records show practically the same periods of vibration for each position.

Fig. 19 shows typical records of frequency, character and amplitude of vibration. Some of the records show simple vibrations of a single frequency, while in others various lower frequency components are present. Amplitudes as great as 1 in. were observed, while frequencies varied from 13 to 30 cycles per second in the spans tested. Standing waves 12 to 16 ft. in length were found in most cases where vibration was present. The normal sustained vibrations are regular in frequency and character and this quality appears to be essential to maintaining the vibration of the conductor. Attempts to set-up vibrations in the ground wire by striking it with the hand resulted in irregular vibrations which soon died out.

Vibration is believed to be due to air currents. Strong winds do not usually produce vibration but appear to have the effect of damping out the oscillations by setting up swaying motions of the wires. A slight air current appears to be sufficient to start and sustain the vibrations.

Means of preventing vibrations are still under consideration. It seems probable that an irregularity in the weight of the conductor might tend to damp out the vibrations and such a plan has been considered. Weighting of the conductor at various points might accomplish the same result. However, the places most affected by vibration are at dead-end clamps and other points where the waves are reflected, and there is objection to increasing the number of such points by clamping weights to the conductor. The most violent cases of vibration have been noted in spans which have been in service for 10 years or more and the fact that no failures have occurred in such spans indicates that vibration alone is not much to be feared. The suspicious failure of steel reinforced aluminum occurred in the Eagle Bell line where the mechanical stress is higher than in the older line, and it seems probable that high stress combined with vibration is liable to cause trouble. However, the evidence is not conclusive as to how much the vibration would contribute to the failure.

The most promising method of preventing the damage due to vibration at points of reflection appears to be to provide a joint where movement can take place without bending or shock to the cable, and new clamps have been designed with this in view. Fig. 20 shows a new cast aluminum dead-end clamp which is being tested. The mass of the clamp has been reduced to a minimum so that it will move about its supporting pin, vibrating as a part of the conductor instead of reflecting the waves from its outer end by reason of its inertia. Simple mechanical devices are provided for holding the aluminum strands and steel cores. The aluminum is held by the standard compression joint which has proven by long service to be electrically and mechanically good. The steel core is held separately by long taper conical wedges which have been tested to the ultimate strength of the core. Several other improvements are embodied in the design. Cast aluminum terminals are attached to the jumpers by means of compression joints and a plain bolted connection is made between the jumper terminal and dead-end clamp. This arrangement eliminates the troublesome process

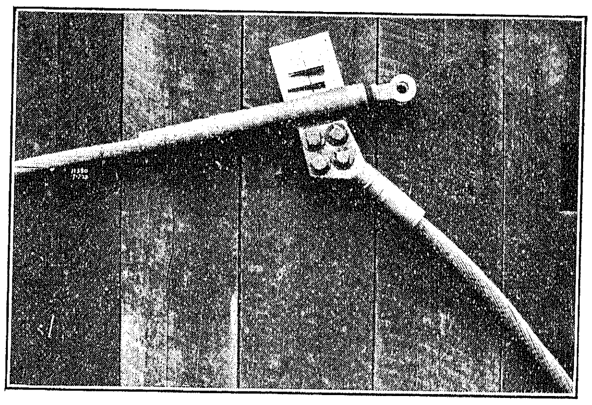

Fig. 20

of bringing out the aluminum strands separately at the side of the clamp for attaching the jumper, and the more or less uncertain bolted clamps for splicing the jumper. Ample current capacity is provided in the cast aluminum body of the clamp and current-carrying connections are all made with the standard compression joint or by means of flat bolted surfaces. This clamp has been installed on an experimental span and will be tested to determine its performance under vibration conditions duplicating those on the line.

Section 5—Location and Right of Way

BY V. D. ELLIOTT
Associate, A. I. E. E.
Southern California Edison Co., Los Angeles, Cal.

Transmission line location is an art which has been somewhat neglected as compared to other branches of the electric utility industry, or, as compared to railroad or highway location. This has come about in a natural way because transmission lines in the beginning were comparatively cheap affairs and even with the advent of steel tower construction and higher voltages the cost per mile was far below that of a railroad or well constructed highway. Often much time and engineering skill were expended on power houses, dams and pipe lines and even on transmission line design, but the location and construction of the

line were put off until the last moment and then rushed through in a haphazard fashion with resultant losses.

The cost of 220-kv. circuits on separate parallel lines of towers, such as the recently constructed Eagle Bell line, is in the same class with that of a railroad or highway, hence the business of selecting and securing a right of way is worthy of considerable thought and careful balancing of all factors involved. Many points which are of minor consideration on lower voltage lines become of real importance on the 220-kv. line.

In choosing a location for the Eagle Bell line and for a new line to Big Creek, known as the Vincent Line, which is still in the process of being located, the same general methods that are applicable to any transmission line location work have been used but with modifications or refinements which will be described.

In rough or mountainous country the controls are the natural topographic features and the main points to be borne in mind are safe and suitable locations for towers and a general alinement such that material may be delivered by motor truck via existing roads, or such that new roads can be built without too great an expense. With high tonnage of material and men to be delivered, this becomes a very important item and must be given more consideration than with smaller lines.

In flat or agricultural lands the controls are all artificial or man-made and influence the right-of-way cost.

The final choice of location must usually rest on reconnaissance work which proceeds the actual line survey. This reconnaissance is therefore a very important part of the job and holds great possibilities for saving or spending money unnecessarily on construction or right-of-way purchase.

The problem naturally divides itself into the two classifications previously indicated, *viz.*, the case of rough or mountainous country of little or no commercial value and the case of relatively flat, tillable land highly developed with crops, highways, railroads and farm or residential buildings where land values are high and natural topographic features of little or no importance. There are, of course, gradations between these two extremes in which may be included land of low commercial value possessing no controlling topographic features. In this case no problem exists and a straight line is laid out.

A portion of the Eagle Bell line is located on a right-of-way 250 ft. wide, in a highly developed territory near or within incorporated city limits where land values range from $2,000 to $5,000 per acre. Aeroplane reconnaissance was found to be a very valuable help and aerial maps of this territory were particularly useful in projecting the line among improvements to the best advantage and buying parcels of land or negotiating for a strip without the inevitable advertising resulting from a survey. It should be understood that useful as these maps and aeroplane reconnaissance were, they did not reduce the amount of final survey work necessary nor entirely eliminate ground reconnaissance. The actual saving, due to the speed and accuracy with which the purchases proceeded, cannot, of course, be determined but all indications are that it was many times the cost of the maps.

A location through land of this character giving minimum total cost resulted in a very crooked line.

Aeroplane reconnaissance over mountains or hilly lands gives one a comprehensive general view and impression which cannot be secured in any other way. At a height of from four thousand to six thousand feet above the ground details are visible in good weather but the topographic features assume their proper proportions and relations to one another so that important ones stand out and produce the proper impression on the mind of the observer. When observing from a high point on the ground, part of the terrain is hidden from view and a certain distorted impression is gained due to the different distances from the eye of the various features in the range of vision.

Despite this defect in ground observation it is a necessary supplement to the aeroplane view in choosing a final location. In addition to this preliminary or trial lines are often justified. These may ordinarily be run by stadia and only the major controls or those of especial bearing on the question taken. While a profile of this kind does not accurately represent the country, it is a great aid and will usually contain enough information to enable one to make an intelligent choice between two or more alinements. When it is considered that the cost of one tower is equal to the cost of several miles of such preliminary line the wisdom of this refinement is evident.

Experience with aerial maps of mountainous territory show them to be difficult to produce with satisfactory accuracy and to be of little benefit. Dangerous and adverse flying conditions and scale distortions, due to uneven ground elevations, multiply enormously the cost and mechanical difficulty of producing accurate maps and the information conveyed concerning relative elevations and other controlling topographic features is so meager that their cost cannot be justified.

Having chosen a final alinement, a survey must be made which will show to a predetermined accuracy the horizontal and vertical distances between points on the line and also the relation of the line to property corners and legal subdivisions of land. This last is, of course, purely for right-of-way purposes. This general statement regarding survey is true of a transmission line of any voltage but with the 220-kv. line, the cost and importance of it justifies methods of survey which will give a higher degree of accuracy and are less likely to contain errors than those frequently used.

Two methods have been tried thus far. In the first case, conditions were ideal for choosing an alinement,

setting signals on probable tower locations and tying these points into a triangulation system from base lines conveniently located. Stadia topography was taken in the vicinity of the probable tower points and at points of doubtful clearance in between. No center line profile was run but one was plotted from the topography. In the second case, a center line profile was taken by means of slope chaining in the roughest country and horizontal chaining with a line of levels where the country was not so rough. While the triangulation method with local topography worked out fairly well where it was used, the second method appears to be better and of more general application.

The Eagle Bell right-of-way is intended to accommodate three tower lines of horizontal construction, the towers being 78 feet apart, center to center. The right-of-way is 250 feet wide and with a conductor spread of 22 ft. 3 in. leaves only 24 ft. 9 in. from the outside wire to the edge of the right-of-way. With a calculated conductor swing of 18 ft. 6 in. in the normal span, a clearance of 6 ft. 3 in. remains to the edge of the right-of-way. This is not all that could be desired but on the high priced land this was considered the maximum permissible width. On public lands in the National Forest and private lands of lower value a 300-foot right-of-way was secured. On the new Vincent line to Big Creek a 200-foot right-of-way is being secured to accommodate two tower lines.

Projecting and securing a right-of-way as wide as this becomes a real problem, not only because of the acreage involved but also on account of the difficulty of finding wide enough spaces between obstructions.

On the Eagle Bell line the right-of-way was purchased in fee. Due to its proximity to cities and towns and rapidly developing territory this was considered a wise precaution in order to make the position of the line more secure. With a right-of-way of this width it is practically necessary to purchase in their entirety small land parcels which are hopelessly cut up by such a strip. The left-over pieces can, however, be grouped together or rearranged and sold to advantage when they are under one ownership. This was done on the Laguna Bell line and, due to the rising real estate market, showed a profit in many cases.

On the Vincent Line, easement is being secured except for a few cases where fee is being purchased for the same reasons as on the Eagle Bell line. The protective clauses in the easements are more effective than usual and for the class of territory traversed easements are believed to be adequate.

The best job of right-of-way location and survey work may be set at naught by careless or injudicious location of towers and special effort should be made to insure that this part of the work be accurately and carefully done. The old reliable centerline profile and celluloid template of wire curve are found to operate on 220 kv. as well as on 60 kv., but due to the wide spread of the conductors, it is necessary to take account of the cross slope of the ground at critical places to a greater extent than with the lower voltage. This is especially true of single-circuit horizontal construction in which the spread is greatest.

The experience in tower locating on the Eagle Bell line showed that in rough country the exact location of towers, as well as their elevation and type of extension, if any, must be determined on the ground. Reasonably good topography with a one-foot contour interval was found inadequate for properly locating towers, mainly because of soil or other conditions which could not well be shown on a map.

Discussion

PAPERS ON SOUTHERN CALIFORNIA EDISON SYSTEM

(Michener, Stauffacher, Shaw, Carlson, Gaylord, Elliott)

Pasadena, Cal., October 14, 1924

H. A. Barre: As you know, our initial problem was something very different from building a 220,000-volt line. We had the existing Big Creek Line. We didn't have time to build a new line; we had to get in and make that one work at a higher voltage to carry the additional amount of power that we had to transmit. That was quite a serious problem.

The failures that have occurred on the line have been very instructive. One incident will be sufficient to show the things we ran into. In making the shield rings we worked over a number of different possibilities and finally hit on the idea of using aluminum alloy. We were told by the Aluminum Company that aluminum was a metal which would melt and drop away under heat and hit the ground in a comparatively cool condition and eliminate one of the causes of trouble we had which was setting fire to the whole countryside during our dry summers. Of course, you know what happened The concentrations of power were so enormous that the aluminum rings actually ignited and burning pieces fell like a star-shell and set the ground afire. This condition applies to the shield and not the aluminum conductor.

Now, in operating the line we clear away the grass around the towers and in that way eliminate the trouble.

In regard to the matter of relays, I will say that, of course, we know that relays are not 100 per cent perfect; however, they are better than nothing, very considerably better.

R. Wilkins: I would like to talk on Section 2, the "Protective System." In the past most of the time and energy has been spent on the economic construction of transmission lines and very little time spent on the possibilities of being able to operate those lines economically after they are constructed.

Relays have made such networks as are now operating on the Pacific Coast possible and economically feasible and in the final analysis it is switching and relaying that will determine how many and what kind of lines there shall be to deliver large blocks of power.

In the company by which I am employed it has by trial been proved that it is not feasible to break up that system into sections in times of trouble and the accepted method now is to separate completely the smallest practicable section of that network in such a manner as to give the least possible disturbance.

We use a relay system in which each line is complete in itself and which allows selective directional tripping on any number of lines. In this work relays relying on direction of trouble are superior to those using time for selectivity, and relays using current only for direction are superior to those using both current and voltage on account of power-factor troubles.

With the power available in a large network it is essential that a line in trouble be cleared at a low current value and very

quickly in order to prevent serious damage. Emergency repairs on a 500,000-cir. mil line is a real job and takes considerable time.

On the high-tension network of the Pacific Gas and Electric Company we now clear selectively on grounds and unbalances of about 25 per cent and in all cases less than ½ of the normal line current. During the year 1923 out of 1569 high-tension relay operations there were 1490, or 95 per cent correct.

If the relays don't clear a line attached to a system which can deliver approximately half a million k-va., it takes but just a fraction of a second to do considerable damage. The lower current for which you can get the relays set and still make them selective, the better relay system you will have.

J. Mini, Jr: I am glad to see that Mr. Elliott does not hesitate to speak of transmission-line location as an art. In the final success of the working of a transmission-line system, and without a careful consideration of this problem much money can be squandered. Regarding the use of airplane surveys, I will say that we have tried that to a small extent. It gives, as stated in the paper, a comprehensive picture as a whole and saves running a number of preliminary locations, but in the end the final detailed location work is not in any way minimized. Another important point is, I think, that it does avoid preliminary advertising that goes with a survey party and which immediately causes property values to sky-rocket over night.

A wide right-of-way is desirable especially through timber country to better avoid accident and forest fires. It is possible, sometimes, to have a narrow right-of-way by arranging to cut all of the tall trees outside of the right-of-way which later might fall across the line. In a rough hillside country it seems important that a proper fill be made for the particular conductor on the uphill side of the right-of-way. While we have, in the past, made office locations, with final checks in the field, we are changing our practice and doing more of the locating directly in the field without the necessity of taking notes to the office and having them returned again later to the field.

The paper by Mr. Gaylord, on the vibration of conductors, is an interesting and important one. We had some trouble from this cause on our long Carquinez span. The details of this trouble and how it was remedied, were discussed by Mr. L. J. Corbett last year at the Del Monte Convention and I will say nothing further here.

It has been our practise to string our conducters with moderate tensions, meaning more sag and lighter towers. This matter was presented in a paper last year by our Mr. Dreyer at the Del Monte Convention.

The paper by Messrs. Carlson and Shaw about "Economic Studies of Transmission Line Design with Particular Reference to the Mechanical Features," is a modified form of Lord Kelvin's law abreast of the times, and includes many factors not thought of in the day of Lord Kelvin. Since some of the intermediate steps are not shown I am not sure whether the corona loss was figured in but I presume so. It is fortunate that the economic zone extends over such a wide value of kilowatts delivered because it must be remembered we cannot afford to lower them to the economic limit for when one of the birds that Mr. Michener speaks of comes along we are going to be deprived of that circuit for awhile, at least, and the remaining circuit must have a margin of capacity left to take care of the loss temporarily.

With reference to Mr. Michener's paper, I will say that some flashovers on the Pacific Gas and Electric Company's system have taken place, on both the 110-kv. and 220-kv. systems. The trouble on the 220-kv. line consisted of thirteen flashovers while still operating as a 110-kv. system. There were a number of flashovers on the 110-kv. system and only a few on the 220-kv. system.

I will classify flashovers as of four kinds: (1) That due to being struck directly by lightning; (2) dirty insulators, with light drizzling rain; (3) dirty insulators with dew formation. The two last classes of flashovers occur during the night. We have never had very much experience with dirty insulators where the trouble has occurred in heavy rains, but in light rains, or heavy mists, there has been considerable trouble. The dew-formation trouble is of somewhat a different character. The insulator is dirty, as in the former case, but the trouble usually does not happen until the early morning hours, practically at sunrise, or on cold nights, but the insulator has been lowered in temperature during the night period, and in the early morning hours, practically after the time the sun rises, dew will rise off of the surface of the earth as high as the insulators in the towers. When this highly humidified air reaches the cold surface of the insulator, beads of water are condensed on the surface of the insulator and often form to such a large extent that the different beads are almost connected, making a heavy sheet of water, and, under this condition it is not hard to see how flashovers may occur.

Then, there is the fourth class of insulator flashovers which we call the mysterious type. It occurs on insulators that are in the very best of condition regarding their surface resistance. It occurs in the middle of the day, in the bright sun when the temperature is high and of the insulators that have been examined the surface was found in perfect condition. As I have said, we call those the "mysterious type." We have, for some years, had various devices on the lines trying to see if there was some transient condition of rising voltage which might be responsible, but so far we have not been successful in finding any evidence to that effect. Nevertheless, we still believe that such a possibility is there.

Now, as regards the "bird theory:" I am in perfect accord and willing to blame the bird for a portion of these flashovers of which I call the "mysterious type." We have had absolute evidence that this is so in a few cases. I refer, particularly, to types of strings of insulators that were formed, or hung on the tower in the form of an inverted "V" with the apex at the cross-arm and insulators spread at the base where they were clamped at the wire. I know of one case, in particular, where the flashover was seen by a rancher and the trouble was found by the patrolman after he had notified him. In that case the evidence was so clear that there was no doubt about it. The bird excrement had run down the insulators, which formed a series of steps, being hung at about a 45-degree angle, and the arc absolutely followed the path of this excrement. There have been a great many strings of flashovers found perfectly clean and no evidence of any bird soil on them. We have suspected for sometime that the theory advanced by Mr. Michener was possible. As far back as 1915 we attempted some experiments, which are described in the paper as being credited to Mr. Peek, but we were not as successful, however, as Mr. Peek was, in our experiments. We poured some white-lead paint down alongside the insulator string, but due to the fact that the testing transformer was of small capacity we were not able to establish an arc following the path of the paint. However, I think if the testing transformer had been of a large capacity, as no doubt Mr. Peek's was, we probably would have established a similar experiment. I think the way to make this experiment, however, is actually to take a real transmission line with lots of power behind it, get it out of service and then pour down some liquid of that type. I think the experiment will show, without doubt, that it is entirely feasible to cause flashovers and that they do happen by this very method.

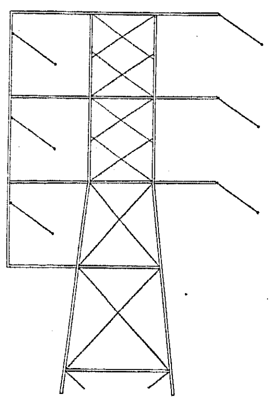
I have some photographs which I took out of a string of insulators which had been on the tower but a few months. The bottom of the string has an insulator shield of spun copper 16 in. in diameter. That string of insulators has in it units 10 in. in diameter and several units 13 in. in diameter. That is an overhang on each side of 1½ inches. The photographs plainly show some of this excrement had caught on the 1½-in. ledge and yet the string of insulators was perfectly clean.

H. C. Sutton: The papers seem to indicate that vibrations are more serious in the longer spans. We had a case with one of

our companies where vibrations were observed in 100-ft. spans on a 11,000-volt copper wire where the vibrations were quite excessive in a fairly light wind. I have also heard of a case where vibrations on a similar line were great enough to lift the insulator off the pin. This particular type of pin was of the lead-tip type where the lead had been disintegrated due to the vibration.

We have experienced trouble recently in Connecticut on 66,000-volt lines with normal spans of 800 ft. The lines were built of 2/0 and 4/0 copper. During a severe wind storm with the wind at an exceedingly high velocity, there were four locations in the line, which is 30 mi. long, where the wind apparently deflected from the side of the hill and raised the conductor a distance of at least 8 ft. and wrapped the conductor around the conductor above it. Now this trouble may have been due entirely to the excessive wind and not to vibration, however, vibration may have contributed to the trouble.

It has also been observed in some places that there are certain spans that are more subject to vibration than others and these spans are not the longest spans in these particular lines. Apparently there is some harmonic condition set up where the vibration reaches a considerable magnitude, the vibration being sufficient to bring the conductors together. This harmonic



Cut Showing Recent Method of Avoiding Dead-End Construction on Angles

vibration has been corrected by changing the sag in the conductor.

Now, in the particular instances where we had trouble with the 66,000-volt lines in Connecticut, we decided to change the sag in the wire. We decided that if a harmonic condition was in any way responsible for the trouble, at least we could correct this condition by changing the sag in the wire. We would like to have sent observers to check up these spans and to determine definitely if a harmonic condition contributed to the movement of the wire, but we felt that we could not afford to run the risk of having a reoccurrence of this trouble.

In looking at some of the high-tension lines in California, I note that there seems to be a considerable number of dead-end points in the line, that is, where the insulators are in dead-end position. Some of these dead-end points are at locations where no angles exist. If vibration is serious, of course the dead-end points should be avoided as far as possible. There are other reasons for avoiding dead-end construction, in that dead-end construction causes other trouble. With the higher voltages the wire loop at dead-end points is excessively long. These loops sometimes swing into the tower and this in turn makes necessary the holding of these loops down by some complicated mechanical means.

In the State of Connecticut where we built a number of 66,000-volt lines, we have avoided the use of dead-end construction as far as possible. We cannot construct our lines on perfectly straight right-of-way. It therefore becomes necessary to install angles in the line. At these locations we have used the so-called pull-down type of construction, installing the pull down on the side of the tower where the line would swing into the tower. On the other side of the tower we allow the conductor to swing away, putting in a single string of insulators. There are other methods of avoiding dead-end construction on angles. A recent method is shown in the illustration. This will allow the use of single strings of insulators on each side of the tower and will avoid some of the objectionable features of the pull-down type of construction.

D. I. Cone: The problem of the location of a high-voltage line, as so interestingly discussed by Mr. Elliott, has a deep interest for the communication engineers. Actual experience on the Pacific Coast has shown that with these very high-voltage lines the situations of proximity between power and communication circuits are limited to occasional crossings and situations in which there is parallelism at separations of the order of 1000 ft. Under these circumstances the fields of influence, with which we are concerned, are chiefly the magnetic fields, due to current returning through the earth and to balanced load currents. The latter can be cared for by transposing. Thus, the chief problem becomes that of guarding against the effects of earth-return currents arising from star-connected transformers with grounded neutrals, the corona effect that has been discussed here in previous papers, or other causes.

We have two situations to guard against: transient disturbances, at time of flashovers or other accidents, and the steady-state or normal, induction. The data given in the symposium by Messrs. Michener and Stauffacher, on the occurrence of flashovers and the amounts of ground current, are a most valuable contribution to the knowledge of the communication engineers, enabling them better to gage the frequency of occurrence and severity of these disturbances. Likewise, for the steady-state conditions, the data presented in such papers as that of Mr. Wilkins are of great value.

J. A. Johnson: I would like to add a small contribution on the subject of vibration and also on the subject of insulator flashovers.

Some years ago the Canadian Niagara Power Company built a transmission line from their Canadian Plant to Buffalo, which crosses the Niagara River between Fort Erie and Buffalo, with two spans, one of about 1900 ft. and one of 2200 ft. These conductors, originally, were all aluminum and this vibration trouble was experienced on that crossing so severely that the conductors were crystallized at the point of attachment to the towers and in a few cases broke and fell into the river. The solution of the trouble adopted at that time was to interpose a chain between the conductor and the point of attachment to the tower thereby changing the constants of the vibrating system and introducing an ineriat effect from the weight of the chain so that the vibration was considerably mitigated. However, this solution as applied there was not completely effective. The conductors continued to break and were later changed to copper-clad steel. However, it would seem to me that a solution of this character, with possibly a graded weighting of the conductor as it approaches the point of support, might constitute a solution of this particular trouble.

Now, in the matter of insulator flashovers due to deposits on the insulators: One of the most recent 60-kv. lines which we have built passes in fairly close proximity to the chemical plants at Niagara Falls where one of the products is hydrochloric acid. This acid is stored in a tank outside of the plant proper and this tank gives off a considerable amount of fumes. This particular line is located immediately on the bank of the Niagara River and in the Spring and Fall is subjected to a considerable amount of fog. During these fogs, in the early morning usually, we have had cases where the insulators, four units of Jeffrey-Dewitt, have flashedover. We made an investigation of this trouble, taking samples of the material which we found on the surface of the insulators, which is, when moist, a slimy substance that is

practically impossible to wipe off the insulator. We found it contained a mixture of zinc and calcium chlorides. The zinc chloride came from the galvanizing of the hardware of the insulators, which was completely removed from the iron. The calcium came from a nearby carbide plant which belches into the air a large quantity of lime dust. The solution we found was to wash the insulators and we have been doing that now for nearly a year, both on these particular transmission towers and also at our substation, which is in this same neighborhood. We do this while the line is alive. The substation is a mass of insulators of both suspension and post type. We use a fire hose with about a ¾ in. stream and play it over this mass of insulators, allowing the water to fall on the insulators like a heavy rain. On the transmission towers we have placed pipes up the towers with nozzles arranged to play a stream on the insulators and we periodically visit them with a pump mounted on a truck and drop a suction hose into the river and play the water on to the insulators. We find this effective in preventing this trouble.

It will ill become an Eastern engineer, to whom mother nature has handed her water on a silver platter, you might say, to attempt to suggest to Western men how you might get the water to the insulators. However, I have no doubt that your hydraulic engineers, who have shown themselves so efficient in taking water from the place where it is and is not wanted, to the place where there is none and it is desired, will find some way to do it if the electrical engineers decide they want the water there.

L. M. Klauber: In washing insulators we have been compelled to reduce the amount of water used because of inaccessibility of the lines and the scarcity of water along the routes. We have recently used an air-compressor outfit, applying a combined air-water spray with a nozzle of the type used in acetylene welding and by this means have succeeded in cleaning insulators using only a few gallons of water per mile of line. We find that with a nozzle of this type an increase in the quantity of water above a certain amount lessens rather than increases the cleansing effect. The air actually does the cleaning and the water serves only to moisten slightly the deposit so that the air can blow it off. This may be of interest to those who operate in arid or mountainous territory.

The work of cleaning insulators by using compressed air is not only better, from the standpoint of water haul, but is likewise a labor saver. We have found that one crew of men, with one compressor, can clean approximately four miles of line per day, whereas, with the old method of washing the insulators by hand, which frequently necessitated actually removing the insulators from the line in order to clean them properly, a crew of men could hardly cover two miles per day. The insulators washed in the new way are washed with greater thoroughness than by hand washing because the air-water jet thorougly cleans the grooves underneath the insulator. We washed about eighteen miles of line about six weeks ago; prior to the washing we were having flashovers at the rate of from three to six per night, depending on the condition of the atmosphere. Since washing them we have not had a single flashover.

Interconnection of Power Systems
in the Southeastern States

BY W. E. MITCHELL
Fellow, A. I. E. E.
Assistant Gen. Mgr. Alabama Power Co., Birmingham, Ala.

Review of the Subject.—*Superpower systems have become one of the prominent economic and political factors of the day. Because in the Southeastern States interconnection of systems and interchange of energy have been practised longer and to a greater degree than almost anywhere else. The author reviews briefly the history of interconnection in this section and the underlying principles that brought this about.*

The advantages of interconnection in reducing capital investment, operating expenses and outages, as compared with isolated operation are shown.

The necessity of thorough engineering studies to get the best use of the interconnected systems is brought out.

The importance of having the proper kind of interchange contract is stressed and the workings of some interchange agreements are illustrated.

The load dispatching and other operating problems are discussed, bringing out the necessity of careful voltage and frequency control, accurate adjustment of protective relays and the proper handling of wattless current.

The value of close cooperation through engineering and operating committees in studying the most economical handling of present plants and the proper sequence of new development are stressed.

* * * * *

SUPERPOWER, or giant power, as Governor Pinchot prefers to call it, has been very much before the public for the last two years. General Tripp with his clear vision and masterly exposition of this great subject has done much to clarify and make understandable to the general public the problem involved and the effect of its solution. The appeal to the imagination of a completely electrified country has resulted in great public interest in the matter, so that it is but natural for the politicians seeking an issue and the advocates of government ownership to give their attention to this new problem as being fraught with more possibilities than the more settled railroad, telephone and telegraph systems. While there is a tremendous engineering problem involved, there are other and equally important phases that must be carefully considered before superpower and complete interconnection will be an accomplished fact.

To those of us actively in public utility work, the widening out of the field has been so gradual that unless we mentally turn back ten or fifteen years we cannot properly appreciate what tremendous advances have been made, nor yet how much greater fields there are ahead. Our problem is always to serve the public, but who is the public? Thirty years ago it meant the dozen blocks that could be reached at 110 volts or 220 volts d-c. from the old Edison bipolar. Twenty years ago it meant a radius of 25 miles around a plant with the beginning of real central station development and transmission. Ten years ago systems had widened to take in many hundred square miles of territory with straightaway transmission of power over distances up to 250 miles at 132,000 volts. Today great systems in adjoining states are being interconnected so that we have one great system covering many states, and serving thousands of square miles of territory and millions of people.

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

Our great problem for the next ten years is to increase the capacity of these interconnections, to develop the distant waterpowers, the mine mouth, or other strategically located (from an economic standpoint) high-capacity steam plants and connect them with the great load centers by means of superpower networks at 154,000 volts or higher.

Up to this time the growth and development of our utilities has been rather haphazard. We have been in an unstable condition, due to a number of causes, and the load has usually been ready in advance of the power plant and system. The reversal of the government's attitude of 10 or 15 years ago, culminating in the passage of the federal water power act, and sane public service commissions have been two great factors in stabilizing our business and in giving the public confidence in our securities. As a result public utility securities are now enjoying an unprecedented popularity. This makes the financing of needed extensions and new developments a much simpler problem and one that can be handled on a sound economic basis. If we are wise we will now plan, as some companies are doing, for ten years in the future. The use of central station power has become as universal as the use of the telephone and its growth can be predicted just as accurately. Planning ten years ahead will appall some of us because we find it hard to believe our own figures, and yet a look backward should convince us of their correctness.

In less than ten years nearly all of us will be faced with the problems of interconnection, power interchange and the operation of interconnected systems. While these problems differ in detail in different parts of the United States, there are certain elements in common. For this reason a review of what has been and is being done in the Southeastern States may be of interest to members of the Institute.

The territory embraces Mississippi, Alabama, Tennessee, Georgia, North and South Carolina. The

principal power companies in this territory are Southern Power Company, Carolina Power & Light Company, Georgia Railway & Power Company, Central Georgia Power Company, Columbus Electric & Power Company, Alabama Power Company, Birmingham Electric Company, Tennessee Electric Power Company and Memphis Light & Power Company. The accompanying map shows the territory and the principal transmission systems.

The drainage area is that of the southern extremity of the Appalachian Mountains. The flow characteristics of our rivers are very different from those of the far West or the North. We do not have the melting snows of high mountains to give us the maximum stream flow during the summer and fall seasons when our ice, cotton-gin and cottonseed-oil mill loads are heaviest. W. S. Lee, a distinguished member of our Institute, has well called them "the fugitive waters of our Southern streams." Variations of 1000 to 1 between maximum and minimum are common, and the wide variations in stream flow necessitate large steam reserves or storage reservoirs. The stream flow curves shown herewith are typical.

The topography of the country is such that the majority of power developments utilize heads of from 50 feet to 150 feet. The exceptions are the plants of the Georgia Railway & Power Company on the headwaters of the Tallulah River, where a maximum head of 608 feet is developed in one plant and the plants on the upper Ocoee River of the Tennessee Electric Power Company where heads of 250 feet are developed.

There are no coal deposits in Georgia or the Carolinas or Mississippi. Freight rates from the Alabama, Tennessee, Kentucky or West Virginia fields to Georgia or the Carolinas are high. Therefore, the great steam reserve plants of the future for this district will be located in Alabama or Tennessee, with the probability of the connection of the North Carolina systems with mine mouth steam plants in West Virginia. The Southern Power Company in its Bridgewater plant has developed a water storage equivalent to 110,000,000 kilowatt hours of energy. The Georgia Railway & Power Company, in its Burton and Mathis Dams has developed approximately 90,000,000 kw-hr. of storage. Alabama Power Company, in its Cherokee Bluffs project, now building, will have an available storage of 60,000,000,000 cu. ft. of water, which is equivalent to 300,000,000 kw-hr.

Hydroelectric development in the South on a large scale was started by James Duke and W. S. Lee of the Southern Power Company about 20 years ago. Mr. Duke started the cotton mill industry to manufacture cotton goods from the raw cotton near the point of production, using power from the hydroelectric plants he built to run these mills. As a result, the marvellous growth of North Carolina has not been exceeded by any state in the Union. The system serving this territory has one of the greatest transmission networks in the country and its peak load is in excess of the 275,000 kw. It was followed by the Yadkin River Power Company in North Carolina, the Georgia Railway & Power Company on the Tallulah, The Tennessee Electric Power Company on the Ocoee, the Columbus Electric & Power Company on the Chattahoochee, and the Central Georgia Power Company on the Ocmulgee River. Development in Alabama did not start until 1912 when construction of the Lock 12 Plant on the Coosa River was commenced. The load was developed very rapidly by Alabama Power Co. and today it ranks second to the Southern Power Company in output.

The first interconnection between large systems in the South was made in 1912 near Atlanta between the Georgia Railway & Power Company and the Central Georgia Power Company. In 1914 the Georgia Railway & Power Company connected with the Columbus Electric & Power Company at Newman, Georgia, and about this same time with the Tennessee Electric Power Company near Rome, Georgia, and with the Southern Power Company at their Tallulah Plant. In 1921 Georgia Railway & Power Company and Alabama Power Company joined their systems at the state line by a 110,000-volt line from Gadsden, Alabama, to Lindale, Georgia. This year a 110,000-volt line was completed between North Auburn, Alabama, on the Alabama Power Company's system and West Point, Georgia, on the Columbus Electric & Power Company's system. The Georgia Railway and Power Company is now completing a new 110,000-volt line between Lindale, Georgia, on its system, and the Ridgedale substation at Chattanooga on the Tennessee Electric Power Company's system. There is under consideration a line at 110,000 volts between Huntsville, Alabama, on Alabama Power Company's system and Hales Bar, Tennessee, on Tennessee Electric Power Company's system. We have a complete interconnected network embracing ten companies and extending over five states. An important feature is that the interconnections have what until recently would have been considered high interchange capacity, that is, of the order of 20,000 kilowatts to 25,000 kilowatts.

In the Birmingham District, the Tennessee Coal Iron & Railroad Company has ore and coal mines and steel mills with a demand in excess of 40,000 kilowatts of electrical power. The advantage of an interconnection with a large system was realized and an interchange contract was made in 1914 with the Alabama Power Company. At night and over week-ends the Tennessee Coal Iron & Railroad Company is able to return a large amount of power at low cost as the by-product gas used in firing the boilers would otherwise be wasted. The interconnection has also proven of great advantage to the steel company because it has permitted rapid expansion of its finishing plants without the delay and cost of construction of additional power facilities.

The fall line marking where the rivers of the Central States and of Tennessee and Alabama break through to the costal plain swings down from Keokuk on the Mississippi to Muscle Shoals, Alabama, on the Tennessee, to Lock 18 a few miles above Montgomery on the Coosa, to Tallassee on the Tallapoosa River and to Columbus on the Chattahoochee River. There is no water power of any magnitude south of these points to the Gulf of Mexico. If, therefore, Mississippi and Louisiana are to have the benefit of widely distributed hydroelectric power, it must come from Alabama. It is logical to anticipate, therefore, that within the next five or ten years power from Muscle Shoals and other Alabama hydroelectric plants will be transmitted to Memphis, Tennessee, across Mississippi and even to New Orleans, Louisiana, a distance of approximately 300 miles. When this is done, seven states with a population in excess of 16,000,000 people will be served from what, due to interconnection, will be virtually one great system.

Prior to 1920 the lack of any federal water power laws hindered hydro development on so-called navigable streams and forced the building by the Alabama Power Company, in 1916, of the Gorgas Steam Plant about 35 miles from Birmingham, Alabama, in order to take care of the rapidly growing load which exceeded the low water capacity of Lock 12. The Gorgas plant is exceptionally located from the economic standpoint, situated as it is on the shore of Lake Bankhead, formed by the government navigation dam at Lock 17 on the Warrior River, and in the center of a large coal field with good steam coal mined within 1000 feet of the plant. Here it might be noted that the location of a large mine mouth steam plant is not the simple matter some of the popular writers on superpower systems seem to think, for the tremendous amount of condensing water required for a plant of 100,000 kw. or 200,000 kw. capacity is seldom found near a coal mine.

The entrance of the Unites States into the world war and the War Department's decision to build a great nitrate plant at Muscle Shoals led to a 30,000-kilowatt extension of the Gorgas Steam Plant, the construction at Muscle Shoals of a 60,000-kilowatt steam plant in 1919 and the start of construction on the Muscle Shoals Dam No. 2 or Wilson Dam, all of which have been more or less in the public eye for the past two years, due to the controversy as to whether the Wilson Dam and the nitrate plants should be sold for a pittance to Henry Ford, or leased to the Southern Power companies and the energy not used in fertilizer manufacture distributed throughout the entire South.

From the foregoing, it will be evident that much pioneer work had been done prior to 1917. The leaders in this were the Southern Power Company and the Georgia Railway and Power Company. The world war emphasized the necessity of coordination of resources. In 1918 a survey was made by the War Industries Board, under the direction of Frederick Darlington, of the available power in these states and of how the power resources should be developed and coordinated to give the greatest service. This report recommended large capacity tie lines between companies and showed clearly that the most economical use could be made of the power to be generated at Muscle Shoals by operating it in connection with the plants of the existing companies.

Following the close of the war, there continued to be a serious power shortage, particularly during dry seasons. This led to the construction of a line between Gadsden, Alabama, and Lindale, Georgia. This was very advantageous, because it permitted the Alabama Power Company's mine mouth steam plant to operate at 100 per cent load factor, 24 hours a day, the surplus power above that required in Alabama going into the Georgia

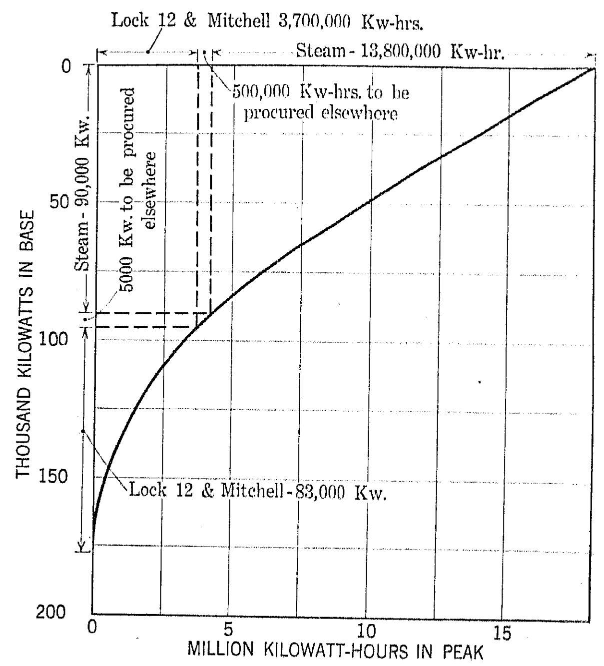


FIG. 1—EXAMPLE OF USE OF LOAD DISTRIBUTION CURVES FOR LOW FLOW CONDITIONS

Company's system where it could be absorbed even at night, as this company had ample storage capacity and so could completely shut down its hydroelectric plants after the peak load hour in the evening.

Eastern Georgia and the Carolinas are one hour ahead of Tennessee and Alabama and this causes a difference in the time of the peak on the different sytems. The Georgia and Carolina companies' industrial load being very largely cotton mills, their annual load factors are in the neighborhood of 33 per cent, whereas the Alabama and Tennessee companies with mining and a more diversified industrial load have annual load factors of about 57 per cent. The dominating part played by the diversified industrial load in Alabama is well shown by the fact that the peak on the Alabama Power Company system from Monday through Friday always occurs between 9.30 A. M. and 2.30 P. M. Not even the

heavy lighting and street railway load of the Birmingham Electric Company in the months of November and December were sufficient to change this.

An interesting operating feature has been the working together for maximum economy of the Georgia Railway & Power Company and the Alabama Power Company systems during the rainy seasons. The Lock 12 and Mitchell Dam plants of the Alabama Power Company are essentially run-of-river plants with only day-to-day storage, whereas the Georgia Company normally

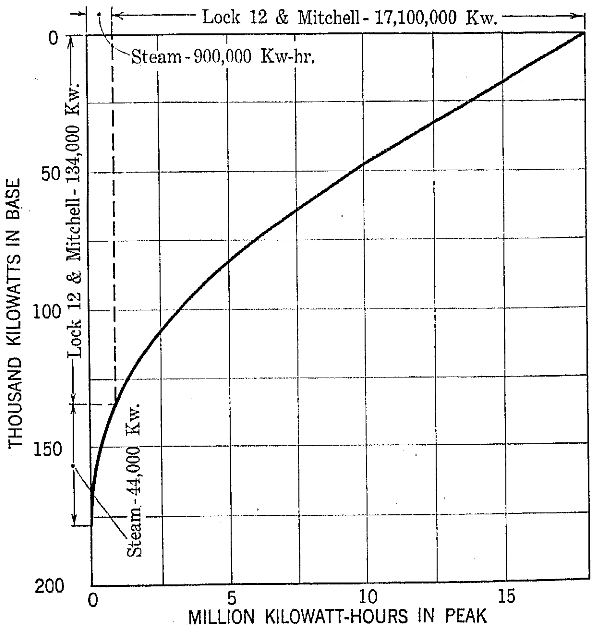

Fig. 2—Example of Use of Load Distribution Curves for High Flow Conditions

starts the rainy season with storage reservoirs, nearly, if not entirely depleted. The Alabama Power Company day loads even during periods of maximum river flow exceed its hydro generating capacity, necessitating considerable steam generation. The Georgia Company's installed hydro generating capacity is in excess of its day peak. Under these circumstances steam generation has been reduced to a minimum by the Alabama Power Company carrying the Georgia Railway & Power Company night load and getting back the equivalent amount of energy during the day time. This, of course, can only be done during the period of filling the storage reservoirs.

There is a considerable variation in rainfall through the district. It reaches a maximum of somewhat over 60 in. in the northwestern corner of Georgia. The normal rainfall for the Coosa River drainage is 55 in. That of the Tennessee, Catawba and Chattahoochee Rivers is about the same. Although the regular rainy season is practically coincident for the entire district, being from December through March, there is a great variation in summer rains and showers, making interconnection valuable in getting full benefit of summer floods at run-of-river plants located on different water sheds.

The value of interconnected power systems was clearly brought out by E. A. Yates in the hearings on Muscle Shoals at Washington in May, 1924.

As illustrated in Fig. 3 in an average year, there is a capacity at Dam No. 2 or Wilson Dam, and Dam No. 3 of 850,000 h. p. for four months of the year. During the three low months of the average year, there is 250,000 h. p. available, while in years of low flow there is a capacity of only 100,000 h. p. in the low water period. Assuming an installation of 500,000 h. p., this being available about 50 per cent of the time, there is required a steam standby of 400,000 h. p., if the system is operated independently and not interconnected with other great power systems. Government regulations require that the flow of the river below 10,000 second feet be passed continuously. This flow is necessary to generate 100,000 h. p., so that it could not be used in the peak of the load curve to increase the horse-power capacity supplied by Dams No. 2 and No. 3 and reduce the 400,000 h. p. of steam needed.

Now if Muscle Shoals is used in connection with the Tallapoosa River development, the steam standby required in a low year will be only about 160,000 h. p., while in an average year no steam will be used. Similarly, the storage and reserve steam plants of the other

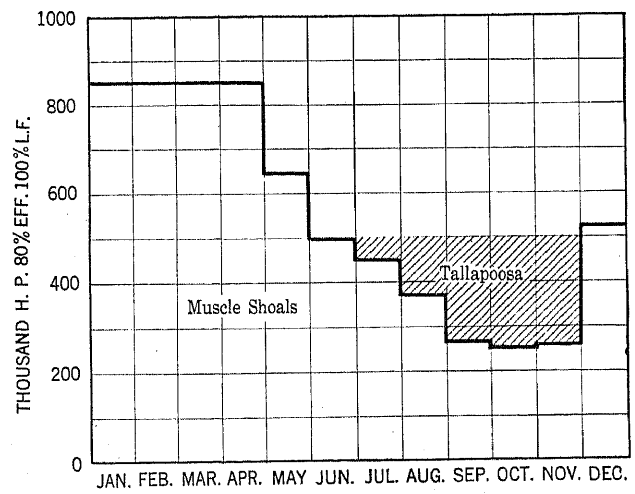

Fig. 3—Tennessee River, Dams No. 2 and No. 3. Power Available in Year of Average Flow. Muscle Shoals Operated Independently Year of Average Flow

Installation	
Dam No. 2	600,000 h. p.
Dam No. 3	250,000 h. p.
Total	850,000 h. p.

companies in the southeast would valorize additional blocks of secondary power at Muscle Shoals which would otherwise be practically worthless.

The estimated growth in load of the Southeastern States, including the seven utilities mentioned and Memphis, New Orleans, and Mobile, will require the following kilowatt hours generation up to 1935:

1923 about	3,250,000,000	kw-hr. (Used)
1926 will require	4,325,000,000	" "
1930 " "	5,860,000,000	" "
1935 " "	7,600,000,000	" "

This is an increase in 1926 of 1,075,000,000 kw-hr. over 1923 and on a basis of 40 per cent load factor requires an additional installation of 306,000 kw. This is practically the number of kilowatt hours that can be generated at Muscle Shoals on a 50 per cent load factor with 300,000 kw. installed.

If a single isolated industrial company attempted to use 1,075,000,000 kw-hr. from Wilson Dam at Muscle Shoals, even on an 80 per cent load factor in 1926, it would require 125,000 h. p. of steam plant capacity and would have to make 200,000,000 kw-hr. of steam to supplement the available hydro power. The Power Companies on the other hand would get this low water kilowatt capacity from their present hydro plants and would not be required to run steam. For example, the Alabama Power Company's Lock 12 and Mitchell Plants on the load of last year, carried about 60,000 kw. during the peak load of the day in low-flow period although the 24-hr. average flow was only about 20,000 kilowatts.

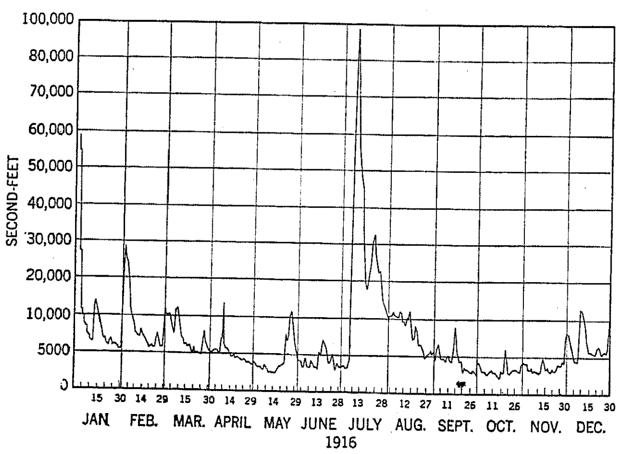

FIG. 4—HYDROGRAPH OF CHATTAHOOCHEE RIVER AT COLUMBUS, GA. FOR 1916

In 1922 the power shortage in Georgia and the Carolinas was even more acute than during the previous two years. There had not been sufficient winter rains to completely fill the Georgia Company's storage reservoirs and there was an unusually dry summer in the Carolinas. All cotton mills served by the Southern Power Company and the Carolina Power & Light Company were put on part time operation and those on the latter company's system were facing almost complete suspension. The situation was brought to the attention of the Secretary of War with the request that the Power Companies be permitted to temporarily lease the 60,000-kw. Muscle Shoals Steam Plant, which was then idle. Following an investigation by army officers proving that the case had not been overstated, the Secretary of War leased the plant and the Alabama Power Company has since operated it for the companies interested. In 1922, 44,137,000 kw-hr. were generated at Muscle Shoals steam plant and 44,646,400 kw-hr. went over the tie line to keep the mills of Georgia and the Carolinas going. In 1923, 46,910,000 kw-hr. were generated at Muscle Shoals and 48,460,000 kw-hr. supplied to Georgia and the Carolinas. Incidentally, during this period over $400,000 has been paid the United States for rental of the Muscle Shoals steam plant.

Interchange between the Southeastern power companies proved so successful that 18 months ago executives of the various power companies decided that still closer cooperation would be beneficial. An operating subcommittee was formed with one representative from each company's operating department. This committee meets once a month, exchanges information in regard to load and rainfall conditions, energy generated on each system by hydro and steam and discusses such matters as voltage regulation, load dispatching and system protection. The work of this committee has proven of very definite benefit. Its successful work has caused the executives to go a step further and an engineering subcommittee has now been formed, consisting of the chief engineer or executive engineer of each company and studies are being made of the possibilities of a coordinated development program, with the object of avoiding construction of two or more large plants by different companies at the same time, if one development plus interchange will handle the load. In this manner one company might save the fixed charges on a very large investment for two or three years while the other company would load its new development from the date of completion with not greatly increased operating costs. Under such circumstances it ought to be possible to work out a mutually advantageous interchange.

While this engineering committee has just organized, there is every reason to expect good results. An assistant engineer or a computer from each company is assigned to the work and these men are putting in full time in the same office assembling data on stream flows, studying rainfall and run-off records, plotting present load curves for both wet and dry seasons and projecting the growth of each company's load for the next ten years and determining the proper sequence of developments to carry the loads. While the proximity of the various systems and the necessarily restricted location of large steam reserve plants may make this a more immediate problem in the Southeast, I believe the principles involved are applicable to advantage elsewhere.

These statements show the value of having an engineering committee working on a coordinated study of all available resources and their most economical development. After the engineers have completed their estimates of what the tie lines will cost and the operating men have worked out their scheme of operation, an interchange contract must be made before the lines can be built and power interchange actually take place. Upon the type of agreement

between the interconnected companies is largely dependent the success of the project and its most economic use. Quite naturally, the first tie lines were built to enable a company having a surplus of energy to sell it to another company which was short of power. Following this came agreements covering emergency service, and later, agreements for straight interchange. All these different conditions must be covered by contract, and rates established. Furthermore, rates must be varied, dependent on whether surplus or dump power, steam power, with a clause varying the rate as the price of coal varies from the base price, or hydro storage power is being supplied. It is readily seen, therefore, that the drawing of a contract is not simple. Fortunately, after the contract is drawn with all its legal phraseology, carefully protecting every right of both parties, and arranging at great length for the arbitration of disputed points, it is usually forgotten, except the rate clause, and operation under it is decidedly simple. O. N. Hollis, of the Detroit Edison

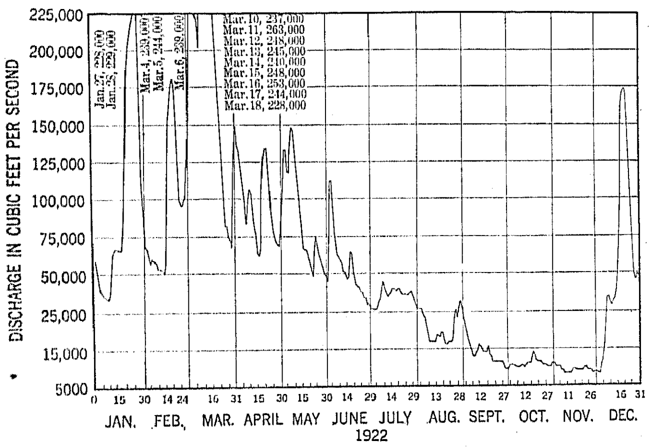

Fig. 5—Daily Hydrograph. Tennessee River at Florence, Ala., Alabama Power Co.

Company has just delivered a most excellent paper before the Association of Edison Illuminating Companies, on the subject of interconnection rates and contracts which brings out in detail many of these points.

In the southeast all these forms of contract are in use. There are the firm contracts for definite portions of the capacity of the Muscle Shoals Steam Plant. If the capacity is used there is a definite flat rate per kilowatt hour, based on the price of coal. The method of billing for the energy under these contracts is interesting, showing how simple a complicated problem can sometimes be made. For example, power destined for the Carolina Power & Light Company is delivered by the Alabama Power Company to the Georgia Railway & Power Company, at the state line and is in turn delivered by the latter to the Southern Power Company at Tallulah Falls and by the Southern Power Company to Carolina at Wateree. Only one bill is rendered, and that by the Alabama Power Company against the Carolina Power & Light Company for the full amount of power delivered to the Georgia Railway & Power Company at the state line. To compensate for line losses, the Georgia Railway & Power Company and the Southern Power Company each deducts a percentage of the power delivered to them for transmission and passes on the remainder to the Carolina Power & Light Company.

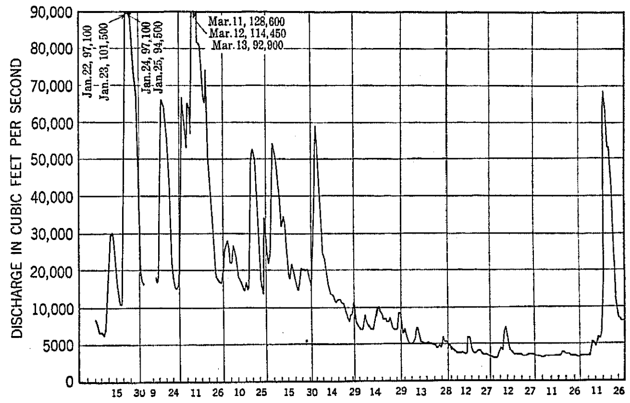

Fig. 6—Daily Hydrograph, Coosa Lock 12 Development, Alabama Power Co.

Interchange contracts under which one company supplies power at night at one rate and gets it back in the day time at a higher rate are common. Nearly all interchange contracts are optional on both parties. This is, if A has power to sell and B desired to buy, power moves; otherwise not, and vice versa.

With the contracts signed and the tie lines built, it

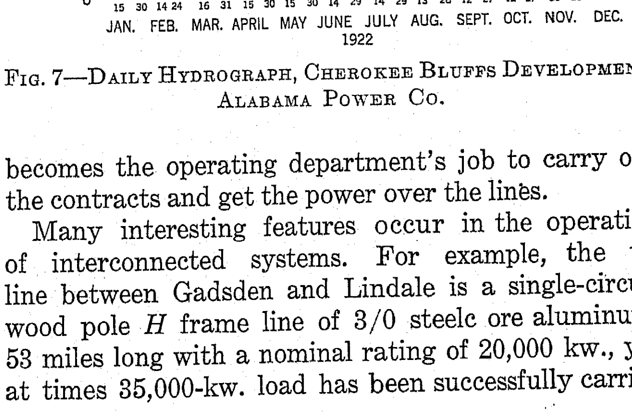

Fig. 7—Daily Hydrograph, Cherokee Bluffs Development, Alabama Power Co.

becomes the operating department's job to carry out the contracts and get the power over the lines.

Many interesting features occur in the operation of interconnected systems. For example, the tie line between Gadsden and Lindale is a single-circuit wood pole H frame line of 3/0 steelc ore aluminum, 53 miles long with a nominal rating of 20,000 kw., yet at times 35,000-kw. load has been successfully carried

over the line. With a load of 20,000 kw. at 95 per cent power factor, the voltage at Gadsden on the 110,000-volt bus is approximately 110,000 volts and the voltage at Lindale drops to approximately 102,000. The voltage at Atlanta, Georgia, is approximately 110,000 and at Tallulah Falls approximately 115,000 volts. The voltage maintained at the generating plants on the Alabama Power Company's system is approximately 115,000 volts under the above conditions. Of course, in transmitting power in

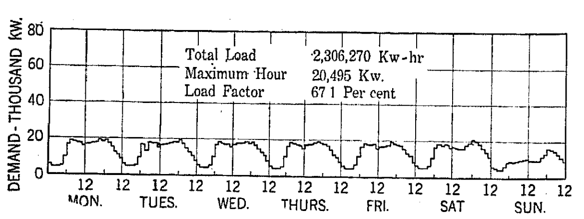

FIG. 8—AVERAGE WEEKLY LOAD CURVE, FEB. 12-18; MAY 7-13; AUG. 6-12; NOV. 19-25, 1923

blocks of 15,000 to 25,000 kw. over these tie lines, power-factor correction is absolutely essential. It is desirable to operate these lines at as near unity power factor as possible. Synchronous condensers are being installed on the various systems for power factor correction. During the year 1923 the Alabama Power Company installed on its system approximately 20,500 kv-a. in synchronous condenser capacity and during 1924 an additional 27,500 kv-a. will be installed. These condensers, of course, are located near the load centers to secure the maximum possible benefit of power factor correction. The Alabama Power Company is now installing a 25,000 kv-a. turbo generator at its Gorgas steam plant and provisions are being made for disconnecting the generator from turbine and operating the generator as a synchronous condenser. This is especially desirable since in the wet season the steam plants are shut down and as the hydro plants are located in the opposite section of the system, operation of the generator as a condenser materially improves conditions throughout the system. During the dry season hydro generators are floated for power-factor correction. By shutting the wicket gates and breaking the vacuum in the draft tube on the machine it is possible to operate generators for power factor correction with only a small loss of water. This same practise is, of course, followed by other companies on the interconnected network and the system supplying energy is relieved, in so far as possible, of excess reactive component by systems receiving the energy, these systems using their spare generator capacity for power-factor correction. Although without doubt the proper place for the major part of power factor correction is at the customers' load, a certain amount of correction is necessary in large load centers where large capacity condensers can be installed and definite control of voltage conditions can be secured.

High-voltage metering equipment is necessary for the interconnecting lines and it has been the practise to install this equipment in substations to which the lines connect. For instance, on the line between Gadsden and Lindale, meters are installed at the Gadsden plant and at Lindale, and energy delivered or received is based on the net amount supplied or received at the State line, though no meters are installed there the losses being prorated. Comparatively little trouble has been experienced in the high-voltage metering equipment. Only one or two cases of current transformer and potential transformer failure have occurred during the past three years. It is customary to carry one reserve potential and one reserve current transformer for each metering equipment.

In general, 110,000-volt oil circuit breakers are used for synchronizing purpose. Inherently, these breakers are slower than the low-voltage breakers in generating stations; however, with a little practise the operators are able to synchronize systems with no adverse effect to either of the systems. Of course, it is necessary to carefully check circuit breaker adjustments so that at all times they will close as quickly as possible.

To successfully operate the transmission systems in parallel and at the same time secure the proper load adjustments between the various generating stations and between the systems themselves, it is essential that the frequency be rigidly maintained at 60 cycles. At first some difficulty was experienced in maintaining a fixed frequency and on numerous occasions in the early days of the operation frequency variations were such as to overload the tie lines to such an extent that the overload relays tripped out the switches, separating the systems. Some difference was always found in the frequency indicators in spite of careful calibration but this difficulty has been overcome by the installation

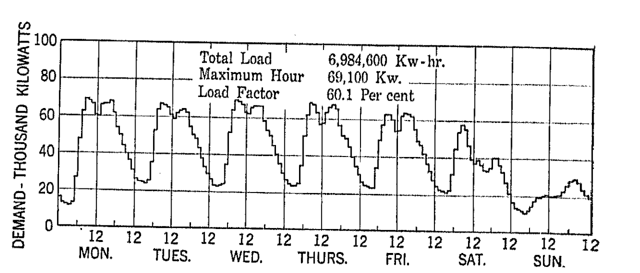

FIG. 9—AVERAGE WEEKLY LOAD CURVE, FEB. 12-18; MAY 7-13; AUG. 6-12; NOV. 19-25, 1923

of Warren Master Clocks at either the principal regulating stations or at the Load Dispatcher's office. The Master Clock makes it possible to maintain an average frequency within very close limits.

It has been found that the regulation of frequency must be controlled by the base load stations and especially the base load station of the system supplying the bulk of the power, all other stations making the necessary governor adjustments to fall in step. The governors at all stations taking the load fluctuations

should be equally sensitive so that all systems can properly carry their share of the fluctuations.

On the system of the Alabama Power Company the base load is carried by the hydro plants and load fluctuations by steam plants in the wet season and vice versa in dry seasons. During the wet season, therefore, the frequency is controlled at Lock 12, and in the dry season it is controlled at the Gorgas Steam Plant. Master Clocks are installed at both stations for the purpose. There is no appreciable difference in manner in which the hydro and steam stations handle load fluctuations.

Operation is handled between load dispatchers on the various systems. It has been found advisable to establish a central load dispatching point at Atlanta and all messages concerning the dispatching are usually relayed through Atlanta to the interested systems. Where a company desires to purchase energy the Operating Superintendent or Engineer customarily advises the Central Load Dispatcher of the amount of power desired on interchange and this is relayed to the dispatchers of the proper systems. In case of emergency, the Load Dispatchers have authority to act and it has frequently been possible to save very important loads by quickly bringing in additional generating capacity. In this way interruptions due to line trouble are reduced in number and duration, because in most cases important load centers can be served over two entirely different routes. For instance, The Alabama Power Company has very important loads at Gadsden and Huntsville, Alabama. This load is served by the Gadsden Steam Plant and by two lines from the hydro plants as well as the interconnecting line to the Georgia Railway & Power Company's system at Lindale. Lightning storms may occur when the steam plant is not in service, causing outages to the

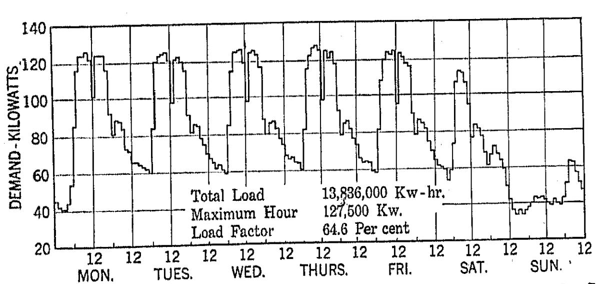

FIG. 10—AVERAGE WEEKLY LOAD CURVE, FEB. 12-18; MAY 7-13; AUG. 6-12; NOV. 19-25, 1923

two 110,000-volt lines connecting the hydro plants. In such cases the tie line is used to supply these load centers until the steam plant can be brought in or the lines repaired. The supply to the Georgia Railway & Power Company's system is from hydro plants located approximately 100 miles northeast of Atlanta and trouble on this company's lines may cause serious interruptions to customers around Atlanta, and the tie line is used to serve this load while the repairs are being made.

Effective relay protection is essential for the successful operation of the interconnected systems and each company has made many improvements in protective layouts during recent years. It is desirable to immediately relieve the system of short circuits by tripping out the faulty line or equipment as quickly as possible. Differential protection for transformers and generators and, in so far as possible, balanced protection for transmission lines have been applied. A diagram of the protective scheme in use on the Alabama Power Company's system is shown herewith. It will be noted that

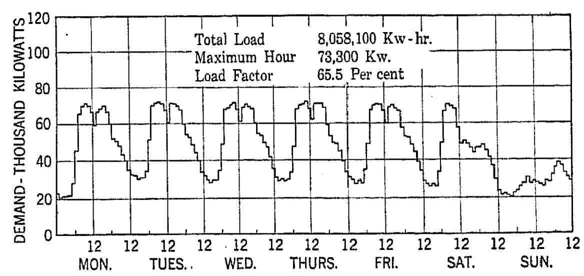

FIG. 11—AVERAGE WEEKLY LOAD CURVE, Feb. 12-18; MAY 7-13; AUG. 6-12; NOV. 19-25, 1923

on this system lines are run in pairs between important load centers and generating stations, and it is therefore possible to apply balanced relays which allow the quick disconnection of the faulty line, allowing the remainder of the circuit to continue carrying the load. The operation of balance relays and differential relays has as a general rule proven successful. Continuous studies are being made with a view of providing the best protection which can be afforded. Short circuit studies are essential in the application and setting of relays as well as of oil circuit breakers. A short-circuit calculating table has been in use on the Alabama Power Company's system for several years for this purpose, and at this time the company is constructing a new board, with permanent resistors for existing transmission lines, generators, and transformers and variable resistors for extensions. The system is reproduced in miniature so that a short circuit may be placed at any point and read by pushing an ammeter button. The total short circuit, as well as the component current in various lines can be determined.

The problem of voltage control is very important since it affects the distribution of reactive current between the various systems, the system maintaining the highest voltage taking more of the reactive component. If the system supplying energy also supplies the reactive component associated with it, then the voltage drop over the tie line will vary according to the load on the line; *i. e.*, from zero at no load to a maximum at full load. Where the range of load is great, too wide a range of voltage is required for satisfactory service. It is possible, however, to maintain constant voltages at both ends of the tie line over the entire range by varying the magnitude of the reactive component transmitted. This method has the disadvantage of increased losses

due to the flow of large reactive currents at light loads over the tie line. The best method perhaps is to strike a compromise and allow the voltage drop over the tie line to vary within permissible limits, allowing reactive currents to flow to maintain these limits. With a heavy load on the tie line this may mean that the receiving system must supply all of the reactive current of the load received and in addition, some reactive current to the line so that the load can be transmitted at a leading power factor.

Typical hydrographs are attached for the Tennessee, Coosa, Tallapoosa and Chattahoochee Rivers. Fortunately for those making hydraulic studies, stream flow and rainfall data are available on these streams over many years. On the Tennessee, for example, rainfall and stream flow data are available over a period of 40 years for the Florence gaging station.

All studies have been made on a weekly basis, both as to available water and to power consumption. Yearly flow curves are plotted, using the 52 weekly flow points instead of 365 daily flow points. While studies have been made of the wettest and driest years, a careful analysis indicates that studies of plant capacities and generation based on what we have called a median year give best results. A median year flow is a theoretical year built up by using for each of the 52 calendar weekly flow points that week which has the same number of years showing this same calendar week with a greater flow as there are years showing it with a lesser flow in the total number of years for which the data are available. There is no such thing as an average year and in our efforts to get a safe typical year and not have to make a study of all load conditions for all the years for which data are available, we have arrived at the median year as here defined which seems to be safe and to materially lessen computations. Typical weekly load curves are shown herewith.

There is necessarily a great deal of tiresome computation in hydraulic studies covering periods of years. To lessen it, Mr. C. James, Assistant Chief Engineer of the Alabama Power Company, has developed a very interesting curve showing distribution of load between different plants, which has proven exceedingly convenient and accurate. While many other forms of curves are used, the one we use lends itself readily to a determination of the position of a given plant in the load curve.

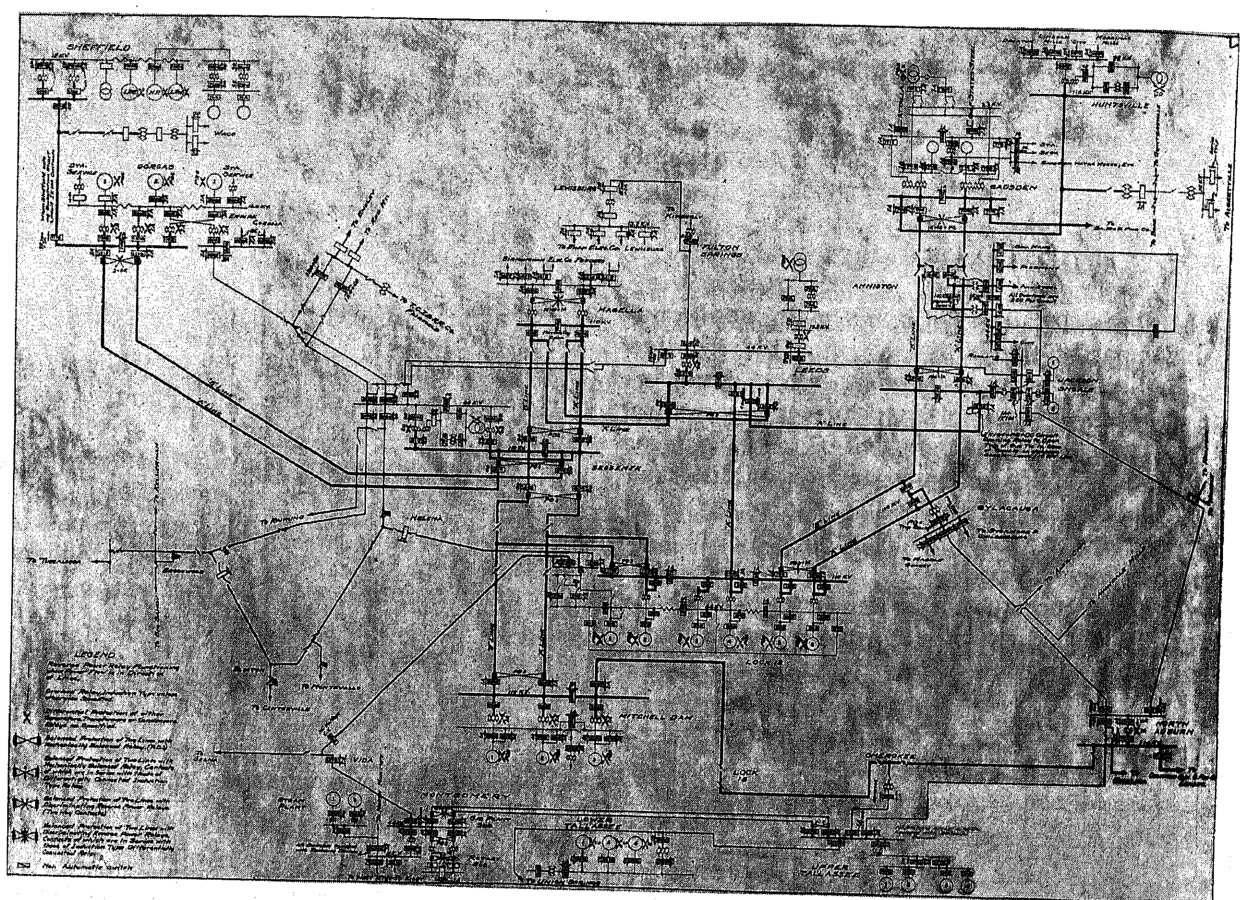

Fig. 12—Single Line System Diagram Showing Principal Relay Protection, Alabama Power Company

The usual weekly load curve as plotted by the Alabama Power Company shows the kilowatt hours generated for each hour of the week consecutively, from Monday to the following Sunday, inclusive. In the power studies it is often important to know the kilowatt hours which a certain plant can generate, knowing

its kilowatt capacity and position in the load curve and the steam flow. This is an area on the load curve as plotted and considerable time would be necessary to determine it in each of the many cases when it is needed. The distribution curves above referred to are in the terms of kilowatts and kilowatt hours, so that for any known kilowatt demand and position on the load curve, the kilowatt hours can be read on the curve or vice versa.

Fig. 1 is an illustration of the use of the curve for low-flow conditions. Under these conditions, in order to use as much capacity of the hydro plants as possible, they are used in the peak of the load curve and steam in the base. Using the entire flow of the river and placing the hydro plants in the peak, we wish to know how much capacity will be obtained. Knowing the installation of steam available, we also wish to know how many kilowatt hours this installation can furnish if used in the base of the load curve, in order never to use a greater amount in our study. Assume a weekly load of 18,000,000 kw-hr. and a peak hour of 178,000 kw. During the low-flow week, the Lock 12 and Mitchell Dam plants of Alabama Power Company will furnish 3,700,000 kw-hr. Our curve is in terms of kilowatt hours in the peak and kilowatts in the base, this being the most convenient form to draw and read the curve. Entering the curve with 3,700,000 kw-hr. in the peak, we read 95,000 kw. in the base. A base load of 95,000 kw. must therefore be furnished in the base load steam or other hydro plants. The kilowatts used in the peak then, by Lock 12 and Mitchell Plants will be 178,000 minus 95,000 or 83,000. Now start on the problem from the opposite angle. Assume we have 90,000 kw. of steam available. We wish to know how many kilowatt hours these steam plants can furnish when used in the base of the load curve. Entering the same curve as used above with 90,000 kw. in the base, we read 4,200,000 kw-hr. in the peak. Subtracting 4,200,000 kw-hr. from the total load of 18,000,000, we have 13,800,000 kw-hr. available with the limits of the load curve from 90,000 kw. of steam. If our load were such as to be able to use 90,000 kw. continuously for the entire 168 hr. in the week, we could, of course, obtain 168 times 90,000 or 15,120,000 kw-hr.

Fig. 2 is an illustration of the use of the curve under high-flow conditions. Under these conditions the hydro plants are used in the base of the load curve and steam in the peak, unless there is enough hydro capacity available to meet the demand without steam. Assume the same weekly load and peak as used under low-flow conditions, 18,000,000 kw-hr. and 178,000 kw. In this case, we wish to know how many kilowatt hours can be obtained from the hydro plants when used to the best advantage in the load curve assuming the flow is sufficient to furnish this amount. We also wish to know how much steam is needed in the peak. The installation at Lock 12 and Mitchell Dam are 80,000 and 54,000 kw. or a total of 134,000 kw. Reading the curve for 134,000 kw. in the base, we find 900,000 kw-hr. in the peak. Subtracting 900,000 kw-hr. from the load of 18,000,000, we have 17,100,000 kw-hr. which can be furnished by Lock 12 and Mitchell Dam, as long as the flow is high enough. If there are no other hydro plants available, the remaining 900,000 kw-hr. and the balance of the demand on the system, or 44,000 kw. must be steam.

In conclusion, it may be said that the various power companies are fully aware of the benefits of interconnection and are intelligently planning to take the maximum advantage of it in the future. Executives, engineers and operating men are working in the closest cooperation. To meet the needs of the rapidly growing industrial load of the southeastern states will tax the ability of the public utilities in this district. Tie lines much larger than the present must be constructed, and their design is a serious engineering problem, when proper consideration is given to protection of service, and to voltage and power factor control. It may well be that a high-tension network of the type proposed by Percy Thomas in his paper before the Institute last April is the ultimate solution. That the problem is worthy of the best technical study is evident when the present capacity of the interconnected systems is considered:

Installed Hydroelectric Generating Capacity......................	782,000 kw.
Installed Steam Generating Capacity	353,000 kw.
Hydro Storage Capacity..........	225,000,000 kw-hr.
System Output in 1923...........	3,250,000,000 kw-hr.
System Peak....................	740,000 kw.

and the further fact borne in mind that, according to the best data available, these figures will be doubled in 1930.

Discussion

P. H. Thomas: Mr. Mitchell's paper is particularly timely since it indicates not only the most advanced point to which widespread interconnection of large systems has progressed in actual practise, but points out the probable solution of some of the problems now being faced in the further extension of interchange.

I have in mind such matters as voltage control at individual stations on a tie line, when the direction of energy flow changes, the proper distribution of true energy between plants, with changes of load and other conditions throughout the 24 hours and the placing and control of wattless. These features would involve no difficulties if the systems could be laid out new, with operation interconnected in view, but may cause very serious trouble if large systems are merely interconnected without proper study of their characteristics.

The scheme of Mr. James utilizing a curve connecting the "peak kw-hr." and the "base kw." for assigning the position of the generating units is most ingenious and useful. I have used a similar curve built up by integrating the kw-hr. shown by the load curve below any given kw. generating capacity. I have extended it to distinguish between minimum stream flow hydro

power and pondage power and to make assignments to individual stations. It is a most useful analysis.

There are two principal points to which I will call attention.

First—In any large interconnection, even where there is no dominating water power plant or single steam station of supreme importance, there will be a considerable amount of installation in tie lines, condensers and power stations in which the interest of the whole will not be the the same as that of some of the individuals. For example, a tie line might be of great advantage to an outlying system but of small value to the system in whose territory it lies, or the construction of a line by a different route or at a higher voltage might be of great future importance to the group as a whole but of no immediate value to the company operating in the territory to be crossed.

The conclusion to be drawn is that there will apparently be a great advantage in creating a common entity or organization, controlled by and working for the interest of the whole, which could properly undertake work that it would not be fair to ask any one company to undertake. The existence of such a unity would greatly facilitate interchange contracts for power. Indeed, it is difficult to see how the full benefit of interconnection can ever be established otherwise.

Second: My second point is to emphasize the necessity for looking ahead and planning a complete skeleton system for the future covering the full zone in conformity with which new installations can be made. Without this there will inevitably be much waste. For example a tie line laid out for an immediate interchange may be directly overbuilt by a higher voltage line a few years later.

If it turns out that single-circuit lines as proposed in my paper presented at the Birmingham convention are of advantage, the building of a two-circuit line may later require the addition of another line to reach some parallel point, which might have been reached by separating the original two-circuit line and running the circuits by different routes.

Again: The divided conductor has a very great theoretical advantage in a widespread interconnected system, both in increasing the capacity to balance lagging current and in reducing inductance to facilitate tie-line interchange of current. If this is to prove the best construction, the sooner this is determined the better.

The full importance of lagging current and wattless component is not generally realized. As long as the lagging could be cared for by running the generator at low power factor and lines were short, wattless current cost little. But with very long lines, wattless current must be largely eliminated at the receiving end and this must often be done by installing new machinery to carry wattless current kv-a.—a very expensive process. Therefore, the gain in charging current by dividing the line conductor may be more important in the future than it has been in the past.

It is not unlikely that very large sums of money may be saved in the next 15 years by proper planning ahead for the interconnection and this is particularly true in the zone treated by Mr. Mitchell.

Large Steam Turbine Generators

BY W. J. FOSTER

Review of the Subject.—*The authors discuss the manufacture of large steam turbine-driven generators touching on what is considered the best practises of the present day. A description of a 62,500-kv-a. 60-cycle generator is included together with test data. The fact is brought out that even on the largest generators yet built, moderate temperatures may be expected. The losses and ventilation problems involved in this type of apparatus are discussed, and predictions made as to the probable sizes at given speeds which may be expected in the future.*

* * * * *

THE power companies that generate and distribute power in the largest amounts have continually asked for larger and larger steam turbine units, with the result that 30,000-kw. units have become quite numerous. The design of the turbine and of the generator at every step to larger sizes involves distinct problems that in nearly all cases are worked out by two distinct groups of engineers. These two groups are in continual competition as to which can produce the larger machine at any given speed,—steam turbine or electric generator.

It is gratifying to the designer, the manufacturer and the user of the largest steam turbine generators that have been built, to find that they prove in service as good in practically every respect as the best of the older and much smaller units. The extremely large generators at the present time are possible, by reason of improvements in materials in both their electrical and mechanical properties, and improvements in details of construction that have in view the protection of the insulation against small movements that are produced by mechanical stresses and by changing temperatures. Progress is dependent, to a large extent, upon research work, improvements in construction and the development of better materials for any given purpose; for example, retaining bands of greater strength to hold the field coils in place at heads of the rotor, or steel laminations for stator cores of better characteristics in the matter of permeability or hysteresis and eddy current losses. Improvements in the mechanical strength of materials in the rotor permit of higher peripheral velocities. At the present time good practise is limited to speeds of about 25,000 feet per minute. Any discovery or development that would permit of an increase of 10 per cent would at once allow the possible size of unit to be increased approximately 33 per cent, since the possible largest size varies approximately as the cube of the peripheral speed.

Installations of several of the largest steam turbine-driven generators built in America have been made during the past year. They are 6-pole 62,500-kv-a. 0.8 power factor, 1200-rev. per min. self-ventilated units. The first of these put into operation is in the Hudson Avenue Power House of the Brooklyn Edison Company—see Fig. 1. Some idea of the size of these units may be obtained from the following weights: rotor 205,000 lb.; stator 205,000 lb.; shields, etc., 25,000 lb.; total, not including base, pedestals or bearings, 435,000 lb. There are some 41,250 lb. of copper in the machine. The stator has 37.6 miles of insulated wire, and the rotor 4.5 miles.

ROTOR

The rotors of the largest generators consist of steel forgings, many of them of a single forging, which serves as a through shaft with journals for the bearings, and machined to receive coupling at one end for connection to steam turbine, and at the other end for connection of direct connected exciter, if one is supplied; the main body of the forging serving as the field part of the magnetic circuit and machined to receive the field windings. The rotor of the 62,500-kv-a. 1200-rev. per min. generator consists of three forgings, the middle one a hollow cylinder.

One of the most interesting processes of machining in the shop is the milling of the slots in these large rotors. Fig. 2 shows two cutters at work at diametrically opposite points on a 4-pole rotor. A great amount of material must be removed by these cutters, especially in the case of a rotor for a 6-pole machine of as great as 62,500 kv-a. capacity. The cutters employed for this work have been developed to their present degree of perfection by little inventions from time to time during

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

the past few years, such as methods of securing cutter teeth in place and removing them quickly. At the same time great improvements have been made in the treatment of the steel used in the teeth. The result of all this improvement is that the quantity of material now removed in a given time is practically twice that of a few years ago; at the same time the cutters themselves

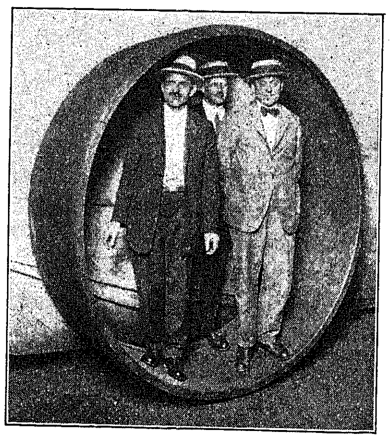

Fig. 3—Rotor Retaining Ring for 62,500-Kv-a., 1200-Rev. per Min. Generator, Ready for Expanding by Heat and Shrinking On

require much less attention, the cutter teeth remaining in fit condition a much longer time before sharpening is necessary.

The forming up of the field coils for such extremely large machines has been made possible by the development of special machines for winding the coils. The winding machine not only bends to a small radius the heavy copper strip on edge, but changes the pitch every turn, since the winding must be assembled turn by turn in radial slots.

The method of securing the windings against centrifugal force by metallic wedges driven into the dovetail grooves in the sides of the slot throughout the body as well as the retaining rings used at the heads of the rotor, remains practically the same as for many years but continual improvements have been made in small details. At the present time steel wedges are employed throughout the slot portion. These are of magnetic steel in the slots immediately adjacent to the pole center and of non-magnetic to prevent magnetic leakage in the outer slots of every pole. The retaining bands regularly used in these machines are of nickel steel, or a similar steel alloy, and are, consequently, of

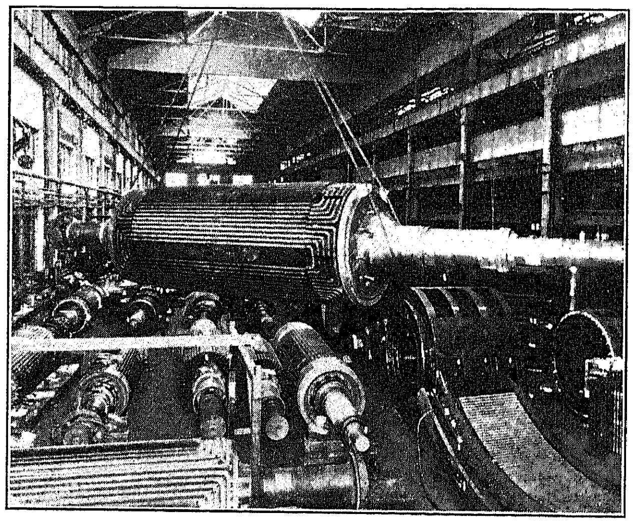

Fig. 4—Rotor of 62,500-Kv-a. 13,800-Volt, 60-Cycle, 1200 Rev. per Min. Steam Turbine Generator

35 ft. long, 205,000 pounds' weight, completely wound and supported from crane for transit through building to receive binding bands in shop where both stators and rotors are wound.

magnetic material. It would be desirable to have these retaining bands of non-magnetic material, if workable material were available that had sufficient strength. Fig. 3 shows the retaining ring or binding band for one end of one of the 62,500-kv-a. rotors. A good idea of the size of this ring can be formed from the fact that three men of average size are standing side by side inside the ring.

Some of the most important problems that have had to be worked out in connection with these machines is the securing in place of the insulation on the ends of the several field coils, as also the securing in place of the completely insulated coil so that the immense stresses of centrifugal force, as well as expansions and contractions of changing temperature will not injure the insulation or disturb the balance of the rotor. As shown in Fig. 5, the present method employed is the encasing of the insulated coils in metallic saddles.

These are made of aluminum. The blocking between coils is of the same material.

Stator

Fig. 6 shows a view of the frame of one of these machines. It is of the well-known fabricated structure,

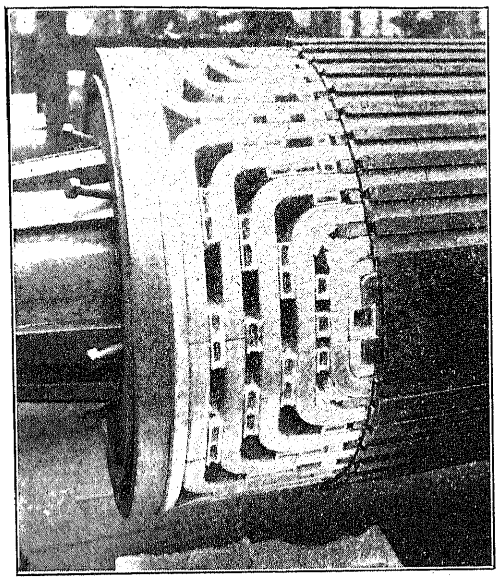

FIG. 5—VIEW OF END OF ROTOR OF A 35,300-KV-A. 1500 REV. PER MIN. STEAM TURBINE GENERATOR ROTOR

Ready for receiving retaining ring, showing field coils encased in aluminum saddles and mechanically supported by specially designed aluminum blocks.

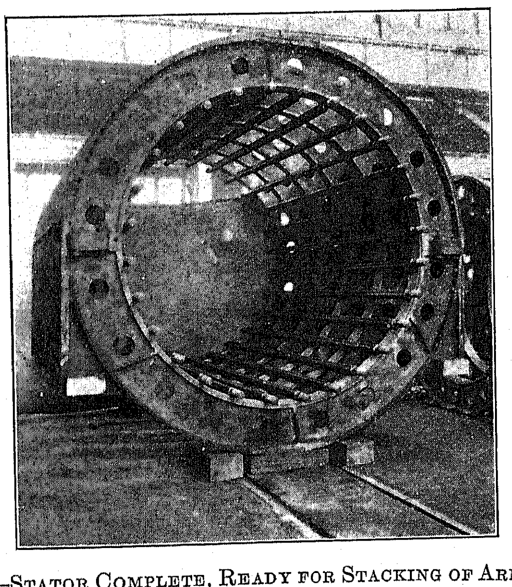

FIG. 6—STATOR COMPLETE, READY FOR STACKING OF ARMATURE CORE OF 62,500-KV-A., 1200-REV. PER MIN. GENERATOR

Showing multiplicity of ring castings tied together by boiler plate riveted to the outer periphery and by steel bars bolted to inner periphery that carry dovetail slots for assembly of laminations and threads at ends for assembly of clamping flanges and nuts.

which has been successfully used for a number of years. As clearly shown, the frame consists of six annular cast *I*-sections, which are held at the outer periphery by heavy boiler plate riveted to the flanges of the sections. This results in an unusually light and strong structure. There are twenty-eight rectangular steel bars bolted to the inner periphery of the *I*-sections. These bars serve a triple purpose; first, they add stiffness to the frame; second, they are slotted so as to receive the dovetail keys and punchings; third, the ends are turned down and threaded so they act as clamping bolts for the flanges which restrain the core at each end of the machine.

As to the winding, there are 126 coils, each having three turns of 85.8 per cent pitch. Each turn consists of sixteen asbestos insulated strands having a section of 0.21 in. by 0.085 in. Connected with six circuits per phase, a current density of 1521 amperes per square inch is obtained. These six circuits per phase are separated into two groups of three circuits each. Inasmuch as the insulation of the winding and connections was guaranteed to withstand a high potential test of 40,000 volts for one minute, extra insulation was applied. The total thickness of insulation from copper to slot wall is 0.280 in. This high potential test at 60 cycles was successfully applied, using a 300-kw. transformer and a separate generator for controlling the voltage. The charging current measured in the grounded side of the 40,000-volt circuit was 5.6 amperes for each of the three phases. This corresponds to 224 kv-a.

The coils and turns are insulated by hand with mica tape throughout their entire length. High thermal conductivity is secured and compact solid insulation is obtained free from entrapped air by subjecting the insulated hot coils more than once for many hours to a vacuum treatment followed each time by injections of a hot sealing compound under pressure.

Nine insulated leads, instead of the usual six, are brought out from the armature connections through the terminal board. Of the three leads per phase, one goes to neutral and one to each of the two groups of circuits mentioned above. This arrangement permits the insertion of the current transformers used with the balanced relay system of protection for generators, also the insertion of a differential current transformer at the line end of each phase of the winding. Normally, current passes equally through the double primary coils of the differential current transformer from the two halves of the divided generator phase winding. Any unbalance of the currents in the two groups of circuits per phase produces currents in the secondary which can be made to trip out the generator at any desired setting in this secondary circuit.

Temperatures and Methods of Determining Same

Searching tests have been made in the shops as well as on generators in commercial service to determine:

1—maximum observed temperature rise on the bare copper of the stator windings:

2—maximum observed temperature rise as commercially measured (between upper and lower coils in the slot) by

(a) 20 in. long, ⅛ in. wide resistance temperature detectors;

(b) 10 in. long, ¼ in. wide resistance temperature detectors;

(c) thermo-couple;

3—differences in temperature at different locations longitudinally in the slot of the commercially embedded detector;

More of these tests have been made on the 35,300-kv-a. 85 per cent power factor (30,000 kw.) generators of various voltages than on any other size. The most recent of these tests was on 13,200-volt machines, when, fortunately, a pair of them came through the shops at the same time and it was possible to run them at full load, zero power factor. Information gleaned from the data obtained, indicates,—

1—that on machines from 12,000 to 14,000 volts, the temperature of the bare copper is approximately 15 deg. greater than the temperature determined by the 20 in. long detector, as located between top and bottom coils in commercial machines, when the latter is from 55 deg. to 60 deg. above temperature of ingoing air;

2—temperatures determined by resistance detector and thermo-couple on bare copper are approximately identical. Temperatures determined by the 20 in. long detector, as located in commercial machines, is approximately the same as determined by thermo-couple;

3—the temperatures at the half-way location in slot are approximately 2 deg. lower than at the quarter-way, which indicates a trifle better ventilation at the half-way.

The actual temperature rises for these 13,200-volt generators, with full-load current, were 48 deg. cent., as determined by 20 in. resistance temperature detector in stator slot, and 72 deg. cent. in rotor winding, as determined by resistance when operating with leading current and, consequently, greater excitation than required for 85 per cent power factor, full load output.

Tests on 62,500-kv-a. Generator

The results of the tests made under actual load on the 62,500-kv-a. generator of the Brooklyn Edison Company are here given in the form of curves:

Fig. 7 shows generator under test equipped with a tall stack for the purpose of determining the quantity of air flowing through the machine. The tests consisted in a series of runs following one upon the other until constant temperature was attained; 1st, at normal speed without excitation; 2nd—at normal speed, no-load, 13,800 volts (the rated voltage); 3rd, at ¼ load; 4th, at ½ load; 5th, at ¾ load and 6th, at full load. Owing to the conditions of the system into which the generator was feeding, the potential at generator terminals increased with load and attained 14,350 volts at the full 62,500 kv-a. The power factor was slightly less than 80 per cent.

The losses were determined from the quantity of air and the temperature rise of the air at the various conditions. The quantity of air was 112,500 cubic feet per minute.

Ventilation

The ventilation of these large machines follows the well-known multi-path radial system used so successfully on generators of this type since 1913. Air is drawn in at each end of the machine through converging ducts formed by the end bells. Its pressure is elevated by multivane fans attached to each end of the rotor. These fans are so constructed that the air stream at each end of the machine is split into two parts, the inner section of fan feeding directly into the air-gap and thence radially out through the ½-in. air ducts with which the core is supplied. The air from the outer section of the fan is carried through sheet iron ducts to a center compartment in the machine, whence it flows radially inward to the air-gap, thence axially along the air-gap until it meets the first stream of air from the inner fan, whence it flows radially outward through the air-ducts. These two air streams are separated at the fan by a third, or inner shield, which also acts as a diffusing ring for the air which passes through the outer fan. See Fig. 11. This system of keeping the two air streams separate has shown better results than when the air is allowed to exhaust into a common chamber and seek its own distribution path through the generator. This is due in part to the diffusing effect of the inner ring and, second, to the characteristics of the fans themselves. On machines of this size it is sufficient to have only two multiple paths. In machines of greater length, or smaller diameter, it is necessary to resort to a larger number of multiple paths through the core. The decision as to the number of multiple paths that shall be used will depend on the velocities in the air-gap and through the air-ducts. A large number of multiple paths will result in a high air-duct velocity and low air-gap velocity, with poor cooling for the rotor and maximum cooling for the stator. Few multiple paths result in low air-duct velocity and maximum rotor cooling. The ideal distribution then would be one in which the air-gap was kept running full of cool air and the air-duct velocity in the neighborhood of 4000 to 6000 feet per minute. Beyond this point the pressure drop to force the air through is greater than the gain in cooling and, therefore, undesirable. In very long machines, where the limit of mechanical possibilities has been strained, the ability to take all of the air into the ends of the machine becomes extremely difficult. When such conditions are met it seems desirable to do away with fans on the rotor and resort to external blowers. The adoption of external blowers has never been viewed with much favor by the operating engineers, due to the fact that it means another auxiliary added to the already overburdened list, and, second, due to a feeling on the part of most operators that the external blower as now built is not as reliable as fans attached to the rotor. These considerations have in the past more than outweighed the advantage of the higher efficiency which was to be

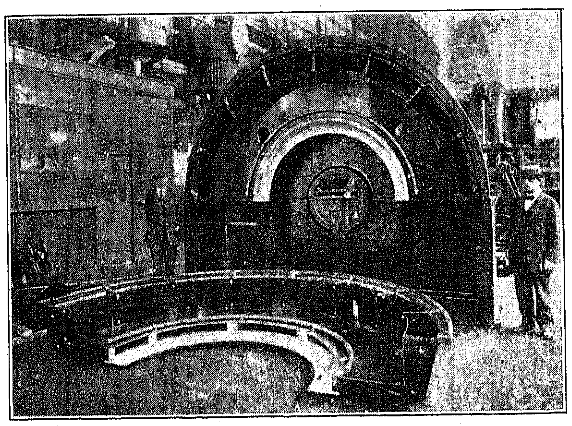

Fig. 11—One of the End Shields or Ventilation Housings for 62,500-Kv-a. 1200-Rev. per Min. Generator Showing in Foreground Upper Half Inner Shield Attached to Outer Shield, with Fire Protection Pipe at Inner Circumference

expected in the slow-speed blower. With the advent of the closed circuit system of ventilation in which the air is recirculated, the losses being removed by surface coolers, new possibilities are introduced which make the consideration of external blowers at this time quite pertinent.

Owing to the limited space, the high peripheral speeds, and the difficulty of recovering the velocity head of air leaving the fan, the design of fans attached to the rotors of large turbine generators becomes difficult

and results in a fan of rather low efficiency. Since the air passes through these fans before entering the generator, the losses of fans are absorbed by the air, which results in the air entering the generator at some 5 deg. or 6 deg. higher temperature than would be the case if the fan losses were not absorbed. When it is considered that the total rise of air through the generator is only 20 deg. to 25 deg., the large sacrifice which must be made to supply sufficient air for ventilation and the handicap which is placed on the generator in the matter of temperatures are at once apparent. If, on the other hand, an external blower is used on a recirculating system, and the blower is mounted ahead of the surface coolers, the temperature of the air entering the generator will be practically that of the air leaving the coolers, and the temperature of the generator, both stator and rotor, will be lower by the amount of heat which would have been absorbed in the air due to the fan losses. A second advantage of the external blower lies in the higher efficiency which it is possible to obtain. The question of reliability of these blowers is one which should not offer any serious obstacles when it is clearly known what the service requirements are.

General

The space for windings in the rotors of all steam turbine generators is limited by the high centrifugal forces. On the other hand, if the stator winding is correctly designed to be free from eddy currents, and slots of ample dimensions are provided, any desired low temperature of the windings may be secured when properly ventilated and insulated by materials of high thermal conductivity; hence, in so far as temperatures are concerned, the permissible electrical power output of a turbine generator need not be limited by the stator winding; provided the electrical stability is maintained, voltage regulation is commercially acceptable and the rating is maintained for which it is designed.

Although it may be said that no well-designed machine should be actually limited by any one element and in keeping with the principles of economy that the stator should be decreased until a balance is reached with the rotor, nevertheless, a certain freedom in design of the stator exists as to the control of losses and temperatures wherein no hard and fast boundary defines what is absolutely safe.

It will be impossible to include here any extended description of stator windings and the several methods which are now being used to partially or completely eliminate the circulating currents in the coils.

The stator conductors of either the bar or coil type consist of many thin rectangular strips of copper insulated by cotton or asbestos. Using a thin strand obtains small strand loss; the segregation of the strands permits the carrying out of the following methods of reducing the circulating current loss to a low value:

(a) Use of stranding continuously through two or more coils;

(b) Use of a total depth of copper in the slot, less than would be used if the d-c. resistance alone was considered;

(c) Use of a large number of circuits and turns per coil;

(d) Use of a two-turn coil turned over at one end only;

(e) Use of a twisted conductor;

(f) Use of coils having conductors segregated into groups and the groups carried separately through two or more coils by proper transpositions.

Losses

Fig. 8 shows the efficiencies of this generator at various power factors. Values upon which the efficiencies are based are made up of the well-known losses, such as friction and windage, core loss, $I^2 R$ of the armature and rotor, and also of certain losses which for a better term, and because they are usually associated with the loading of a machine, are called "load losses." It is not the purpose of this paper to go at any length into the source and magnitude of these last losses; the field is large enough to form the subject of a paper by itself. It is enough here to mention that losses do exist in all of what might be termed the inactive magnetic parts, as well as the active magnetic parts of the machine, and that these losses are of sufficient magnitude to have an effect on the efficiency of the machine. Under the heading of inactive magnetic parts might be classed the clamping flanges, the air shields, the dovetail ribs, frame, etc. Under the active magnetic parts might be classed the rotor core surface, retaining wedges, retaining rings, etc. The difficulties of actually determining magnitude and source of loss in these various parts, on, say, a 30,000-kw. machine, are so great, due to the difficulty in handling such enormous amounts of power, that the idea was conceived of building turbine-type generators in miniature and carrying out investigations on these little machines. Accordingly, two little machines were built which are in every essential detail an exact reproduction of the large machines, reduced in scale to one-third size, and, hence, in capacity to one-twenty-seventh. It is gratifying to record that the percentage losses shown by these little machines were in exact percentage agreement with the large machines. This does not include the $I^2 R$ of the copper, which is excessive. By substituting wood for the various inactive parts, such as shield, flanges, end fingers, etc., the magnitude of the losses in these various parts has been fairly accurately determined. The steel end rings, which retain the end windings of the rotor coils, have for sometime been under suspicion as being the source of considerable loss, although complete data are not available on these parts. Tests on the miniature generators revealed the fact that while there is magnetic field set up by the end turns of the armature winding, which rotates in synchronism with the end bells on the

rotor and, therefore, causes no loss, there is also a high-frequency harmonic flux which occasions a considerable loss in the end structure. These harmonic fluxes are probably associated with certain pitches of the armature winding and are worse with some pitches than with others. However, no exact data are available on this point. A very interesting feature in connection with these losses is that they bear a relation to the magnetic loading of the field. The armature end turns set up a magnetic circuit which interlinks the rotor end structure with the inactive magnetic, and a portion of the magnetic parts of the stator. Under conditions of sustained short-circuit, or of a leading power factor on the machine, under both of which conditions the magnetic loading of the rotor is small, the flux leakage paths are completely dominated by ampere-turns of the armature and windings, and the losses are large. Under conditions where the machine is loaded, or where the power factor is lagging, the end turns of the rotor establish a counter m. m. f. which greatly changes both the direction and magnitude of the end flux leakage and this results in much lower losses and heating.

The data that have been and are being taken on this subject lead us to hope that at no distant time the uncertainty regarding the losses at heads of machines will be done away with and that machines of even higher efficiency than at present will be built.

As intimated above, it may be stated that the temperature rise of the rotor winding is greater than

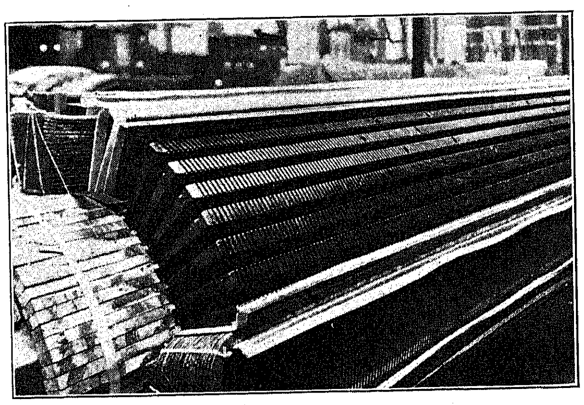

Fig. 12—Partially Wound Rotor of 31,250-Kv-a. Steam Turbine Generator Showing Circumferential Grooves in Solid Forged Rotor to Improve Ventilation and Reduce Pole Face Losses

it would be from the losses of the exciting current alone and the efficiency of the generator is reduced by the following additional losses of the rotor.

1. Friction of the rotor surface upon the cooling air.
2. Eddy currents at stator tooth frequency in the skin surface of the rotor steel. These are dependent upon the variable permeance of the slotted inner periphery of the stator core and the zigzag flux leakage to and from the rotor caused by the distribution of the m. m. f. in the stator slots.

It is now the general practise to groove the surface of the rotor body, see Fig. 12, and thereby secure lower temperature rises of the field winding and higher efficiency. Grooving of the surface with a coarse thread increases the cooling surface, reduces slightly the flow of air, and increases the turbulency of the cooling air in the air-gap. It also increases the resistance to flow of high-frequency eddy currents, thus improving efficiency as well as reducing temperature. In all cases when tested it has been found that grooving has been beneficial.

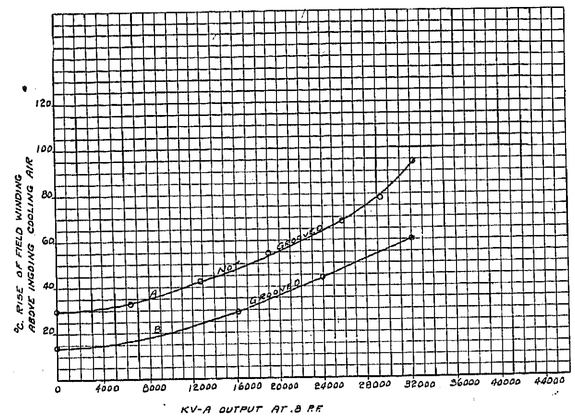

Fig. 13—Reduction in Temperature of Field Winding of 31,250-Kv-a. 13,200-Volt Generator Obtained by Grooving Rotor

An exceptional case of the improvement which has been registered by the grooving of the rotors is seen by observing in Fig. 13 the difference in temperature rises secured during tests upon two rotors identical in all respects except that one was grooved, the other not.

The tests determined the following:

1. The grooved rotor obtained a temperature rise of 58 deg. cent. at closely full-rated load as compared with a rise of 88 deg. cent. for the similar ungrooved rotor. A second grooved rotor tested in the same stator as the ungrooved rotor just mentioned obtained a temperature rise of 53 deg. cent. upon the field winding.
2. The core loss was reduced.
3. The rate of air flow before grooving was 69,200 cu. ft. per min. This was reduced to 54,000 cu. ft. per min. by grooving.
4. The stator was slightly reduced in temperature.
5. The efficiency was greatly improved.
6. The customer has had a third rotor grooved, tests upon which have not yet been made.

Fire Protection. It is particularly important, in connection with large totally enclosed generators, that they be equipped with protection against fire. Differential relay protection should be provided in order that excitation may be removed and the unit disconnected from the system in case of a break through the insulation. The differential relay protection is useful only in connection with dielectric failures. It sometimes happens that fire starts on the surface of the

insulation, without any electrical failure of the insulation. The exact causes of these fires are not always known but they are liable to occur under certain conditions, such as the accumulations of dirt, consisting of carbonized and other highly inflammable material. They are probably started by a spark resulting from some switching operation or sudden heavy short-circuit on the line. Such surface fires are hardly known, except in connection with large totally enclosed machines. It is possible in some cases to discover the presence of fire by means of smoke in the air discharge pipe, in which case it is usually best to immediately remove excitation, shut unit down and make examination. However, all large generators should be provided with equipment to put out fire, whether started by dielectric failure or on the surface of insulation by static spark or spark of any kind. It has become customary to equip these machines with pipes at both ends in proximity to the end windings, and with outlets so placed as to direct steam, water, or whatever agent is employed, in the most effective manner for putting out the fire. Steam and water are the agents that have been generally employed, although carbon dioxide gas has been installed in a few cases. The use of an inert gas, such as carbon dioxide, has a certain advantage over the use of steam or water, in that it causes no temporary or permanent injury to the insulation; furthermore, the operator who suspects a fire, will not wait so long to persuade himself that action must be taken if it is a matter of turning on the inert gas, as he would to turn on steam or water. Undoubtedly, the system of ventilation now coming rapidly into vogue, of recirculating the same air and carrying off the heat by water-coolers, has a decided advantage in the matter of fighting fire, since the oxygen in the air becomes rapidly exhausted and the products of combustion serve as a fire extinguisher. Tests that have been made indicate that a 25 per cent saturation of carbon dioxide is ample to put out a fire. This system of ventilation prevents the accumulation of dirt, etc., and thus does away with surface fires.

Operating Conditions. The handling of the rotor by operators is of extreme importance. Probably everyone will concur in the statement that the ideal condition to maintain in large generator rotors is a constant temperature of such magnitude as 90 deg. or 100 deg. This is not possible, but efforts should be made to maintain temperatures that vary within as small a range as possible.

The distributed field winding assembled in numerous slots and secured against centrifugal force by metallic wedges in the slots, and by metallic binding bands at the heads, is peculiarly susceptible to deterioration if temperatures within the winding change frequently and through a wide range. To appreciate this, it is only necessary to consider the nature of the structure. There are three different materials, one of them a more or less intricate compound, that are subjected to the changing temperatures, and each of the materials has a temperature coefficient of its own quite different from that of the others. The temperature coefficient of the copper is the highest and about one and one-half times that of the steel in which it is embedded, and approximately two times that of the insulation that stands intermediate between copper and steel. To intensify these differences, the copper itself is always subjected to a much wider range in temperature than either the insulation or the rotor body proper, and to a quicker response to changing load. Common practise points to temperature rises in the copper of about 85 deg. cent. above the cooling medium, as the proper range to allow between the no-load starting and the full-load constant running conditions. By simple arithmetical applications of the formula for change of volume, due to temperature coefficient, we find the length of the field conductor in a 10-foot long slot for a quick 85 deg. change, to become $\frac{1}{8}$ in. greater than the length of the envelope of insulation (except as the insulation stretches to accommodate itself to the pulling action of the coil) and 1/12 in. greater than the slot itself, in which the insulated coil is embedded. Undoubtedly, improved methods of forming up the insulation and of holding the winding against centrifugal force allow these movements to take place with very little deterioration, but it is greatly to be desired on the part of the operating people, that the variations in temperature be kept from exceeding 85 deg. cent.

A condition of operation to be avoided is that where the rotor is allowed, if the turbine is shut down, to reach a temperature approximating that of out-of-doors in our temperate climates during the cold season. Undoubtedly cases have existed in the near past, and probably at the present time, where the rotor temperature gets down to 0 deg. cent. after an overnight shut-down. If in such case the turbine is started up and loaded, and for reasons of personal comfort to operators the station air is used, the cooling air temperature will soon attain something like 25 deg. cent., and if for any reason an overload in kilowatts for short period is desired, or an unusual demand for power factor correction arises, requiring excitation amperes to be increased as much as 10 per cent over that stamped on the nameplate, the rotor temperatures may readily attain 135 deg. cent. In such case the unequal expansions of the various materials of the rotor that may occur within a few hours, undoubtedly exert mechanical strains that come with tremendous force on the insulation and must, when repeated often enough, result in disintegration. It is, therefore, strongly recommended to all operators of large steam turbine units, that they make a study of how to maintain the best conditions in the matter of temperature change in the rotor windings.

It is to be recommended:

1. that overloads in excitation be avoided;
2. that such arrangements of ventilation be adopted

as will permit as little cooling down of rotor when at rest as possible, and on no occasion permit the entrance direct of outdoor air;

3. that a practise be established of determining temperature of field winding at stated intervals by observing volts at collector rings and comparing it with that obtained at same load conditions when generator was first put into service;

4. that insulation resistance be measured at the same stated intervals;

5. if for any reason at any time the rotor at rest has become very cold, run it at low speed with excitation sufficient to bring temperature up to about 75 deg. cent. in about one-half hour before raising speed to normal.

Possible Future Units. The possible size of a generator at any speed is limited if the designer produces a "stiff shaft" machine; by this we mean a generator whose rotor at normal speed operates below the critical speed. Assuming adherence to this practise, and to the same type of ventilation at the several speeds, *viz.*, whether by means of self-contained fans or external blowers, the possible size at the several speeds varies inversely as the square of the speed; thus, for 60-cycle generators, 8000-kw. (10,000 kv-a.) at 3600 rev. per min., corresponds to 32,000 kw. (40,000 kv-a.) at 1800 rev. per min. and to 72,000 kw. (90,000 kv-a.) at 1200 rev. per min. The largest sizes at all these speeds should be of high voltage, say 10,000 to 14,000, to permit of the use of a sufficient number of slots and have designs that will not result in too large amperage per slot.

In the matter of size as related to ventilation adopted, it can be greatly increased by the use of external blowers, since the number of multiple paths can be increased and valuable space saved between the rotor proper and the bearings at the two ends, space otherwise occupied by the fans and the chambers below and beyond them for the ingoing air. At the present moment 62,500-kv-a., 14,000-volt 60-cycle generators are being built at 1800 rev. per min. and 60,000-kw. 11,000-volt 25-cycle generators at 1500 rev. per min.

Discussion

A. M. Rossman: The built-up rotor construction which Mr. Foster describes is interesting to us because of an experience which we have had within the last two or three months with a solid forged rotor.

A machine had been operating down in Texas for eight or ten years. The rotor winding had gone bad and the rotor was sent to the factory for rewinding. The factory examined it and found a crack in the rotor which extended two-thirds around the circumference, and rendered it unfit for going back into service. We then split it and found that the only good metal left consisted of a skin of metal about 1/8 in. or 1/4 in. thick on one side and, on the other side, a small wedge 2 in. or 3 in. in thickness extending from the center to the outer surface. How that machine continued to operate with the rotor in that condition is a mystery.

Going into the history of this rotor we discovered that it had been made in Germany and shipped to this country just before the war began. It had an exploring hole drilled from end to end and the factory records showed that a small crack from shrinkage had been detected. They did not, at that time, attach the significance to that small crack that they should have. Now, I understand, such a forging would be rejected. In the built-up rotor described by Mr. Foster such a crack could not easily develop.

Another point is this question of low temperatures. We are very glad, indeed, to see progress made toward cutting down the high temperatures. The earlier machines used to give considerable difficulty. The copper would expand when it was hot and shrink when it was cold, and before we knew it, the insulation had separated from the copper and was bowing out in the ventilation slots; the next thing we had a break-down and the machine would have to be rewound. Low temperature means low expansion and a lessening of mechanical troubles.

C. M. Gilt: The maximum size of turbo-generators has increased in a series of steps with periods of several years intervening in which the size has remained fairly constant. Recently another step has been taken, beginning with the 62,500 kv-a. units for Brooklyn and followed by machines of even larger capacity.

The amount of power developed by, and the money invested in, one of these large units is so great that the problem of adequately protecting it against damage, and of limiting the extent of the damage should a failure occur, is presented with increased force. The older practise of tying generators to the bus without any automatic protection against internal failure has been replaced by a scheme of differential protection of the windings. The method of balancing one end of each phase winding against the other is serviceable in case of a phase-to-phase short circuit, or phase-to ground when the unit is on a grounded system, but will not operate on a turn-to-turn short circuit within the same winding until the damage has spread far enough to develop into a ground or a phase-to-phase short-circuit.

As a further protection the groups of parallel windings within the same phase windings of the Brooklyn machines have been balanced against each other with cross-connected current transformers. This method of protection loses its sensitivity when the number of turns per phase is large for the circulating current sent around the closed loop by the unbalance of the voltage in the parallel paths is a small portion of the total current of each path.

We are considering a somewhat different method of balancing the windings of one of the machines on the system and from such studies as have been made it appears to have some advantages. The method consists in tying together the parallel windings at equipotential points at approximately the middle of the winding and inserting a current transformer and relay in the tie. Normally no current should flow across this tie and the current transformer can, therefore, be built of a size to give the best relay operation. In case of a turn-to-turn short circuit, a ground or a phase-to-phase short circuit occurring in the windings between the ends where they are joined together, a current will flow across the mid-point connection and cause relay operation. The advantage of this method over the scheme of balancing the windings with cross-connected current transformers lies in the fact that the relay operates directly on the cross flow of current and not on a small difference between two large currents. The disadvantage lies in the additional number of leads that must be brought out of the machine and the taps made at the mid-points. The additional leads brought out need not be full capacity, but built only to withstand possible short-circuit currents. While the scheme appears to be selective, there may be difficulty in picking out points on some machines as actually built so that the cross flow of current under all conditions of load and external short circuit will be enough smaller than that which would occur in case of a turn-to-turn short circuit to give posi-

tively selective relaying. This difficulty, however, applies with equal force to the other method of balancing.

We agree with the authors of the paper in favoring a closed system of ventilation for these large machines. Not only is it more effective than an air washer in keeping the machine clean, but we believe has also a decided advantage in case of a fire. The oxygen within such a system will not sustain combustion very long. In addition a gaseous extinguisher, such as carbon dioxide, can be used effectively within a confined space.

We are naturally keenly interested in the development of these large machines, their protection and operation. We believe that there is a real place for them on the larger systems and hope to see them perform creditably.

E. H. Freiburghouse: While it is possible, as Mr. Rossman points out, to inspect thoroughly the cylindrical body and stub ends of a rotor such as has been employed in this 62,500-kv-a. generator at Brooklyn, nevertheless, very rigid sensitive tests are made by which forging faults may be detected and located throughout the interior of the one-piece solid forged rotors.

It has been our practise for many years to use a solid forged steel rotating element having radial slots machined in it to receive the windings. The reliability of the solid forged rotor has been demonstrated by the successful operation of over 1000 units ranging in capacity from 2500 to 62,500 kv-a. and rotative speeds from 1200 to 3600 rev. per min.

No failures chargeable directly or indirectly to forging faults have occurred during operation either in the factory or in service. This is also true of the nickel-steel forged rings which support the end portions of the rotor winding.

Three inspections are made of the interior of the forging, the first being at the forge shop.

The number of rotor forgings rejected from all causes has been less than 2 per cent of the total number received to date.

The scheme of protection mentioned by Mr. Gilt for obtaining protection against internal faults, such as short-circuited turns, has been considered and seems to have desirable features, but to the writer's knowledge has never been applied.

Heating of Large Steel-Cored Aluminum Conductors

BY R. J. C. WOOD

Associate, A. I. E. E.

Southern California Edison Co., Los Angeles, Cal.

STUDIES of the most economical size of conductor for the Southern California Edison Company's third 220-kv. transmission line from Big Creek to near Los Angeles led to the choice of either a 1,033,500-cir. mil aluminum steel core or the equivalent 650,000-cir. mil copper cable.

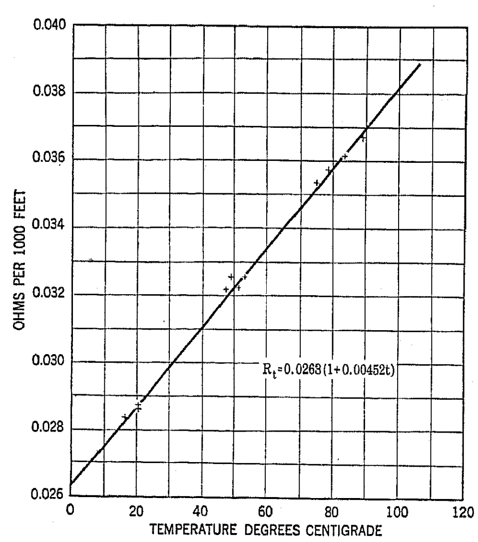

FIG. 1—TEMPERATURE COEFFICIENT OF RESISTANCE 605,000-CIR. MIL ALUMINUM STEEL CORE CABLE

The normal full-load current in this conductor will be about 450 amperes and when a fourth line is put into service, paralleled and cross-connected with the third circuit, it appears probable that sections of the line may be required to carry 900 amperes continuously over periods of time.

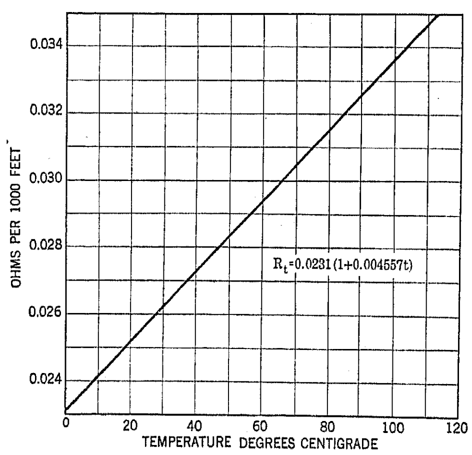

FIG. 2—TEMPERATURE COEFFICIENT OF RESISTANCE 666,000-CIR. MIL ALUMINUM STEEL CORE CABLE

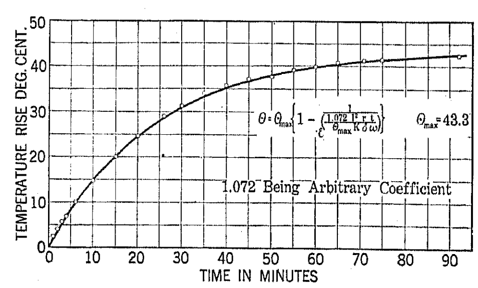

FIG. 3—HEATING CURVE OF 666,000-CIR. MIL CABLE CARRYING 602 AMPERES

The temperature rise of such cables carrying these large currents might prove to be a limitation which

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

would have to be considered, not on account of fusing or burning, but because of the expansion and consequent increased sag in the transmission line which might reduce clearances unduly.

The rulings of the California State Railroad Commission require, at 130 deg. fahr. a minimum clearance to ground of 30 ft. over territory susceptible of cultivation and accessible to vehicles, and over highways and railroads. This provides an ample margin, but special cases occur, such as crossing other circuits either of the same or other companies' systems where insufficient clearances might be allowed, if the reduction in

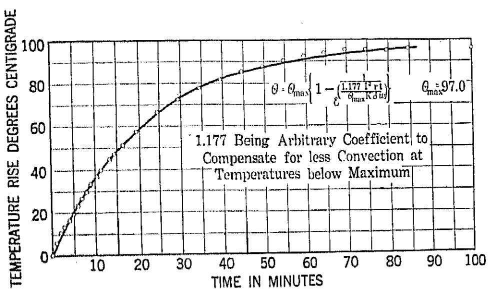

FIG. 4—HEATING CURVE OF 666,000-CIR. MIL CABLE CARRYING 900 AMPERES

them, due to conductor heating, were not taken into consideration.

A series of tests was therefore made to determine the temperature rise, both in still air and in wind, of three sizes of aluminum steel-cored cable; tests upon copper to be made at a future date.

The first tests were upon new clean cable of 666,000 cir. mils.

Afterwards, a sample of 605,000-cir. mil cable cut from the Big Creek transmission line was tested. This cable had become coated with a hard, smooth, black

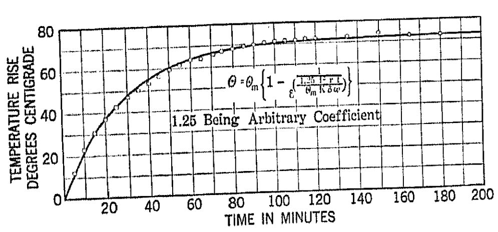

FIG. 5—HEATING CURVE OF 1,033,000-CIR. MIL CABLE CARRYING 1029 AMPERES

deposit which forms on the conductor at high voltages by electric precipitation from the air. This coating can only be removed with difficulty even by scraping; incidentally it reduces corona loss, probably by reason of the mechanical smoothness imparted to the conductor.

Finally, the heating of new clean 1,033,500-cir. mil cable was determined. It should be noted that these sizes as here given do not include the steel core.

The tests were made indoors in the corner of a large room remote from doors and windows. A length of about 20 ft. of cable was suspended so that about six feet was horizontal at a height of seven feet above the floor and six feet below the ceiling; the ends of the cable were brought around to the supply transformer furnishing 50-cycle low-voltage current. The loop of cable thus formed an oval about nine by six feet, its plane inclined to the vertical, to prevent heated air rising into the upper portion.

Attempts were first made to measure temperatures with thermometers, but these were abandoned in favor of a copper-constantin thermocouple having its hot junction placed in the second layer of stranding of the cable, counting from the outside. The cold junction was similarly embedded in a 24-in. length of cable suspended 12 in. below the horizontal portion of the cable under test. This arrangement gave consistent results, measured the temperature rise directly, and was sensitive to 1 deg. cent; stem effect or conduction of heat by the thermocouple wires was practically eliminated by wrapping them once round the circumference of the cable, insulated from it by a single layer of thin paper continued once around outside the thermocouple wires and bound in place.

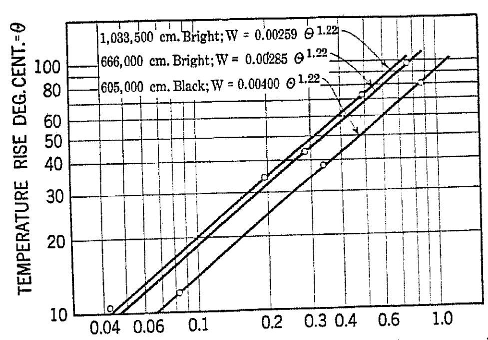

FIG. 6—HEAT DISSIPATED IN WATTS PER SQUARE INCH OF SURFACE

The final temperature rise resulting from different amounts of current was determined, as well as the rate of heating from the time the current was first turned on until a steady temperature was reached, this requiring from 1.5 to 2 hours. From these observed results the watts dissipated per square inch of surface were calculated, the surface being considered as that of a cylinder of diameter equal to the maximum outside diameter of the cable. The rate of heat emission per degree of temperature rise increases with temperature difference as shown in Fig. 6. As might be expected, the black coating referred to above increases the rate of heat emission.

The observed results differ materially from the data published by George E. Luke in the *Electric Journal*, Apr., 1923. Luke found that the temperature rise was practically proportional to the watts dissipated and that the color and nature of the surface had but little effect upon the specific rate of heat dissipation, whereas in our experiments the rate of heat dissipation was found to be about 66 per cent more at 100 deg. cent.

rise than at 10 deg. cent. rise and to increase 17 per cent even between 30 deg. cent. and 60 deg. cent. temperature rise. Blackened aluminum cable dissipated 40 per cent more energy than bright cable with equal temperature rise. It is not to be expected that Luke's curves for the temperature rise of aluminum cables would agree closely with observations made upon steel-cored cable, as the latter has a relatively larger surface.

TABLE I
CONSTANTS OF CABLES

Nominal Size Cir. Mils	Aluminum Cir. Mils	Steel Cir. Mils	Total Cir. Mils	Weight Al.	1000 ft. Steel	No. of Strands Al.	No. of Strands Steel	Dia. of Cable Inches
605,000	605,000	78,000	683,000	568	211	54	7	0.954
666,000	666,000	86,000	752,000	626	232	54	7	1.000
1,033,500	1,033,500	134,000	1,167,500	971	353	54	7	1.247

Wind was produced horizontally by from one to three 12-in. desk fans appropriately placed so as to distribute the air current as evenly as possible, the velocity of the wind was measured by an anemometer calibrated during the tests. This artificial wind differs from natural winds in being very much more constant and in lacking the gusts and eddies of nature, but since the additional emissivity due to wind is approximately a linear function of velocity over a considerable range, the cooling effect as determined should agree with that produced by natural winds of the same average velocities.

TABLE II
OBSERVED DATA, HEATING OF CABLES

Size cm. Nominal	Surface	Wind ft/min.	Current Amps.	Temp. Rise Deg. Cent.	Temp. of Cable Deg. Cent.	Ohms per 1000 ft.	Watts per Sq. In.

"	"	300	900	34.8	53.8	0.02877	0.6180
1,033,500	Bright	0	338	10.5	36.1	0.01751	0.04259
"	"	0	690	34.3	60.4	0.01915	0.1940
"	"	0	1029	72.6	98.7	0.02175	0.4903

When it comes to the application of the results to transmission line design, the effect of wind in cooling the conductor is of great importance, even an almost imperceptible breeze of 0.2 miles per hour has a very marked cooling effect. More information is needed upon the minimum air velocities that may be coincident with maximum air temperatures in different localities.

From the data, empirical equations were obtained for the watts lost per square inch of surface, both clean and black, and for the additional convection losses due to wind, and it is believed that these equations are reliable for engineering purposes within the range of sizes covered by the experiments, and may be used without probability of material error between the limits of 500,000 to 2,000,000-cm. cables.

Resistance measurements were made by drop of potential method at different temperatures as the cable cooled naturally after a heat run. The temperature coefficient of resistance calculated from this data is slightly higher than previously published; a probable explanation is that when heated the aluminum stranding, expanding more than the steel core, loosens somewhat, decreasing the contact pressure between strands and layers. In a suspended conductor under considerable tension this effect will be less or absent. In order to be on the safe side, the coefficient as found was used in the derived equations.

In Figs. 3, 4 and 5 are shown the observed rate of heating compared with an equation of rational form but containing an empirical coefficient.

It may be shown that when

I = current in amperes
r = resistance in ohms of unit length
a = temperature coefficient of resistance
U = coefficient of heat emission from surface
t = time
O = temperature rise above air
K = heat equivalent in watt seconds
σ = specific heat of cable
w = weight of cable per unit length

$$\text{Then } \theta = \frac{B}{A}\left\{1 - \frac{1}{e^{At}}\right\}$$

and the final temperature rise after a long time is

$$\theta_m = \frac{B}{A}$$

$$\text{So that } \theta = \theta_m \left\{1 - \frac{1}{e^{At}}\right\} \qquad (1)$$

$$\text{where } A = \frac{U - a\,I^2\,r}{K\,\sigma\,\omega}$$

$$B = \frac{I^2\,r}{K\,\sigma\,\omega}$$

always provided that U does not vary with θ. As a matter of fact U does vary with θ as is shown in Fig. 6.

It will be noted that the observations as plotted indicate quite consistently an exponential relation between temperature rise and watts dissipated and that within the limits of expected error the value of the exponent is the same for all three cables, including both bright and black surfaces.

The substitution of the equation for U in the differential equation of temperature rise leads to an unwieldy integral. The heating curve for bright cable may be closely approximated, however, by the equation

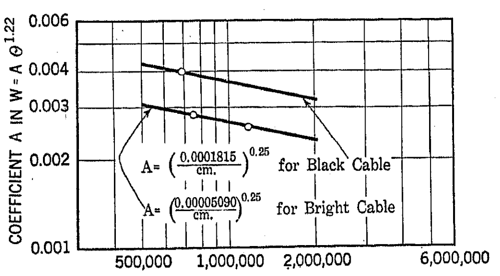

FIG. 7—COEFFICIENT OF HEAT DISSIPATED AS A FUNCTION OF THE SIZE OF THE CABLE

$$\theta = \theta_m \left\{ 1 - \frac{1}{e^{\left\{ \frac{I^2 r t}{[1 - (.0043\, I)^2]\, \theta_m k \sigma \omega} \right\}}} \right\} \qquad (2)$$

this is the equation of the solid lines in Figs. 3, 4 and 5, and is of the same form as equation (1) when

$$A = \frac{I^2 r}{[1 - (.00043\, I)^2]\, \theta_m K \sigma \omega}$$

The agreement with the observed rate of temperature rise is sufficiently good for practical purposes. The number of different sizes of cable used is, of course, much too few to establish a law connecting size with coefficient of heat emission, but the nature of the phenomena suggests an exponential equation which cannot be greatly in error within reasonable limits since the change in emission is small over a large range in cable size. In Luke's paper, above referred to, this matter is considered much more fully, and a curve of dissipation constant and cable diameter is given. This curve is an exponential one lending strong support to the assumption as to the form of the curve.

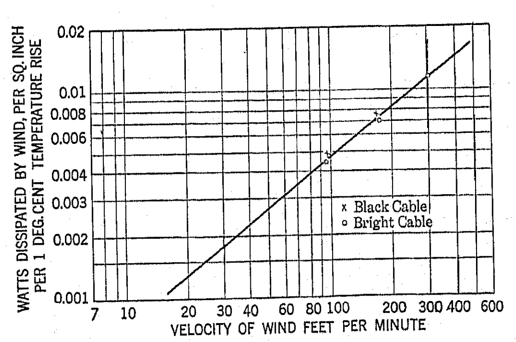

FIG. 8—HEAT DISSIPATED BY WIND IN WATTS PER SQUARE INCH PER DEGREE TEMPERATURE DIFFERENCE

Only one size of blackened cable was obtainable and it is assumed tentatively that the curves for black and bright cables are parallel, which is the same thing as assuming that the ratio of the dissipation constants of bright and black cables of the same size shall be constant and independent of their absolute size.

Fig. 7 shows how the heat emission varies with the size of the cable which is here given, including the area of the steel core. The equation of loss is

$$W_s = \left\{ \frac{0.00005090}{\text{cir. mils}} \right\}^{0.25} \theta^{1.22} \text{ for bright cable} \qquad (3)$$

$$W_s = \left\{ \frac{0.0001815}{\text{cir. mils}} \right\}^{0.25} \theta^{1.22} \text{ for black cable} \qquad (4)$$

where W_s = watts dissipated per square inch of surface. To obtain watts per square inch per 1 deg. cent. the exponent of θ will be 0.22.

The effect of wind is given in Fig. 8 and Table III.

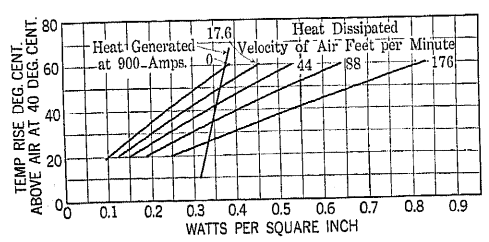

FIG. 9—HEAT DISSIPATED IN STILL AND MOVING AIR FROM BRIGHT 1,033,500-CIR. MIL CABLE, AND HEAT GENERATED AT 900 AMPERES.

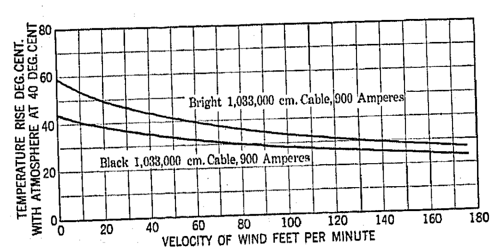

FIG. 10—FINAL TEMPERATURE RISE OF 1,033,500-CIR. MIL CABLE CARRYING 900 AMPERES

The additional heat loss due to wind over and above what would exist in still air is shown as a function of air velocity.

The loss is nearly the same for bright and black cable as would be expected. This loss is given by

$$W_w = 0.0001185\, V^{0.8} \theta. \qquad (5)$$

where W_w = watts dissipated per square inch

V = velocity of air feet per minute.

The total loss from the cable is therefore given by

$$W = \left\{ \frac{0.00005090}{\text{cir. mils}} \right\}^{0.25} \theta^{1.22} + 0.0001185\, V^{0.8} \theta.$$

for bright cable (6)

$$W = \left\{ \frac{0.0001815}{\text{cir. mils}} \right\}^{0.25} \theta^{1.22} + 0.0001185\, V^{0.8} \theta.$$

for black cable (7)

TABLE III
Watts Dissipated by Wind
666,000 cm. Bright Cable

Wind Ft/Min.	Temp. Rise Deg. Cent.	Watts per Sq. Inch per 1 Deg. Cent.		
		Total	Loss in Still Air	Loss due to Wind
96	57.5	0.01152	0.00700	0.00452
175	47.0	0.01373	0.00669	0.00704
300	34.8	0.01776	0.00626	0.01150
605,000 cm. Black Cable				
97	55.2	0.01468	0.00973	0.00495
170	47.0	0.01686	0.00943	0.00743

W being watts per square inch of surface.
The heat generated in the cable is

$$W = \frac{I^2 r_o [1 + a(\theta + t)]}{S} \tag{8}$$

where t = temperature of atmosphere
S = Surface area of a length of cable having resistance r_0 at O deg. cent.

The final temperature rise is easily obtained graphically at the intersection of the curves plotted from equations (6) and (8) or (7) and (8). The method of doing this is illustrated in Fig. 9, the curves giving heat dissipated as per equation (6) and the straight line giving heat generated plotted from equation (8). Intersections are in equilibrium giving the final temperature rise. A cross plot from Fig. 9 and other similar curves are shown in Fig. 10 which presents the final results in a more agreeable manner.

The probable increase of effective resistance of these steel-cored cables on alternating current has not been separately considered but is included in the empirical coefficients.

Discussion

A. M. Rossman: I was shown recently some results of a heating test of a cable passing through a clamp. The cable was 300,000-cir. mil copper cable and the clamp was a drop forging. In that case the current was raised to such a value as to give an appreciable heating of the conductor. The clamp showed a temperature several degrees higher than the conductor. This is contrary to the results which Mr. Wood obtained.

H. W. Dwight (by letter): The question of the effect of direct sunlight in raising the temperature of a large conductor and increasing the sag has a close reference to the problem investigated by Mr. Wood. If the measurements were made indoors under a skylight, the effect of wind would be eliminated. If they were made outdoors, the error due to reflection by the skylight would be removed. The results, though approximate, would give additional data for calculating the maximum sag.

The question of the best size of steel core is one which could be investigated with the apparatus used by Mr. Wood, if samples of cable were obtained having different sizes of steel core but the same cross section of aluminum or copper.

Among the advantages of a larger steel core are: first, reduction of corona loss; second, reduction in skin effect due to the aluminum or copper taking the shape of a thinner tube; third, reduction in resistance due to larger cooling surface and lower temperature, and fourth, reduction in resistance due to the current carried by the steel core, which, although a small percentage, is not negligible, but amounts to about 2 per cent. These advantages are all equivalent to increasing the conductivity of the aluminum or the copper. They should be balanced against the disadvantages due to the larger steel core, of greater cost, weight, ice load and wind load.

Such a comparison might result in the use of a core of low-grade steel for a large copper transmission cable. A core of low-priced steel has usually better conductivity than one of high-grade steel, for alternating current, though not always for direct current.

If accurate means are not available for measuring the watts loss with alternating current, each sample of cable could be calibrated by measuring its final temperature rise when direct current is flowing, for which case the watts loss can be accurately measured. The temperature rise by thermocouple can also be very accurately measured, as is shown by the test readings plotted on the curves in Mr. Wood's paper. Curves would be drawn for each sample showing the continuous temperature rise plotted against watts loss. Then, when alternating current is flowing, the watts loss would be deduced from the temperature rise, and the effect of the steel core on the conductivity of the cable for alternating current could be judged.

For example, if 400 amperes, alternating current, in a 600,000-cir. mil copper cable without a core produced a temperature rise which gave 107 watts in a certain length, from the calibration curve of that sample, and if the same current in a cable with 600,000-cir. mils of copper and a steel core produced a temperature rise which gave 100 watts on the corresponding curve, then the core had increased the conductivity 7 per cent, by reducing skin effect, by lowering the temperature and by adding the conductivity of the core itself. This total percentage increase in conductivity due to the core might be greater than the percentage increase in cost caused by the core, and there would be the added advantage, of probably more importance still, that the corona loss would be decreased.

In making such a test, the samples might be connected in series, so that there would be no doubt that they carried equal currents. Such a test, like many other measurements in physics, could well be made in a room in which a thermostat controls electric heaters of sufficient size to hold the room temperature exactly constant, which is a very easy matter to arrange except in hot weather.

The Development of a Suspension-Type Insulator

BY HAROLD B. SMITH

Fellow, A. I. E. E.

Prof. Elec. Eng., Worcester Polytechnic Institute, Worcester, Mass.

Review of the Subject.—Increasing voltages employed in transmitting large amounts of power over long distances emphasize the need of a better line insulator for this purpose. This paper outlines the conditions under which a suspension-type insulator has been experimentally developed for such use. In the form described, it consists of metallic terminal members to suitably distribute the electric flux and an insulating, impregnated wood (or other material) mechanical strain member, concentric with the hollow electric field produced between the metallic terminal members. The unit described is designed for use on 110,000-volt power lines, two similar units in series for 220,000-volt lines and, when necessary, three units in series on 330,000-volt lines. The fundamental principles of the insulator are established and later continued experience in service may or may not modify detail.

INTRODUCTORY

ONE of the important problems involved in long-distance high-voltage power transmission at the present time is that of the line insulator. For the last 30 years, constantly increasing voltages have been employed for power transmission and each increase in line voltage has brought its problems of design of the several component parts, which together constitute such a system; transformers, bushings, line conductor for corona losses, regulation, control, etc.; insulation, insulators, etc.

Step by step the work of investigation, development, and resulting design of the several parts of high-voltage systems has kept pace with the commercial and economic demands for ever increasing line voltages. Some of the time, possibly, one or more of these factors has lagged behind the development demanded by the situation, but, in general, the engineering investigation and design of the various features have kept pace with and, in certain instances, have clearly pointed out a path of accomplishment in advance of economic needs.

Fig. 1 indicates what this advance in line voltage has been through the years. Voltage values for line insulators, bushings and power transformers, as distinguished from testing transformers, have followed a similar advance. Testing transformers and their bushings have ranged at from four to six times the voltage of the power transformer or line voltage for a given period.

We have been confronted, from time to time, in this progress by what appeared, at the time, to be insurmountable difficulties. First, the transformer could not be insulated, then, when it was insulated, the higher voltage could not be brought out through any available bushing. When this was accomplished, and the higher voltage was applied to the line, the known insulators failed and the line could not be insulated. After securing a line insulated from earth with improved insulators, the atmospheric and corona line losses were found to be such that the possible limit for line voltage was at one time set at 60,000 volts. Within three years of that time, it was shown that 60,000 volts was not the limit and within six years, the law of design for corona line losses was established. Recently we have had limits set for the amount of power which can be transmitted over long distances.

As frequently as some apparently impossible barrier has presented itself, it has been surmounted and this has gone on, time after time, through the efforts of many engineers and scientists, until the earlier and, at the time, really difficult barriers to surmount, now look as simple from our present point of view as our present

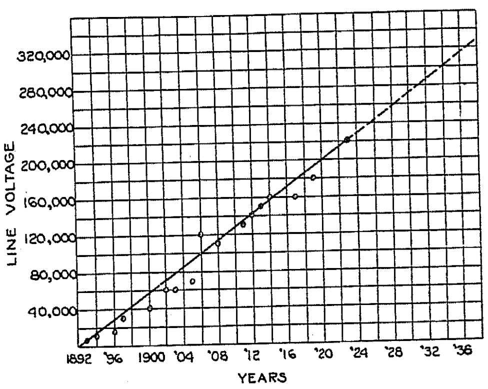

FIG. 1

"impossibilities" are likely to appear a quarter of a century from now.

The advance in power transmission line voltages, from the beginning of its advance over thirty years ago to the present time, has been consistent and uniform. It, at least, suggests the possibility of a continuance of a similar rate for some years to come. Whether we reach 300,000 or 350,000 volts for superpower transmission line potentials before or after 1935 or 1940 is perhaps not important. However, the case does appear to be clear that we are to advance in this direction, and that the times and the values for such line voltage increase are to be set, mainly, by economic rather than by purely engineering limitations.

These considerations, together with stimulation from

Presented at the A. I. E. E. Regional Meeting, Worcester, Mass., June 4-5, 1924, and at the Pacific Coast Convention, Pasadena, Cal., Oct. 13-17, 1924.

work on other related factors of this problem, led the writer, early in 1920, to apply himself to the definite problem of the rational design of an insulator which might be better adapted to increasing line voltages than those then available. This paper will present the results thus far secured on that portion of the problem which relates particularly to the suspension type of high-voltage line insulator. Parallel work has been carried out on the application of these principles to the design of pin type insulators and to transformer and bushing design, but an account of this work will not be attempted within the limits of this paper.

In order to show the relationships of this problem, it may be well to outline most briefly the gradual development of the high-voltage line insulator. The first telegraph lines required insulators and, starting with the early split tube insulator of Ezra Cornell as an illustration, we have a duct with the insulating material (glass, pottery or porcelain) placed in compression. The development of the insulator, until most recently, has been along purely empirical lines upon this original basis of a capped duct or tube with the insulating material in compression. A fairly standardized glass, pottery or porcelain insulator for telegraph and telephone service yielded many years of satisfactory experience before there was need of insulators for the early light and power circuits. These early light and power circuits did not range above 700 volts, except certain series arc and incandescent systems which ranged up to 5000 or, in some cases, as high as 10,000 volts.

When 5000 volts or more were applied on the line, although below corona effects, difficulties were experienced and merely making a large capped duct or tube type telegraph insulator did not entirely answer the question. However, this type was still adhered to, and by making modifications of an empirical character, improved materials, petticoats, etc., improved puncture and leakage loss values, creepage surface, hygroscopic conditions, etc., etc., an insulator resulted which served its purpose for the higher voltages.

With the advent of corona forming voltages, there opened a new chapter of insulator development, in which much of the earlier experience was no longer applicable and a number of new theories and resulting designs appeared. These principles at first neglected the direct question of the surrounding electric field and were applied empirically to the preceding type of insulator,—still a capped duct with the line and tie wire at or near the top of pin and the insulating material still in compression. Corrugated surfaces, multiple parts, multiple petticoats, improved dielectric strength of materials, creepage current distribution, leakage losses, etc., etc., produced insulators which again served their purpose, although usually of faulty design and often concentrating electric flux unnecessarily so as to lower breakdown values they might otherwise have possessed.

A more careful study of this problem next led to a departure from the continued empirical development of the original tube or duct type and the rational application of theory to insulator design as based upon the study of dielectrics in air and the electric field of the insulator and its surroundings. The theory was stated by Maxwell many years ago, but its application to the improvement of insulator design was then new and is now firmly established in its application. The fact, then appreciated, that a conformity of the contour of the surface of the insulator to the electrostatic lines of force of the electric field gives a closer practical approach to the dielectric strength of surrounding air than can be secured by any other surface, was applied in the production of a new type of insulator. This insulator had introduced a new element into this class of design and, because the lines of mechanical stress were parallel to the electrostatic flow lines, an insulator was produced in which the material (porcelain) could be used otherwise than in simple compression and need be no longer of the simple tube or duct type. It was no longer necessary for the line and tie wire to surround or approximately surround the top of the pin. The resulting insulator introduced these principles together with surfaces of rain sheds conforming to equipotential surfaces of the surrounding electric field.

With further increase in line potentials above 100,000 volts, even this development of the pin-type insulator no longer met the demands and, even before this latter development, suspended strings of insulating (porcelain) units came into high-voltage line practise. This was another departure from the earlier empirical duct or tube type and appeared, at first, to take care of the difficulties imposed by steadily mounting line voltages. However, it was soon found that a string of such units, because of capacity relations, would not withstand a voltage equal to the sum of voltages which could be applied to the individual units. This effect, together with increasing costs and lengths of such strings of units for the higher voltages now in use or contemplated in the near future, leaves much to be desired and possibly presents another barrier.

Statement of the Problem

In former insulator designs, and until the application of the flow-line principle and the use of the string of suspension units, it has been the practise to design for higher and higher voltages by increasing the dimensions, improving the materials, multiplying the parts, etc., as based empirically upon previous experience with the tube or duct type insulator and its modifications. Even with the application of the flow-line principle to commercial designs, the surfaces of the porcelain were shaped to conform to the lines of force of a field resulting from previous practise as to location and shape of metallic terminals.

In all of these designs, the porcelain insulating surfaces, or some of them, were in the path of maximum potential gradient and along the path by which corona formation and final breakdown and arcing would occur.

In order to proceed effectively to the design of insulators for higher voltages, it appeared advisable to introduce certain elements and principles not heretofore employed and looking toward:—

(1) Placing the insulating surface under more favorable conditions for operation, especially as to corona and arcing.

(2) Simplifying the form of the insulating surface for convenience in manufacture.

(3) An insulator free from corona prior to breakdown.

(4) Reducing weight.

(5) Reducing over-all length.

(6) Reducing costs.

(7) Producing a higher voltage unit insulator.

(8) Elimination of porcelain, if possible.

These results may be attempted by the application, among others, of the following features:—

(9) The production of a hollow electric field[1], in which to place the insulating member.

(10) In combination with the hollow electric field, to so shape metallic electric flux distributing terminals as to produce along and near the axis of the field a field of force with lines so distributed as to conform to the surface of an insulating (mechanical strain) member which shall be most desirable from purely mechanical considerations of strength and manufacture.

(11) In combination with the above, to so proportion the metallic flux distributing terminal members as to eliminate corona formation anywhere on the insulator prior to a close approach to breakdown voltage, and well above operating voltage.

(12) An insulating mechanical strain member, to meet the purely mechanical conditions imposed by a higher voltage line insulator and, conveniently manufactured, may be an elongated cylinder or frustum of a cone or close approach to such forms.

(13) A mechanical strain member employed in the above combination should either be of some material of better mechanical properties than porcelain or of a porcelain having mechanical properties superior to those heretofore employed in insulator construction.

A proper combination of the above features should result in an insulator which will offer, among other advantages:—

(14) No possibility of corona or arcing along its single insulating surface; opening the possibility of the use of other material than porcelain.

(15) Maximum practicable dielectric strength along its insulating surface.

(16) Ample mechanical strength.

(17) A single unit suitable for use on 110,000-volt power lines, two such units in series for 220,000-volt lines and, when necessary, three units in series on 330,000-volt lines.

1. By a hollow electric field is meant an electric field surrounded symmetrically along its axis (plane or other surface) by a stronger field of higher average and maximum potential gradient.

Experimental Development

The preliminary experimental work of development

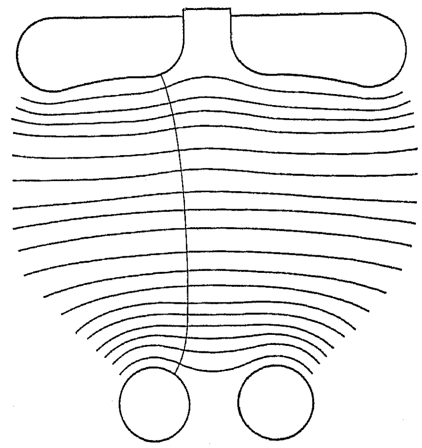

Fig. 2

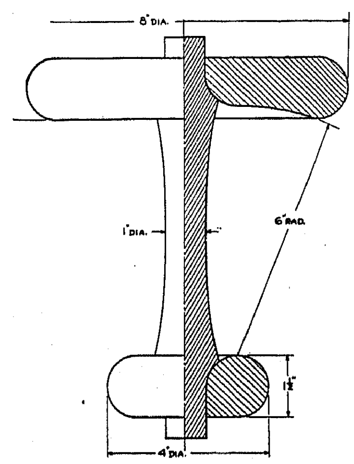

Fig. 3

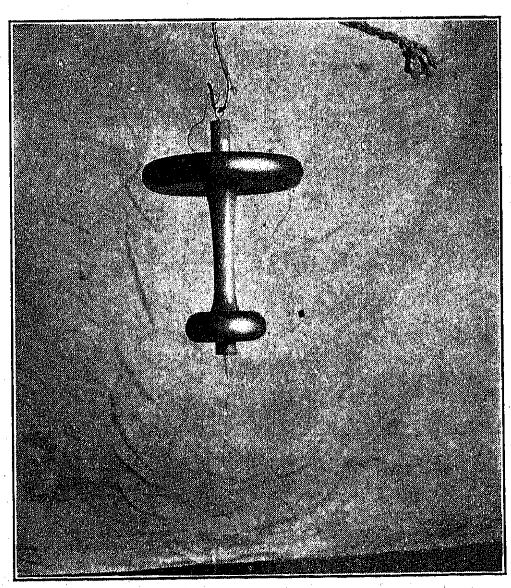

Fig. 4

of an insulator to meet the above conditions has now been completed and a few preliminary commercial

model suspension insulators have been built to place on high-voltage power circuits. This will give service experience with a view to detail modification, if necessary, before placing such insulators in general service in quantity.

The results obtained in this experimental development are of interest and, without attempting a full account of all the experimental work involved, may be outlined as follows:—

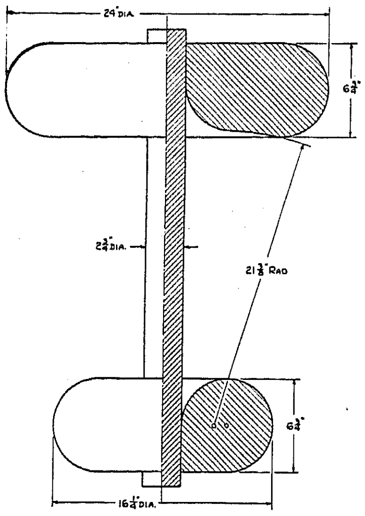

FIG. 5

An early attempt to determine, by theoretical analysis, a suitable form of insulating surface resulted in a form of spindle shown in Fig. 2 and dimensions as in Fig. 3.

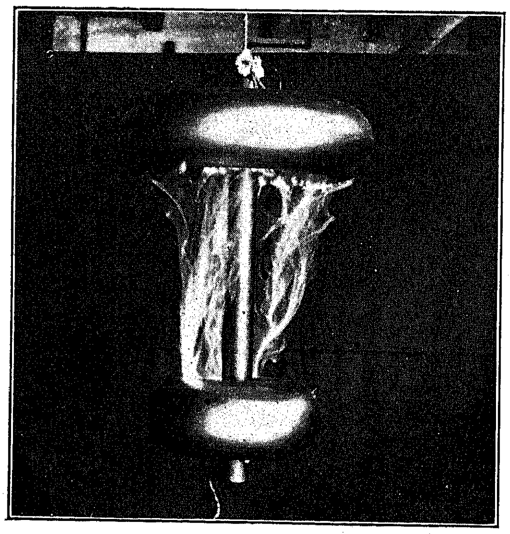

FIG. 6

This was constructed of wood with gilded terminal members giving appearance of Fig. 4 and yielded breakdown values of from 130 to 145 kv.

For convenience in manufacture, it appeared advisable to so shape the metallic flux distributing terminals that a cylindrical spindle, rather than the shaped spindle of Fig. 4, could be used, if possible, without too great loss of breakdown values. An insulator was, therefore, constructed as shown in Fig. 5 with gilded wooden terminal flux distribution members. Under test, this showed absolutely no corona up to nearly 400 kv. and at 400 kv. broke down without sign of previous distress. Fig. 6 shows appearance at breakdown with

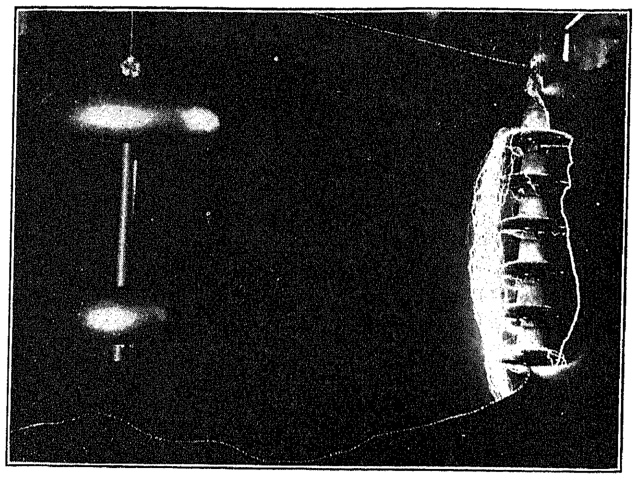

FIG. 7

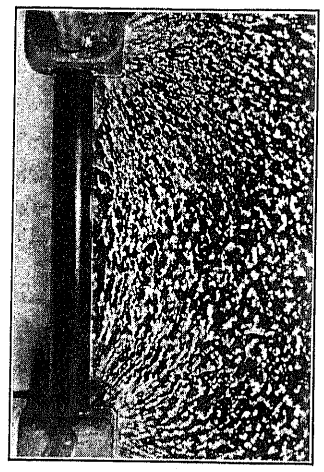

FIG. 8

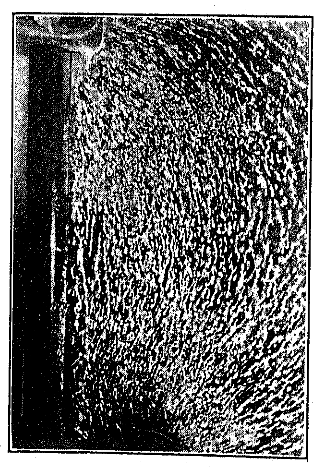

FIG. 9

no corona or arc along the insulating spindle. Hung in parallel with a string of six unit insulators of somewhat greater overall length, results were as shown in Fig. 7 at 360 kv. and no sign of corona on the single unit.

These results gave encouragement for continued work and considerable effort was expended in the exploration of the surrounding fields and on the study of field forms secured with shredded asbestos. Fig. 8 shows the field form around a cylindrical spindle with metallic rods at each end and at right angles to the axis of the spindle. This is a condition which, clearly, does not give an insulating surface conforming to the lines of force of the

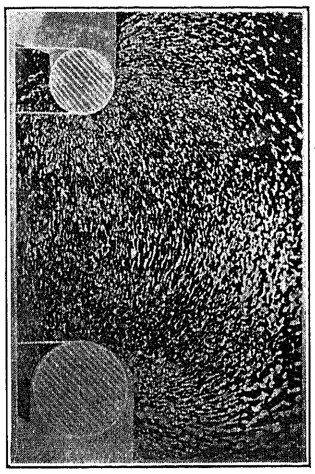

FIG. 10

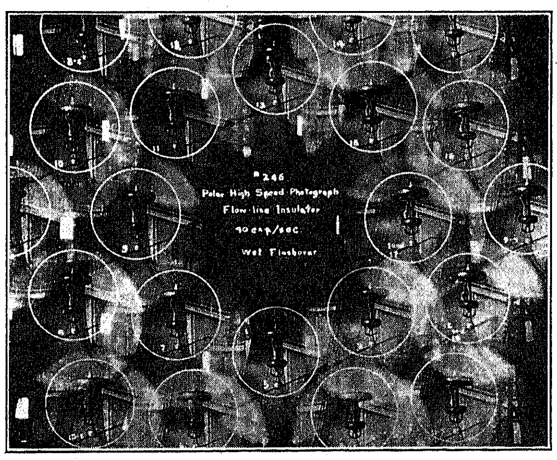

FIG. 11

field. Fig. 9 shows the effect of placing a metallic torus surrounding one end of the spindle. The field of force has flow lines more nearly conforming to the insulating surface. Fig. 10, with a torus surrounding each end of the spindle and concentric with its axis, gives a field with lines of force parallel with the surface of the insulating spindle throughout most of its length and also places the spindle in a hollow electric field where the strongest part of the field, with a maximum potential gradient, is a cylindrical belt immediately along the shortest path between the two toroidal surfaces and entirely surrounding the spindle.

Visual observation determined that with such arrangement undesirable corona formation did not occur up to about the breakdown voltage, but the eye could

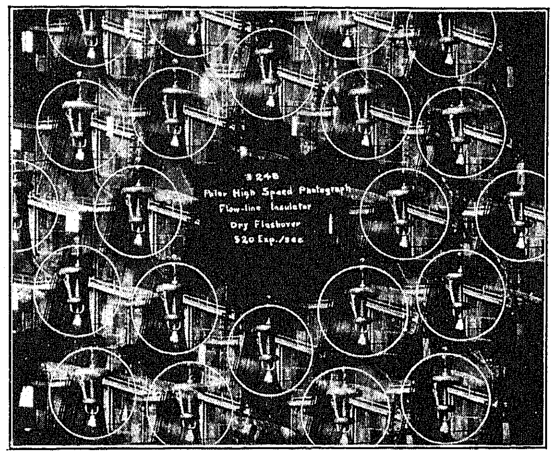

FIG. 12

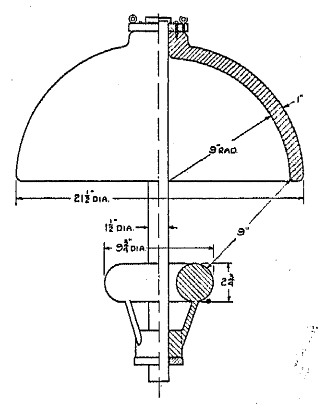

FIG. 13

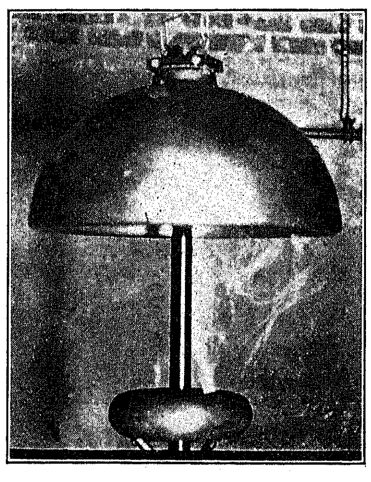

FIG. 14

not detect with certainty if static streamers or power arcs might not occasionally, and for an instant, traverse the surface of the insulating spindle. In order to determine this with certainty, polar high speed stereoscopic photo-

graphs were taken. Fig. 11 shows such a photograph at 48 exposures per second and Fig. 12 shows a similar photograph at 520 exposures per second. In no case was a streamer or arc formed along the insulating spindle nor could one be blown upon it by strong air currents. Up to this point no attempt had been made to secure results except under dry conditions, as it was believed

FIG. 15

that absence of complication of wet conditions would help to an understanding of the necessary fundamental relationships. The next step involved study of the modifying elements introduced by wet spray test and storm conditions.

A model corresponding to Fig. 13 was constructed and gave the appearance of Fig. 14 on breakdown. This

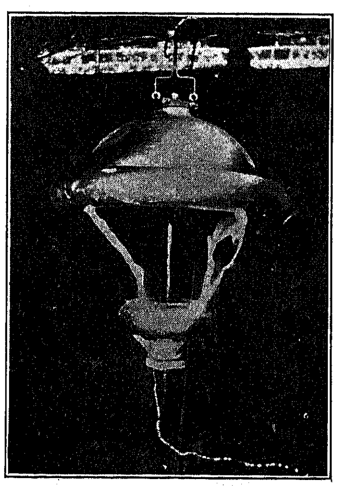

FIG. 16

did not yield as good results as hoped for, although the following results were obtained.

	Dry		Wet		
Spacing	Kv.	Kv./in.	Kv.	Kv./in.	Ratio
9 in.	201	22.3	102	11.3	51
12 in.	240	20.0	131	10.9	55

In order to determine the influence of the various factors involved, and to secure more favorable results, a long series of comparative tests was carried out on a variety of models and combinations. Of this series, a

FIG. 17

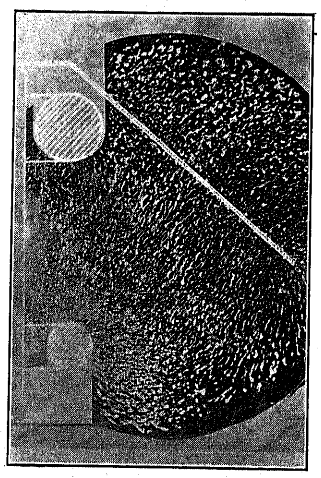

FIG. 18

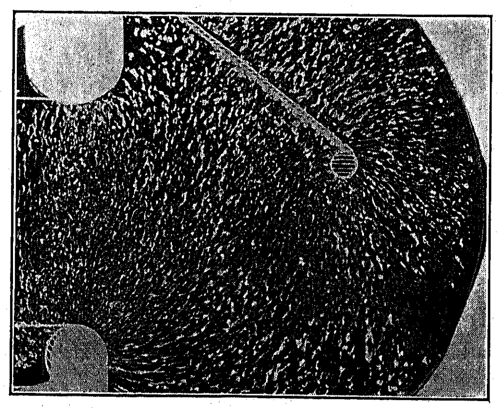

FIG. 19

few typical combinations and their results are given in Fig. 15. The appearance of two of these models, under arcing conditions, is given by Figs. 16 and 17.

These tests showed clearly the direction in which further development should proceed and a careful study

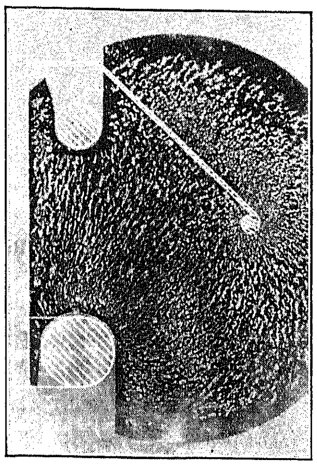

Fig. 20

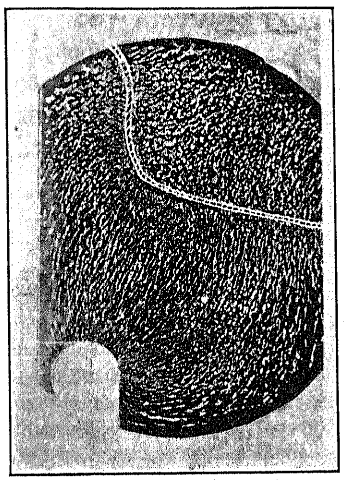

Fig. 21

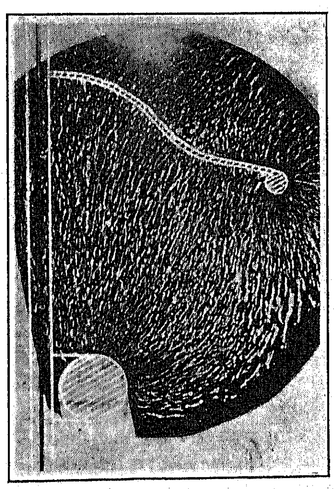

Fig. 22

of field forms was made on several models, in confirmation, and as shown in Figs. 18, 19, 20, 21, 22 and 23.

As a result of this, and work on other models, a final model of insulator was constructed in limited number with dimensions as shown in Fig. 24, for the collection of data under service conditions on high-voltage power lines with a variety of climatic conditions. The field

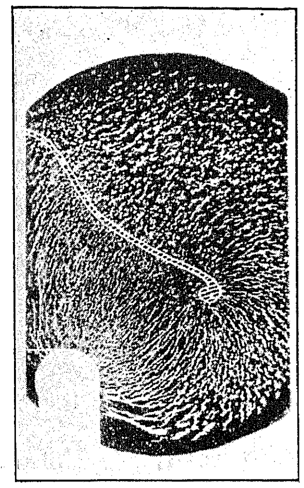

Fig. 23

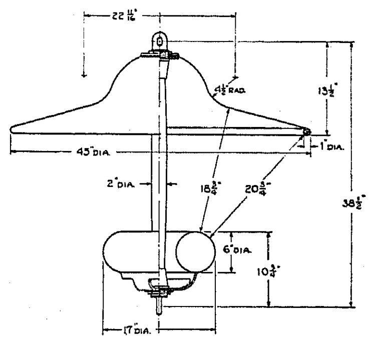

Fig. 24

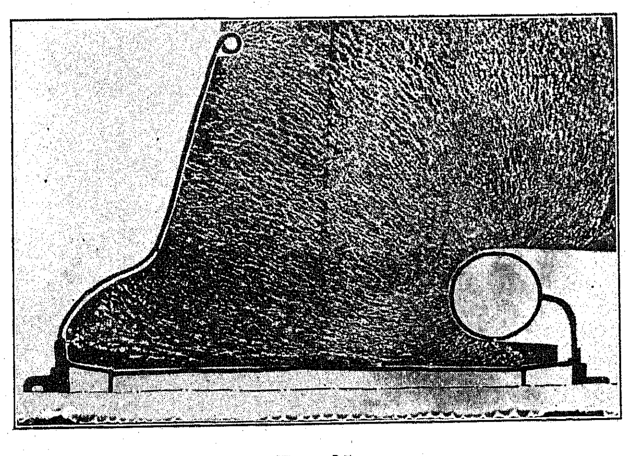

Fig. 25

form of this model is shown in Fig. 25. The appearance of this model, following severe snow conditions, is shown in Fig. 26 and under heavy arcing conditions at 280-kv. in Fig. 27.

With sufficient experience, under service conditions,

its rating can be established, or, if necessary, dimensions modified to meet any desired rating.

The test values on this insulator range at about 280 kv., or over, dry and 200 kv., or over, under standard wet spray test per unit. No corona is visible on any part of the insulator until within about five per cent of

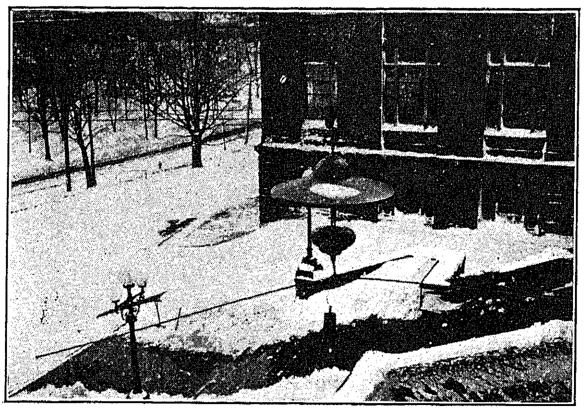

Fig. 26

breakdown voltage. Two units in series require about 500 kv. dry or 350 kv. wet for breakdown. These values are without capacity modification which could be readily secured to improve these values.

During the period in which the electrical features of

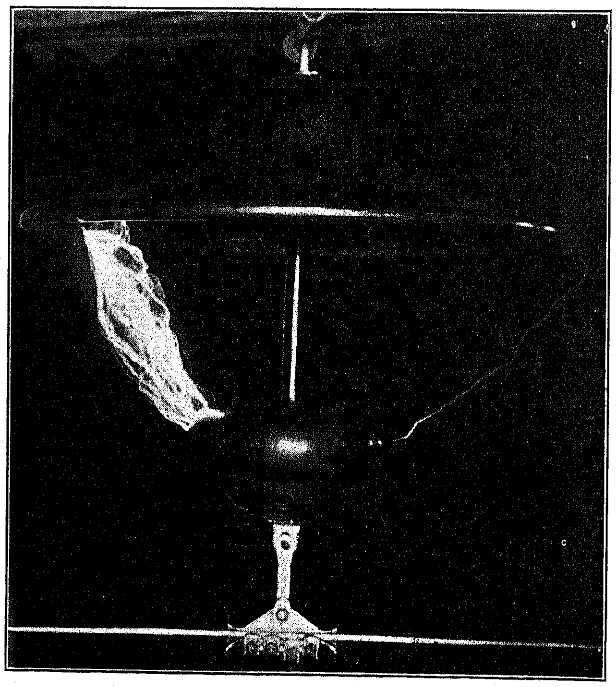

Fig. 27

this insulator have been under development, H. C. P. Weber, of the Westinghouse Research Laboratories, has been engaged in the development of impregnated and treated wood spindles for use in this insulator. His results are such that, with absence of corona and arcing conditions on the surface of the insulating member, there is definite promise of an insulating strain member with satisfactory dielectric properties and mechanical properties far superior to any porcelain yet available. The spindles used in demonstration tests accompanying this paper have been prepared under methods developed by Dr. Weber, but will not be further considered in a paper devoted to the electrical rather than the chemical features of this problem. Artificial aging and weathering tests of great severity accompanied by repeated electrical tests, extending over a number of months, have been applied to these spindles.

Special acknowledgment should be made for the thorough cooperation and great assistance which has been rendered in this problem by D. F. Miner and H. W. Tenney, both of the Westinghouse Electric and Manufacturing Company, through work which they have carried out in Pittsburgh.

Acknowledgment should also be made for the interested and valuable assistance which has been given on this problem by assistants who have worked with the writer in Worcester at one stage or another of the development of the problem. These are R. H. Bryant, H. W. Tenney, A. W. Hill, D. E. Howes, O. B. French, R. M. Field, S. T. Chen, C. L. Denault, R. L. Kimball, R. D. Paul and E. Topanelian, Jr.

Discussion

At Worcester

E. M. Hewlett: In trying various materials in experimenting on the first suspension-type insulator we found that any compound or any material that *can* carbonize, *will* carbonize. I am in hope that by distributing the strain in the way that Professor Smith has done, the carbonization will be reduced and the life of the rod lengthened, but it seems that in this electrical work, anything that *can* happen *will* happen. For instance, when an insulator is subjected to fog, you get a little dampness on the surface. Or when you get it out in the Middle West, in the Salt Lake section, where you get alkali dust, then you get a surface condition that will start a little static and start a little leakage. These conditions, with the available materials, are likely to result in deterioration.

The thing that we have always been looking for on all insulators, and I think in a good many other things, too, has been a suitable material.

Now, of course, if we can get a better porcelain, a porcelain twice as strong, or 50 per cent stronger, a little tougher, with a better dielectric strength, we can do quite a good deal, even with our present design. If we had a ceramic material, which we felt was safe under tension conditions and wouldn't crack and drop the line, why, then we could work something of this kind of a design. On the wireless antennas, they use a 50-in. long tube, 3½ in. in diameter, and they shield the ends with a ring very much in the same way as Professor Smith has done here. They do not use the rings for rain shields, but just as distribution rings.

On transmission voltages above 110,000 volts, it has been found that the lower disk on suspension-unit strings takes a larger percentage of the total electrical stress than the other units of the string. Therefore, on the higher voltages it has been found necessary to put grading rings on the strings in order to balance up the stresses. That process can be carried on so that the present types of suspension units can be used for any voltages that we know of at the present time.

We are in need of materials that will withstand arcing static and corona. The discovery of such materials will not only render possible numerous suggested designs, but will also open the field to many new designs of insulators for high-voltage transmission insulation.

C. F. Scott: In 1904—twenty years ago this summer—the International Electrical Congress was held in St. Louis. It had many sections. One of them was "Power Transmission." I happened to be its Chairman. One of the best groups of transmission people that had ever come together were there, presenting and discussing papers—something like half of them related to the line or the insulator.

It is interesting to read now the criticisms of the pin-type insulator, its construction, its theory, its size and its performance. V. G. Converse, who was the man who had made the underhung insulator that Mr. Skinner spoke of, had a long paper on insulators, a historical paper which described and illustrated all the different sizes and types. He refers to his underhung insulator or underscrewed insulator and goes on after saying that the pin insulator had been growing in size until it approximated a Chinese pagoda, to give another form of the same thing with an improved construction.

Dr. Perrine suggested the building of a little cottage over each insulator to protect it from the weather, a sort of a cubical, 4 or 5 ft. in size, open on two sides to let the line run through. Everybody was pointing out the insulator as the limitating element in transmission which had then reached 66,000 volts. We had the transformers but not the insulators.

M. H. Gerry, the man who started the first 50,000-volt plant for the Missouri River Power Company—spoke of his insulator experience, and made some very significant remarks. He described and illustrated some experiments showing the discharge over glass plates—simple static experiments—and he said, "The direction in which we will have to look in the future is a study of the electro-static conditions. They are coming into consequence at these higher voltages."

Three years later, in 1907, papers at the Niagara convention of this Institute by Buck and Hewlett presented a new type of transmission. The problem had been to hold the line in place, to hold it steady. It had been above the cross arm. They proposed putting it below. They proposed long spans hanging the wire from a succession of suspension insulators. They changed the law of the insulator from the third power to the first power. When you double the size of a pin insulator, you increase its weight as the cube; when you double the underhung type, you use two insulators increasing the weight by two instead of eight. There were two very significant things; one was the presentation of a new system, and the other was its reception. The insulator caused a new era in transmission, but the hearers didn't recognize it; the discussion was trivial.

The curve of increasing transmission voltages for the last 30 years or more runs up fairly uniformly to 1903 and then keeps on a pretty straight line at about 66,000 volts for five years. Then there is a sudden jump up to 110,000 all at once. Then it went on up. Why? The suspension insulator had come; it changed the whole trend of transmission.

Now we have again something new. When Buck and Hewlett discarded the upright insulator, because it was mechanically wrong, they got it mechanically right by shifting the position 180 degrees. What has Prof. Smith done? He has treated the problem in a broad, engineering way. Most people have tried to hang on another insulator or change the shape of the petticoats or change the metal clamp or improve the porcelain.

Professor Smith does not modify; he starts *de novo.* He proposes a dozen or more different requirements to be met and they seemed wonderfully exacting and almost impossible. But he had the courage to lay them out and then to meet them.

Now, what has it come down to? Why nothing at all but a metal umbrella with a wooden handle with an ornament at the bottom, but it apparently meets the mechanical and electrostatic requirements.

I wonder whether we are going to be as slow as the American Institute of Electrical Engineers was nearly twenty years ago in recognizing that maybe some new thing with big possibilities has come such as was presented by Buck and Hewlett.

V. Karapetoff: I should like to ask Professor Smith a question or two in regard to his design, if I may. Electrostatic systems may be divided into *glow* systems and *spark-over* systems. Take two large spheres, a short distance apart and raise the voltage to a point where there is ionization on the adjacent surfaces. The flying electrons will also ionize by collision the remainder of the space between the spheres. Therefore, there is no intermediate stage of corona formation and a breakdown takes place almost at the same voltage as the first corona appears. On the other hand, take two small spheres, placed quite far apart. As the voltage is raised, a potential gradient is reached at which ionization by collision begins at the surfaces of the spheres, where the voltage gradient is at a maximum. As the air is broken down, the diameter of the spheres is seemingly increased because the ionized portion may be considered as part of the metallic conductor. Therefore, a condition is reached at which a stable equilibrium is possible, because the voltage gradient beyond the ionized range is not sufficient to cause further ionization by collision. I call such a system a glow system. As the voltage is raised higher, the ionized layer increases in thickness and then streamers begin to form. Finally a complete breakdown takes place. This is, then, the difference between a spark-over system and a glow system.

If I understand correctly, the apparatus to be protected should rather have glow characteristics, while the protective apparatus should preeminently have spark-over characteristics. If I want a quick gap to protect some apparatus, naturally I would select a condition in which there is no intermediate corona stage; while if I want something protected then, I should judge, a glow arrangement is preferable. When the voltage rises beyond a certain limit, the apparatus becomes partly self-protecting by the formation of ionized corona regions, and when the voltage goes down, the apparatus field becomes normal again.

I understood Professor Smith to say that in his insulator a sparkover takes place without previous corona formation, and I should like to ask him if this is theoretically possible, with the shape of the guard ring that he has, or with the lower terminal and the umbrella above. His photographs show that the electrostatic flux spreads out from the lower ring reaching a maximum dielectric flux density there. So that, theoretically, at least, a stage is reached at which the voltage gradient at the ring exceeds that necessary for ionization by collision and an ionized layer is formed. The same applies to the edge of the umbrella. I do not say that with the construction used these layers are necessarily harmful; I only should like to know if they exist.

Another question which I should like to ask Professor Smith is this: He spoke of a hollow field. To me, a hollow field means a field which is more intense on the outside than on the inside. For example, if we have an iron pipe, longitudinally magnetized by a coil, we might say that it has a hollow field, in the sense that the flux density in the material of the pipe is greater than in the interior space. Now, the permittivity of wood is at least twice, if not more than twice, that of the air, so that with the same applied potential and the same average voltage gradient we should expect a higher flux density in the central wooden stick than in the surrounding air. Can such a field be called hollow? The field is very skillfully arranged and the lines of force are almost parallel to the outer surface of the wood, so that there is no corona formation on the surface. I understand this point. But is it not true, nevertheless, that the dielectric flux density is higher in the rod than it is in the air?

This may seem like splitting hairs, but seeing that we are now in the midst of a new and rational epoch in the development of

insulators, let us start our terminology right, before it is too late.

H. A. Stanley: All the experiments we have seen, and the talk we have heard, have had to do with the insulator in the vertical position. I assume that we are not going to get away from the use of insulators in the strain position. This particular insulator is not adapted for use horizontally. For instance, the lower bowl, I should judge, would hold water in the horizontal position, and I would like to inquire if the thought is to work out something different for use in the horizontal position?

The second point is the copper. I suppose that when the manufacturers get around to selling this device to us they will try to make it in some cheaper material. I would like to inquire if there is any reason, theoretically, why it couldn't be made of galvanized iron.

Mr. Bowlen: The point Mr. Stanley just brought out about the insulator being placed in a horizontal position, is, I think, of considerable interest, and I believe, in that connection, there is a strain insulator on the market at the present time which uses a wooden core as its principal tension member, covered with porcelain tubes filled with petrolatum or oil. That is used on a span something like 3000 ft. long and it is in successful operation; it has a means of re-filling the space between the wooden core and the porcelain. That might be the answer to putting it in the horizontal position.

Discussion at Pasadena

W. A. Hillebrand: Professor Smith, perhaps, has revived the first form of suspension insulator that was brought out. We have insulators today that operate and constitute a not unreasonable charge upon the system. If you take into account obsolescence, their charge is less than that of many other elements of the system. Today, it is probably less than the direct depreciation charge of wood poles and cross arms, and taking into account obsolescence, it is less than the charge upon the earlier and comparatively recent types of prime movers, generators and oil switches. It is a charge which the industry is able to bear without imposing an undue burden. I think it is the best practical insulator we have today because it works. The only question is that of making it a commercial success. It has got to be something better or cheaper, to offer equivalent service at a lower cost than that which we have today. The only question then is that of application. Unquestionably it will be tried out and in sufficient quantity to give a demonstration. The operation of this insulator depends upon the satisfactory maintenance under field conditions of an initially established gradient.

This matter of bird droppings causing flashovers, to my mind, is a question as to whether with two units your field will be strong enough to exclude foreign particles and moisture. There is a leakage problem that is, perhaps, the most serious of all. We have a new material, which is treated wood.

Now, there is one thing that is fundamental, and which applies to both the manufacturer and to the user of that type of insulator, that is, the failure of a single piece of dielectric. and that applies to any known dielectric, means the dropping of the line. That is, a failure from any cause whatever, straight mechanical failure, puncturing, burning due to leakage, arcing due to flashover—anything that causes a line interruption means a loss. Now, experience has shown that you can have as many as 30 per cent of the pieces of dielectric fail mechanically, or electrically before obtaining the first line interruption. That is solely a matter of the number of pieces used; that determines the reliability. With insulators of the types now in common use, the reliability is the function of power of the number of insulators in the string. That is one of the most commonly overlooked and one of the most fundamental applications in regard to insulators today. On the other hand, the probabilities of interruption with an insulator of this kind is in direct proportion to the number of pieces of dielectric in use. That is, that every additional piece of dielectric you add constitutes an additional hazard instead of an additional protection. It puts on the manufacturer an almost unbelievable requirement with regard to reliability. You may be able to obtain it, but on the basis of experience I would say it should be approached with the greatest of caution.

J. B. Whitehead: Professor Smith has adopted in his insulator two devices which we have known for sometime, namely, the arcing ring and impregnated wood as an insulating material. The particular aspect of his work to which I want to call attention is the study that he has made of the properties of the arcing ring, or screen, and the method that he has adopted in that study. We have had arcing rings that will take the arc and save the insulator for sometime, but Professor Smith has made a study of the shape of these rings in a systematic and scientific way and has arrived at a form of ring which gives a uniform potential gradient over the insulating member. He thus eliminates regions of high potential gradient and has, therefore, reduced to a minimum the probability of an initial brush, or corona, or spark-over. It is a scientific investigation and it should, therefore, be emphasized as an example which we should all attempt to follow in putting experiments of this kind under way.

I suppose that the methods are being followed in the study of the impregnation of the insulating member. Of course, the open question in connection with the insulator, is the life of the single insulating member. It would appear to me that it is going to be a question of the power of the surface of this member to withstand the action of the elements. We know that porcelain, originally apparently perfectly safe, eventually, under the action of the elements, temperature and so on, developed a cracked surface which eventually leads to failure. In the case of the impregnated wood member we would seem to have the possibility of avoiding in a large measure, that particular type of failure. If we can obtain an impregnated material, which is more or less plastic, and which, therefore, will yield to the expansions that are brought about by temperature change, it would appear that we might have a surface which would accommodate itself to existing conditions from day to day. It appears to me, however, that if we do not obtain such a type of impregnated material, there is a considerable element of danger in such an insulating element. For, if this impregnated wood disintegrates we will get a fibrous substance in the path of the potential gradient and this will lead to brush discharges.

C. E. Skinner: As I understand it, Professor Smith's investigation is not based primarily on the use of wood in a strain insulator; but on a study of the potential gradient and a design such as to permit the use of a strain member so placed that when an arc is formed it will not be along the surface of the insulation. This arrangement permits the use of wood, which in the past has proved most satisfactory in many other applications as an insulating material. It has the advantage of great mechanical strength and is readily obtainable. It has the disadvantage of being carbonizable and difficulty has been experienced from time to time in providing suitable impregnation.

Methods of impregnation have been studied and results have been obtained which seem to warrant the assumption that methods are now available which will justify the use of wood in this connection, provided it is not subject to arc-over, and Professor Smith's tests show that this need not be feared in this particular design.

Professor Smith's insulator is especially interesting as being the first radical departure from the type which has been generally accepted as standard for many years. Line insulation has for some time been considered the limiting factor in the use of high-voltage transmission. This insulator gives promise of removing this limitation.

I do not understand that Professor Smith is ready to advocate this insulator for commercial work until more field experience is obtained, and tests are under way which will give this field experience. The wood strain is merely incidental to this type of construction, and any other material which will satisfy the mechanical and insulation demands could be used to replace it.

H. F. Elliott (by letter): Electrostatic shields, or terminals, of the type proposed by Professor Smith, have been used with rod, tubular and other forms of insulators for radio antennas and associated services since 1914 or perhaps even earlier.

The high losses which accompany corona at radio frequencies, and the extremely destructive character of corona at the higher frequencies, forced the adoption of special types of insulators with suitable shields to control the electrostatic fields at this comparatively early date. The accompanying photographs, taken during 1916, 1917 and 1918, may be of some historical interest in this connection.

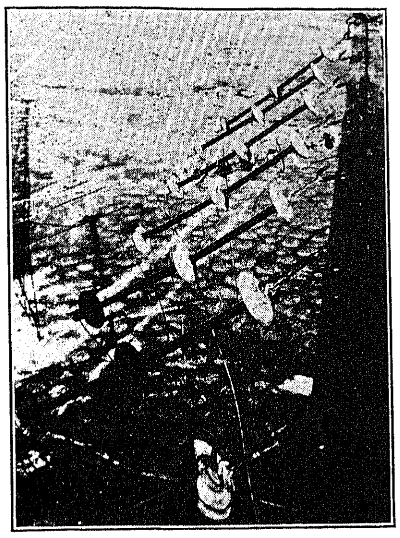

Fig. 1

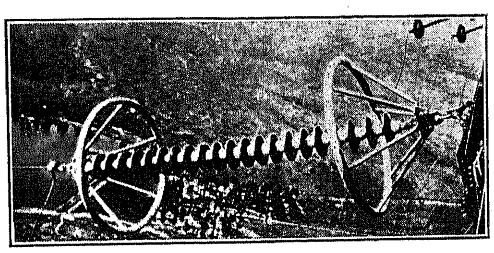

Fig. 2

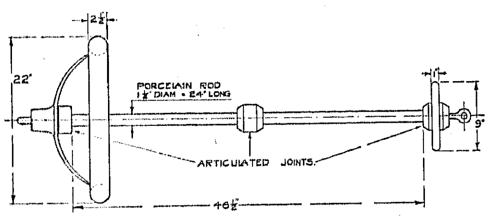

Fig. 3

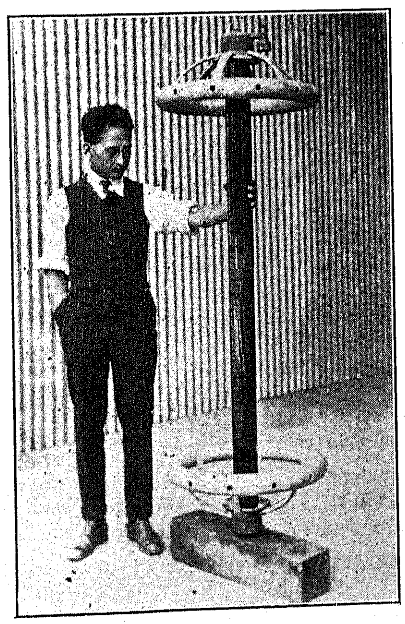

Fig. 4

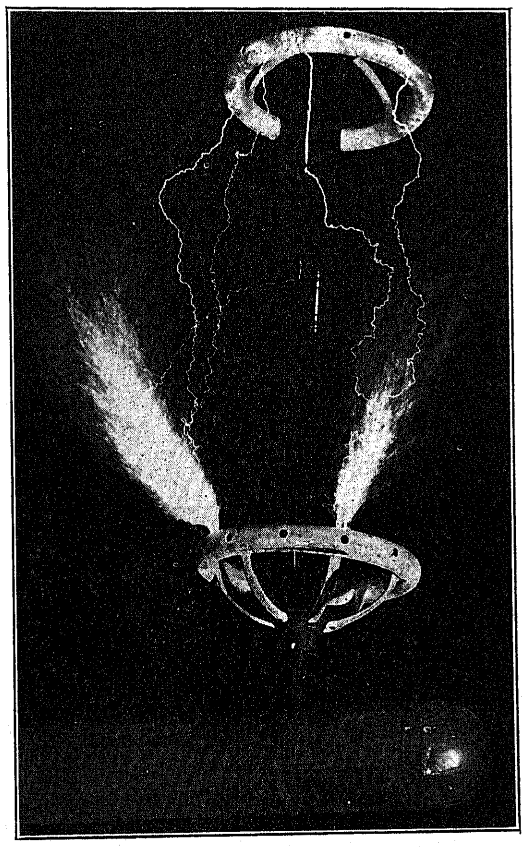

Fig. 5

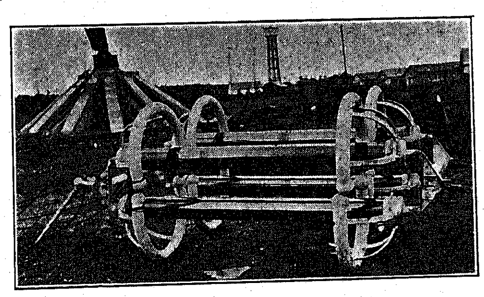

Fig. 6

Fig. 1 shows the type of porcelain-rod insulator and disk shields which were used for several high-power radio antennae during 1916 and 1917. Fig. 2 shows a specially shielded string of standard suspension units which was used with the same antennas. All of these insulators functioned satisfactorily and without visible corona at potentials of the order of 100,000 volts, r. m. s., and frequencies ranging from 15,000 to 50,000 cycles.

Shielded strings of standard suspension units in a variety of combinations were tested at the Stanford University high-voltage laboratory during 1917. The results of these tests will be found in the paper by Mr. Frank G. Baum entitled "Voltage Regulation and Insulation for Large-Power Long-Distance Transmission Systems," PROCEEDINGS A. I. E. E., Vol. XL, 1921, pages 1067 and 1068.

Fig. 3 is a sketch of a porcelain-rod antenna insulator designed during 1917 and tested at the Stanford University high-voltage laboratory during the same year. Using 60 cycles, and with the insulator dry, the first pin points of corona appeared at 140,000 volts; intermittent streamers occurred at 225,000 volts and large streamers but no flashover occurred at 350,000 volts, which was the limit of the testing equipment. With the insulator thoroughly wetted, there was some brushing at 100,000 volts, but the changing currents quickly dried the surface.

During 1918 porcelain-tube insulators of the type shown in Fig. 4 were developed. These have since come into general use and have proven highly satisfactory, both as to electrical efficiency and mechanical reliability. Fig. 5, shows such a unit under test at 183,000 volts, r. m. s., and 46,000 cycles. The shape of the surrounding electrostatic field is clearly shown by the position of the corona streamers, which are entirely clear of the insulator proper.

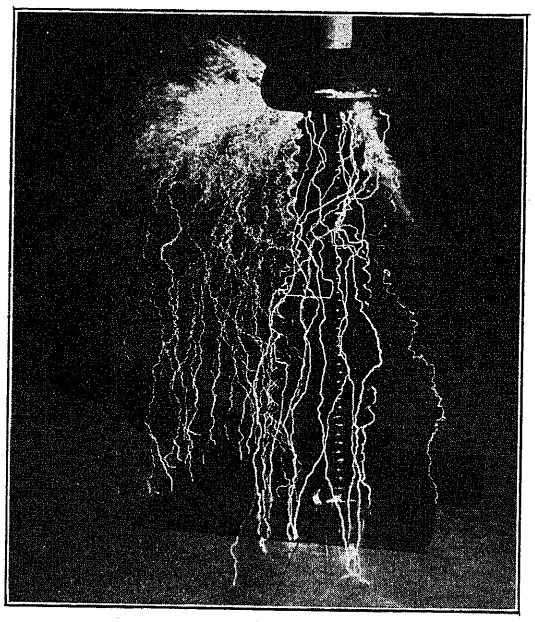

FIG. 7

Fig. 6 shows a special high-strength antenna insulator designed during 1918 for service involving potentials of 135,000 volts, r. m. s., to earth, frequencies of 12,000 to 30,000 cycles and a working load of 20,000 lb. *in tension*. Each of the four porcelain tubes comprising this unit was approximately 6 in. diameter by 6 ft. long and each tube had an ultimate tensile strength over 20,000 lb. Recently, similar units have been constructed whose ultimate tensile strength exceeds 35,000 lb.

Fig. 7 shows a pedestal-type insulator, with electrostatic shield, under test at 234,000 volts, r. m. s. to earth and 51,000 cycles. This unit was one of a number used for special radio-frequency switches which were operated, without the slightest indication of corona, at a potential of 135,000 volts. The shape of the electrostatic field as controlled by the shield is indicated in the photograph by the corona streamers.

The possibility of constructing the electrostatic shields of antenna insulators so as to shed rain was considered at an early date but was not immediately adopted because the insulators had to operate in a nearly horizontal position, as shown in Fig. 1. More recently, however, the practise of using cone-type electrostatic shields which also act as rain shields, has been adopted with great satisfaction for radio antennas employing insulators in a vertical position. An account of the development and testing of units of this type is given in a paper by Mr. W. W. Brown in the PROCEEDINGS of the Institute of Radio Engineers, October, 1923.

It will be noted that all of the insulators described in the foregoing are of porcelain. Many other materials have been tried, some with apparently excellent success in the laboratory, but none, except porcelain, has proven satisfactory in service for potentials above a few thousand volts.

H. B. Smith: In response to some of the questions that have been asked, I will make a few suggestions.

First, with respect to the suggestion regarding fog and dust which has been made—and I will combine with that the question Professor Karapetoff raised with respect to the hollow field.

Professor Karapetoff is correct in stating that there is greater density of the dielectric flux within the stick than immediately outside, but comparing the space along the length of stick, as compared with the short spacing between metal terminals, we have outside of the surface of the stick a density variation exactly conforming with his description for a hollow field and the stronger field on the outside tends to deflect particles of moisture, dust, etc., in the direction of that field and away from the stick.

Reference was made to the size of the insulator. It does look large, here in this room, but it doesn't look large out on a transmission tower for such a voltage as would be employed where such an insulator would be used. The parts are not heavy.

A question was raised as to the material. These, you understand, are the first insulators of this size, and for convenience, the hood is made of spun copper. That was just for the small number. It was not feasible to prepare dies for pressing, as would be done in quantity. As soon as that is done, the material cheapest for production, considering depreciation, will be used. There is nothing in the metal that is used that affects the operation of the insulator, theoretically.

If I may take just a moment in retrospection, referring to what Professor Scott has said, I would say that when his paper of 1898 was presented—depending upon wires of small diameter—it was felt that a limit for voltage might be reached of 55,000 or 60,000 volts. It stimulated us here in Worcester in 1900 to 1902 as soon as we had developed the transformer, (which is now in the room below and was used in the demonstrations this morning), to apply higher voltages to a transmission circuit that was placed along Boynton Street, and we used wires of larger diameter.

In a thesis presented by Cook, Davis and Wiard in 1901, the results are shown of the effect of increasing diameter and prove clearly that 60,000 volts was not prohibitive.

In those days, before Professor Ryan went to California, we were in close contact with each other—we were working together more or less on this question—and this fact was communicated to Professor Ryan and we had quite a little correspondence on the matter.

Soon after that, Mershon made other tests in Colorado and the results of those tests were sent to Professor Ryan. Mershon's results did not agree with our results in Worcester, so that both Professor Ryan and myself were somewhat skeptical as to the accuracy of either Mershon's work or the work that we had done here in Worcester.

Professor Ryan later sent to Worcester results of his experiments on the effect of pressure, and also going back to some old work on the same subject, made seventy-five years before—the work of Paschen, so that taking into account the difference in elevation of Colorado and Worcester, he found that our results agreed, substantially.

We then had confidence and Professor Ryan went on with his

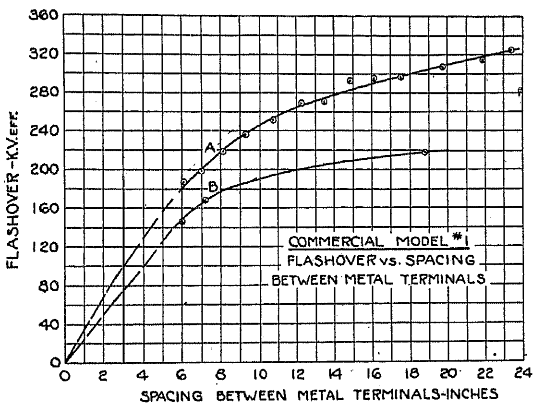
classical paper that he presented to the Institute in 1904, which gave us the foundation for the law of corona losses between conductors.

Reference was made to the large diameter of the hat of this insulator. You must remember that the hat is connected to earth. You can make one continuous hood for three or four insulators, if you choose, instead of splitting it up.

The question of deterioration of organic materials, under such conditions as these, is, of course, the important question, and it is a question that can only be answered finally by experience on the insulators in service. We have tried to put the insulating member under the most favorable conditions possible to prolong its life. We have attempted to remove visible corona. Whether ionization coincides with visible corona, may be a question. Visible corona does not appear until very close to the point of break-down, and we operate the insulator at half, or less than half that voltage.

With regard to the question of the horizontal strain insulator, there is no attempt to meet that condition with this present insulator. The same principles can be employed in such a type of insulator. I think there is a little misunderstanding as to the construction of this torus. It has a perfectly continuous surface.

The comment of the operating people who will have to deal with these insulators in service, is perfectly fair—that it should be tried out. That is the thing that we propose to do. We will then know just the limitations and just what may be necessary to



do to apply these same principles, which I believe to be right, to the actual conditions as imposed in service. We hope that we can meet them the first time they go into actual service but that isn't always done.

H. B. Smith: Possibly some of you may have thought that the insulator I am suggesting is radical because of its apparent departure from existing practise, but I cannot regard it in that way. It happens that in 1898 I succeeded in producing a transformer for 175,000 volts in a single unit. I think that at that time it was the highest voltage single unit transformer. Transformers had previously been used with high-tension circuits in series, that is, a number of units in series but not in cascade as we are doing now. In 1901 we built our single unit 500,000-volt transformer. As a result of having these transformers many people from all over the country were sending us insulators for testing. Therefore, the present insulator is the development of a quarter of a century and it is not a recent thing in my mind, except in its final form at the present time. It has been a gradual development of thought and experience through a great many years.

The pin type of insulator reached its limit and we all recognized the importance of the work that was done in producing the multiple-unit string in carrying us past a stumbling block at that time, and, in the present form of insulator the importance of the unit is recognized. The difference is mainly in producing a unit for a higher voltage per unit and an insulator which gives a uniform distribution of potential along its insulating surface, and terminal connections for that surface such that corona is eliminated until very nearly the flashover voltage. It is that early development of corona, preceding the final voltage limit,—a result of an excessive gradient, which overthrows the whole dielectric field and fixes a lower flashover limit.

The question of puncture, as we have had to deal with it in the porcelain insulator in the past, where at the head you have a relatively thin layer of dielectric stressed to the maximum, is eliminated in the present design; we have wholly different relationships.

If we plot flashover voltage against spacing between the metal surfaces we have a curve for dry flashover as shown in *A* of the accompanying illustration. With 18½ in. spacing between metal surfaces on the unit, we have about 300,000 volts flashover value. Now, you can reduce that to 8 or 9 in., and you then have the more pronounced characteristics of the sphere-gap, higher kilovolts per inch for flashover, and only a very small reduction in the total flashover voltage; with a very much lower spacing. With that smaller spacing, you will have capacity variation.

In reference to Mr. Wood's point of a standard unit, or of a variety of units, it may be a question for the operating engineer to answer whether he cares to use two standard units, with flashover of 300,000 volts each, or two together in series, as we saw yesterday, with a flashover of 520,000 volts, or whether he will use a shorter stick for one or both of those units and a more uniform distribution.

The wet flashover values run along in a flat curve as shown in *B* so that with the greatest spacing the ratio between wet and dry—for instance on the unit we saw yesterday,—is in the neighborhood of 82 per cent. As you go to lower spacing you have a higher ratio between the wet and dry flashovers. In fact, in many laboratory tests we have had unity ratio, when we had the right kind of water. With ordinary tap water and rain it will run up to 90 per cent or 92 per cent.

Now, I have not had as many rocks thrown at this, as many rifle shots at it, as I hoped might be experienced. Some of you saw the demonstration of a single unit in Worcester, many of you saw the demonstration of two units in series yesterday afternoon (at Pasadena). Perhaps, I ought to say, as it was difficult to announce the matter there, that on the two units that were hung up in the laboratory, were applied 520,000 volts before flashover and I presume you noticed that up nearly to the point of flashover you could not see (in a dark room) the location of the insulators. That showed that we really have succeeded in the elimination of corona to way above working voltage. That is one of the features that makes it possible to consider the introduction of such a material as impregnated wood. We should not consider that the experience of the past, under *other* conditions, is necessarily applicable in *this* case. We all know that the use of wood insulation has been disastrous in most cases, especially, where exposed to the weather. Nor are we limited to the use of wood in this case.

The insulating member, or stick, is placed in what I have called a hollow electric field. That is, the shape of the metal hat and the torus below it is such that we have entirely surrounded the wood stick by a field of higher potential and maximum gradient than that which the insulating surface sustains. We also have an insulating surface parallel to the lines of force along that surface which gives us a uniform distribution of potential along the surface. Now, the presence of the field of higher gradient outside of the insulating surface accomplishes two or three things. It, to a certain extent, deflects particles, moisture, dirt, even heavy particles, as pieces of straw, etc., so that they do not come in contact with the stick. I don't mean to say that it will wholly *prevent* moisture, or a heavy fog, settling on the stick, but it will minimize this effect and the stick will withstand the discontinuous moisture. You may have certain conditions in manufacturing, particularly in chemical manufacturing areas, or where exposed to fogs,—especially where, coming with other

deposits, where it may be necessary to clean the surface periodically, as is the case with other insulators but this insulator provides as good a surface for cleaning as I can imagine, if that proves to be necessary. Only experience in varied service will tell us what the needs will be in that respect.

You understand, I am sure, that this insulator has just passed through what I consider its developmental stage. We have now had, for some months, a group of these insulators, of which I will show you slides, on a tower in the Pittsburgh area where they are at line voltage and subjected to the Pittsburgh atmosphere near a large foundry where foundry gases are blown across them. Since I left Worcester I have received word that after several months in that service they have just passed through a period of 60 hours of continuous rain, fog and wind and there have been no failures as yet.

Now, as to the life of the sticks, we feel confident as to the thoroughness of the impregnation of the wood. The question of the weathering of the surface of the stick can only be told by service. Last winter we, for a number of months, had sticks soaking in tepid water throughout the day, freezing at night, and subjected to flashover tests twice a day. Now, I don't know how long a life period that would equal. Those are the facts of the case; you can form your own guess as to what length of time in normal service that would mean.

The plan that I hope to follow with this insulator is not to recommend its application on power lines at the present time with the view to superseding present methods of insulation. That would be very unwise. Following these preliminary service and life tests, I hope to place them in limited numbers, upon a number of service lines, under a variety of climatic and other conditions, so that the experience in such service will tell whether it is a better, a cheaper, or more desirable insulator for general power line application than those now in service. That will *then* be a question that anybody can answer for himself. Of course, I would not do this except that the evidence at the present time has impressed me of the very excellent probabilities before the insulator.

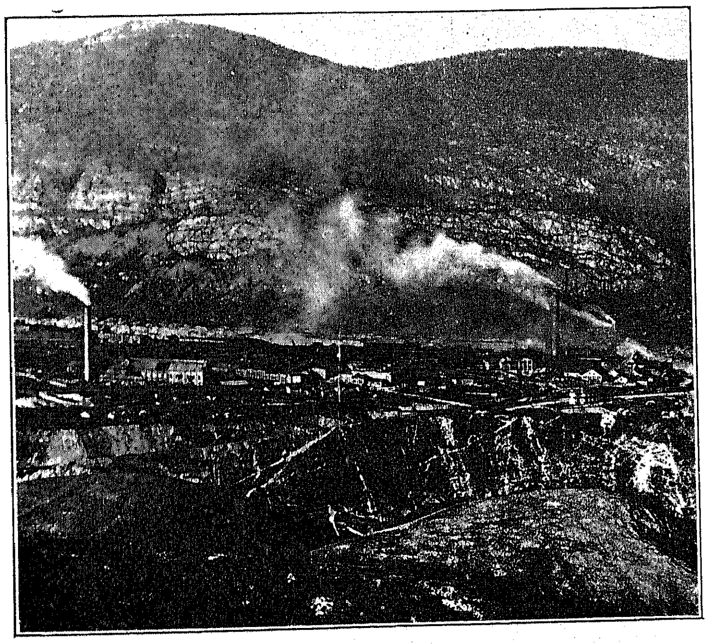
Electrical Equipment

Consolidated Mining and Smelting Company's Zinc Plant, Trail, B. C., Canada

BY R. N. LOCKYER
Member, A. I. E. E.
Asst. Supt., West Kootenay Power and Light Company, Bonnington Falls, B. C.

Introduction

THE great demand for supplies of zinc required in the manufacture of munitions, especially in the manufacture of brass shells which contain 66.6 per cent copper and 33.4 per cent zinc, led to an investigation in 1915 to ascertain the feasibility of producing metallic zinc in Canada. This resulted in the establishment of a zinc plant by the Consolidated Mining and Smelting Co. of Canada at Trail, B. C., at an initial cost of $2,500,000.



General View Trail Plant

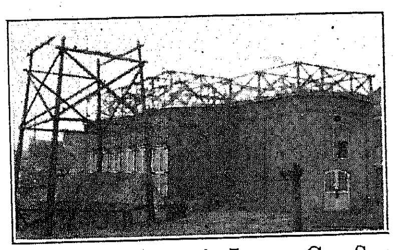
The production of zinc was increased from a daily output of 1000 pounds (453 kg.) to the present production approximately 80 tons (72,500 kg.) daily, having a purity of 99.9 per cent. The present annual capacity of the zinc plant is approximately 29,200 tons (29,500 metric tons). The starting up of the electrolytic plant at Trail and the almost simultaneous starting of one at Anaconda, Montana, and the placing of orders with both of these plants, broke the German strangle hold on high grade zinc, in fact other grades as well.

Until about 1915 all commercial zinc was produced by distillation, a process involving many difficulties. The resultant product was comparatively impure and there was also a very decided factor of loss due to certain peculiar tendencies of zinc vapor to solidify in undesirable forms. Today a great deal of the zinc which is produced in North America is deposited electrolytically; a process which results in a purer and more homogeneous product and therefore, one which is more desirable in the trades than that made in the old way.

It is not the intention of the writer to devote for any length of time on the zinc process as this article is intended to cover only the electrical equipment of the plant. For a complete description of this process the reader is referred to an article by L. W. Chapman in the *Chemical and Metallurgical Engineering Magazine*, August 11th, 1920, Vol. 23, No. 6, pages 227-237.

Power Supply

The power supply is derived from a distributing station located between the two generating rooms. This station being the property of the West Kootenay Power & Light Co., a subsidiary of the Consolidated Mining and Smelting Co. The Power Company is one of the pioneer concerns engaged in hydroelectric development in British Columbia which has played such an important part in the mining development of the Kootenay District, in fact without such power this development would have been impossible.



West Kootenay Power & Light Co. Substation

Power is transmitted to Trail, a distance of approximately 32 miles (51.2 km.) from the company's hydroelectric plant, over two transmission lines at a pressure of 60 kv.

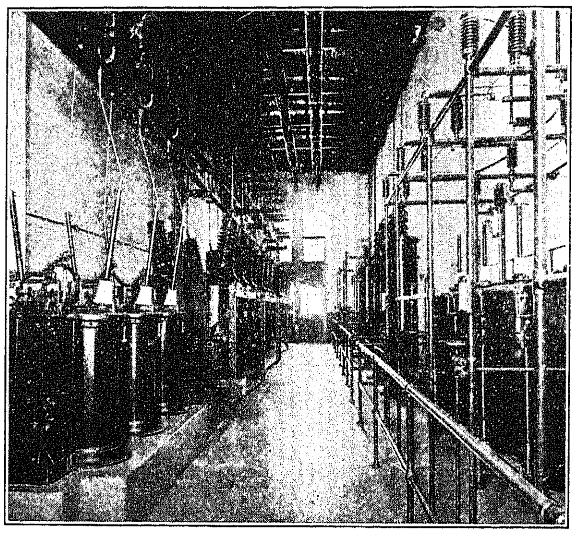
The substation is of solid brick construction, the incoming lines entering through the roof. The interior is subdivided into three sections, namely, transformers, high-tension switches and lightning arresters, and low-tension bus structure with the low-tension switches and control panels.

Electrical Equipment in Distributing Station

The transformers are of the Canadian Westinghouse Company's manufacture, each bank, of which there

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October, 13-17, 1924.

are two, is located in a fire proof compartment and consists of three single-phase, 2500-kv-a. water-cooled, oil-insulated transformers with primary and secondary connected delta. It is to be noted that no spare transformers have been installed. In the event of a transformer breaking down, service would be restored by operating the damaged bank open delta while repairs were being made. Each transformer is mounted on a truck. The high-tension switches on both the incoming lines and transformers are of the Canadian



High-Tension Room, West Kootenay Power & Light Co. Substation

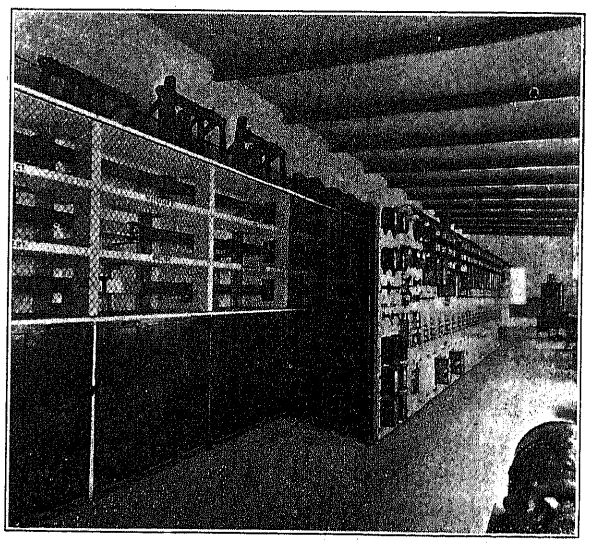
General Electric Company's manufacture; these being their form K-26-70 kv.-300 ampere. These switches are equipped with tank lifters, and are protected through inverse time limit series trips mounted directly overhead on the bus structure.

Two sets of aluminum lightning arresters protect the two incoming lines. Directly adjoining, the high-tension room is the low-tension bus structure which is of concrete. On this structure are mounted all the low-tension switches. Two form *H*-6 connect the secondaries of the transformers to the bus. Eighteen form *H*-3 switches are on the outgoing feeders, connecting the smelter substation and Lead Refinery substation. There are thirteen motor generator feeders and a circuit for lighting the city of Trail. All the switches are protected by time limit overload relays. A d-c. panel is mounted at one end of the control panels from which is operated a 5-kw. 125-volt motor generator set for charging a 60-cell storage battery. This battery energizes the operating bus for the remote control switches as well as supplying an auxiliary lighting source in case of power failure. This is accomplished by a quick throw over switch operated by a no-voltage release. The city lighting system is fed from a 3-phase automatic induction voltage regulator set for 10 per cent boost or buck. The street lights are controlled from a series mercury arc rectifier operating magnetite arc lamp.

Some mention should be made of the two 20-kv. lines passing through this station. Up to the time of building the Zinc Plant, the only lines coming into Trail were the 20-kv. lines feeding directly into the Consolidated Mining and Smelting Company's substation which has now been dismantled. These lines originally fed from No. 1 power house, but as the load conditions very seldom require both plants to be in operation at the same time, these lines are usually supplied from a 20-kv. bank of transformers in No. 2 power house.

In the event of conditions necessitating the operation of both plants, No. 1 plant can be paralleled with No. 2, or No. 2 can drop the load on the 20-kv. lines, leaving No. 1 plant to handle this. Generally No. 1 and 2 plants are operating in parallel through Trail, all phasing being done at the power house. These lines are controlled from Westinghouse Type "G. H." Oil circuit breakers and protected by reverse power relays.

The total maximum demand from this station to date has been 20,900 kw., in other words the equipment has safely withstood an overload of 22 per cent. R. A. Ross, M. E. I. C., Montreal, acted as consulting engineer for the power company.



Low-Tension Room, West Kootenay Power & Light Co. Substation

Generator Rooms

The generator rooms at Trail, although they do not embody any new features, are of interest due to the fact that it is another application of electric power to a new industry. An industry that has sprung up since the commencement of the late war. They are of hollow tile and steel construction. No. 1 Generator Room is 266 ft. (81.1 m.) in length and 30 ft. (9.14 m.) in width. No. 2 generator room is 218 ft. (66.4 m.) in length and 30 ft. (9.14 m.) in width. The floor and foundations of the motor generator sets are solid

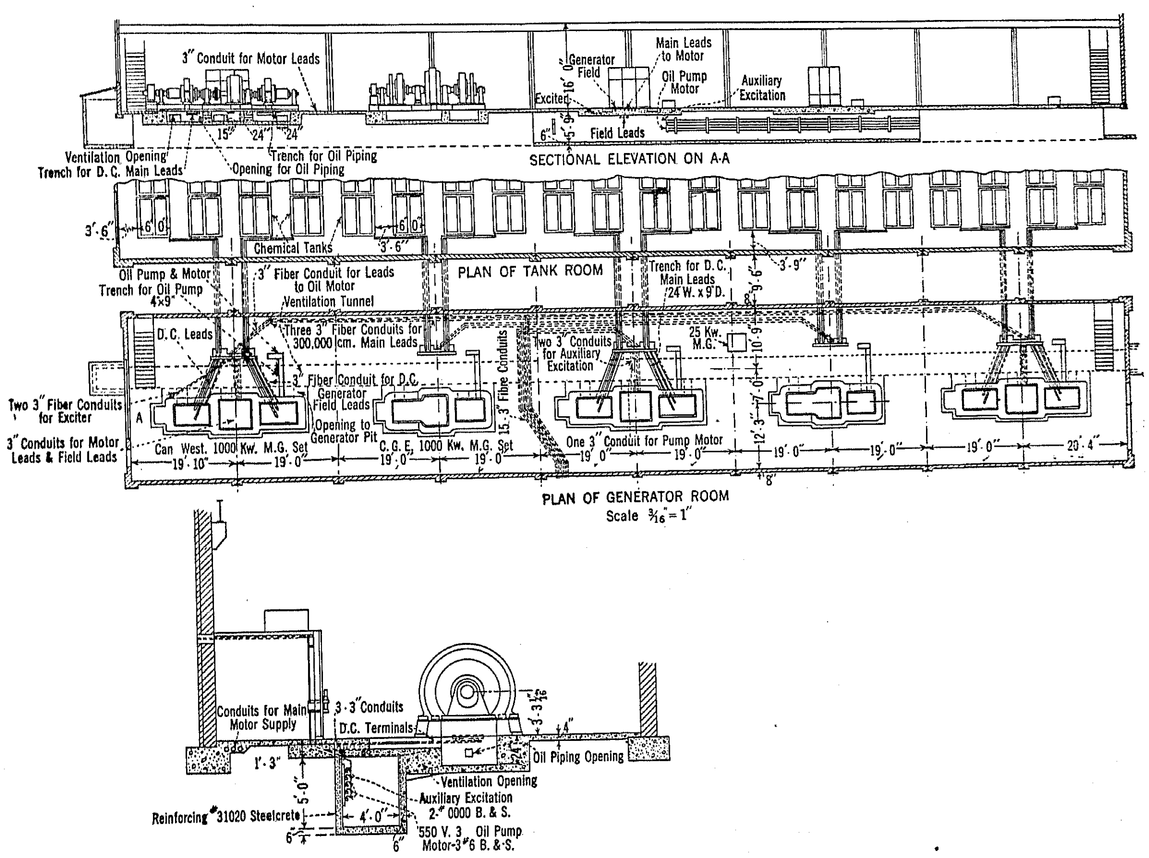
concrete. For the purpose of erecting and facilitating the making of repairs, these rooms are served with a 10-ton (9075 kg.) electric crane, having an electric travel and hoist, the traverse being manually operated. No. 1 Generator Room has seven double-ended sets while No. 2 has six, each consisting of 2500-kw. 125-volts, 4000-ampere (maximum) generators. The two d-c. generators are direct-connected to a 1150-kv-a. synchronous motor, the exciter for which is connected to one end of the shaft. All the machines are arranged longitudinally with the building as can be seen from the photograph.

ventilation. Approximately 30 tons (27,400 kg.) of copper was used in connection with this installation.

Motor Generator Sets

Let us now turn our attention to the motor generator sets. The over-all length of the Westinghouse bed plate which is one single casting is 28 feet (7.62 m.) and the total weight, including the oil pump, is approximately 71,000 lbs. (32,200 kg.) or 71 pounds (32.2 kg.) per kilowatt. Holding-down bolts are used, the bed plate being grouted in on top of the foundations.

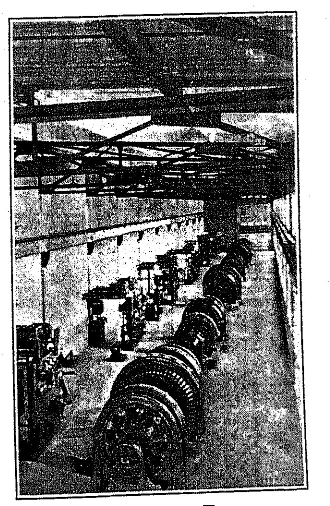
The generators are 8-pole shunt-wound interpole



The switch boards are located between the sets and the wall adjoining the tank room. This arrangement being decided upon so as to minimize the amount of copper bus used in connecting the tanks.

In the early development of the plant, considerable thought was given to the arrangement of a transfer bus in order that any set of tanks might be connected to any machine, thereby permitting more frequent inspection of the units. But when the yearly interest on a bus of the required size and the high cost of copper at that time was considered, it was decided the investment would not be justified.

The d-c. bus bars from the generators to the switchboards and from the switchboards to the tanks, are made up of four 5-16 inch (8 mm.) x 4 inch (10.1 cm.) copper bars separated by 5-16 in. (8 mm.) spacers for

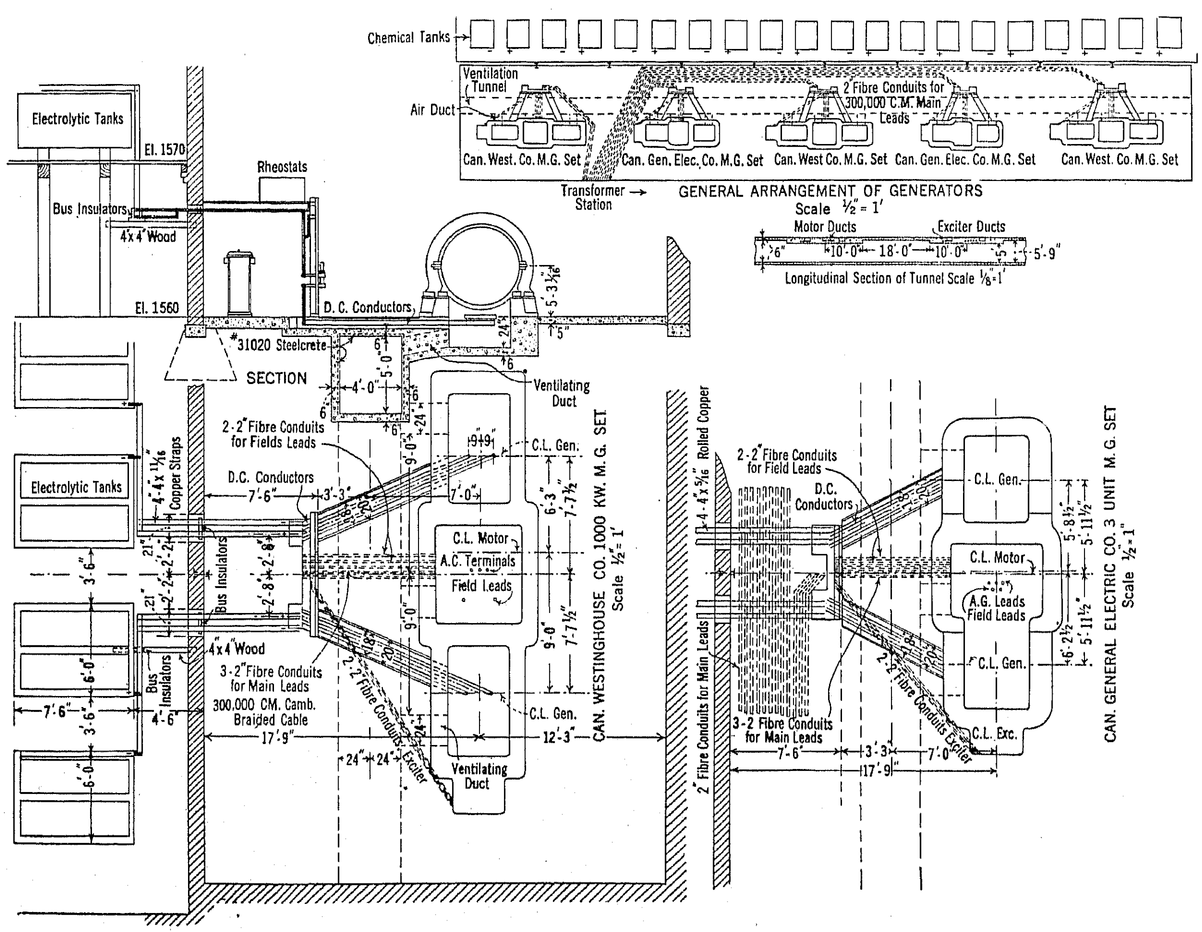


Generator Room

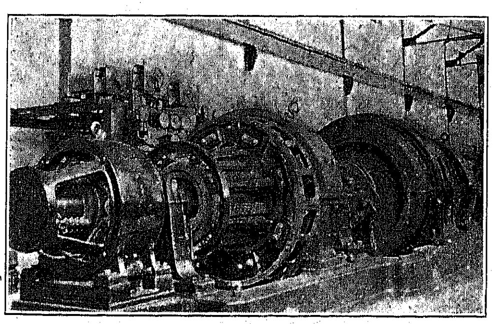
type of 500-kw. capacity and have a voltage regulation of from 50 to 125 volts. The speed is 600 rev. per min.

Two noteworthy features are the commutator and the interpole or commutating pole winding. The length of the commutator is 2 ft. 2.5 in. (67.2 cm.). The diameter is 1 ft. 10 in. (53.3 cm.) The peripheral speed is 3970 ft. (1210 m.) per minute.

With commutators of this length and speed, it has generally been found necessary to shrink a steel ring around the center of the commutator, but in the case



of three machines, this has been overcome by the use of three "V" rings which allows the whole face of the



CANADIAN WESTINGHOUSE MOTOR-GENERATOR SET

commutator to be utilized for the collection of current. 'll commutator bars, of which there are 128, are equipped with radiators to aid in expelling the heat generated.

"Le Carbone" soft graphite brushes are used, operating at a current density of 63.5 amperes per square inch (12.5 amperes per sq. cm.). A spring tension of 1.25 pounds per square inch (0.15 kg-m. per sq. cm.), *i. e.*, 1.75 to 2 pounds (0.79 to 0.90 7 kg.) per brush has proved to give the best satisfaction. This, of course, necessitates having the mica undercut to a depth of about 1/16 inch (1.5 mm.). The peripheral speed is sufficiently high to prevent dirt from sticking in the recesses. The commutators revolve in a leading direction, *i. e.*, they revolve from the heel of the brushes. This has given the best possible wear on the brushes and has minimized their tendency to lock in their holders.

The interpoles are arranged so that the coils receive only one half armature current. This being attained by dividing the total number of interpoles into two sets and connected series multiple. The field frame is of high grade iron and the poles so proportioned so as to minimize the armature reaction.

The shunt field winding is separately excited. The four pillars which support the bearings are insulated from the bedplate, thus preventing the circulation of stray currents through the bearings which would have a tendency to pit both the shaft and the bearings.

The generators were subjected to an insulation test

of 1500 volts a-c. for one minute in accordance with the rules of the A. I. E. E. The insulation will stand 90 deg. cent. without injury. The generators have an efficiency of approximately 91 per cent at full load.

As can be seen, the synchronous motors are located in the center of the set, being 1475 h. p. output, 1158 kv-a. input, 3-phase, 2200-volt, 60 cycles, 600 rev. per min. 314 amperes per terminal.

The stator or armature winding is a twelve-pole single-star connection. The stator consists of a cast iron frame. The inside of the frame being provided with ribs which have dovetails machined in them to receive the armature punchings which have dovetails to correspond. The outside of the frame is provided with large ventilating ducts to provide a good circulation of air. The armature core, which consists of built-up laminated sheet steel, is held in place by end plates, there being ventilating spaces provided at intervals across the armature.

The armature coils are machine wound and of the diamond type. These are formed and insulated before being placed in the slots, there being two in each slot held in place by fiber wedges. The ends of the coils project beyond the armature and are securely corded to a cold rolled-steel ring which is supported by cast iron arms bolted to the frame. This has been done to protect the coils against any undue magnetic strains.

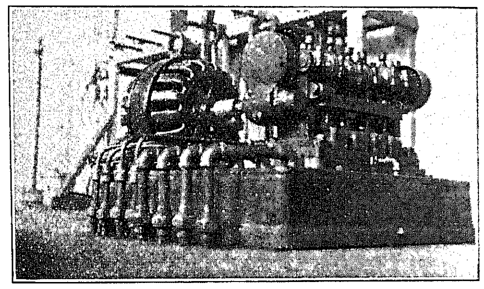
The starting winding is of the interconnected poleface or amortisseur winding.

The rotor consists of a cast steel spider with laminated steel poles and a copper strap winding for the field. The spider has machined dovetailed slots into which the dovetail projections of the poles are fitted and are held firmly in place by tapered keys. A small end plate is bolted on each side of the pole to prevent the keys from moving sideways. These plates are made wider at the top and adjusted in a radial direction so as not only to support the field coils on the bottom side, but also to make the coils fit the poles snugly and firmly, thus eliminating any trouble due to loose field coils, especially after the motor has been in use for a long time.

The bed-plate is so arranged that the armature can be slid clear of the rotating field by means of jack screws for this purpose which is of aid in making inspections and repairs.

The motor was subjected to the following insulation test as recommended by the A. I. E. E., field 1500 volts a-c. for one minute and armature 5000 volts a-c. for one minute. The operating efficiency of the motor at full load is approximately 94.5 per cent.

The exciter is a 125-volt, 200-ampere type "*S A*" 4 poles, 2 interpoles, compound-wound generator mounted on the extreme end of the shaft, in other words overhung. To minimize the starting current to approximately 400 kw. An oil-jack or high-pressure duplex pump forcing a film of oil under the bearings at a pressure of 1000 lb. (458 kg-m.) per sq. in. (6.4 sq. cm.) has been used. This eliminates the static friction to such an extent that the whole revolving member whose weight is approximately 9 tons (8225 kg.) can readily be turned by hand. This oil-jack is on the floor at the left hand side of the switchboard. The whole pump unit is self-contained, the base of same being the oil reservoir having an approximate capacity of 10 gal. (378 liters). The pump is driven with a 1-h. p., 110-volt, 3-phase type C. C. L. induction motor connected to the pump through a worm gear. The

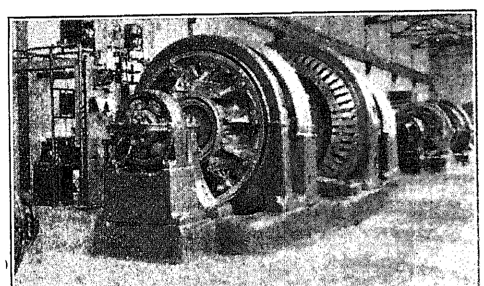


OIL-JACK

pump itself has four cylinders, each cylinder being equipped with high-pressure relief valve.

CANADIAN GENERAL ELECTRIC MOTOR GENERATOR SETS

The over-all length of the Canadian General Electric bed-plate which is built up in three sections, bolted together, is 21 feet, 9 inches (6.62 m.). The total weight of the set is approximately 81,000 pounds (36,700 kg.) or 81 pounds (3.6.7 kg.) per kilowatt. This bed-plate employs no holding down bolts.



CANADIAN GENERAL ELECTRIC MOTOR-GENERATOR SET

The generators are 10-pole shunt wound machines of the interpole type and of 500 kw. capacity. They have a voltage variation of from 0-125 and speed of 514 rev. per min.

The interpoles received full armature current, consequently are of a massive construction. The length of the brush bearing surface on the commutators is 1 foot, 7 inches (48.1 cm.), diameter 2 feet, 6 inch (76 cm.), giving a peripheral speed of 4025 feet (1228 m.) per minute. The commutator is built up of 140 bars and revolves in a leading direction.

The commutators are operated with a graphite

brush manufactured by the Morgan Crucible Company, having an operating current density of 47.6 amperes per square inch (12.2 amperes per sq. cm.). The spring tension being 1.5 pounds per square inch (0.15 kg. per sq. cm.). This, of course, necessitated having the mica undercut.

Note should be made of the strength of the yoke supporting the brush arms; this being a characteristic feature of the machine. The field frames and brush yokes are split horizontally which is of great assistance during erection or the making of repairs. This feature is also found on the Westinghouse sets. The bearings for both makes of machines are two part and are provided with oil ring lubrication, together with sight feed oil gages.

The temperature rise after operating at full load is in the armature 40 deg. cent., in the commutator 55 deg. cent. and in the fields 40 deg. cent. The generator efficiency at full load is 92 per cent.

The motor of this set is a Type *A T I* 1150 kv-a., 2200 volts, 60 cycles and runs 514 rev. per min. Two bearings are insulated from the bed-plate to prevent the circulation of shaft currents.

The stator winding is a 14-pole single-star connection. The bed-plate is so arranged that the armature may be slid clear of the revolving field, if necessary. The starting winding is of the interconnected pole-face type, the bars being of a special high-resistance monel metal alloy.

The operating efficiency of the motor is 95 per cent at full load. The exciter which is a 126-volt, 11 kw. six-pole machine is mounted on the end of the shaft.

Artificial Loading of Generators

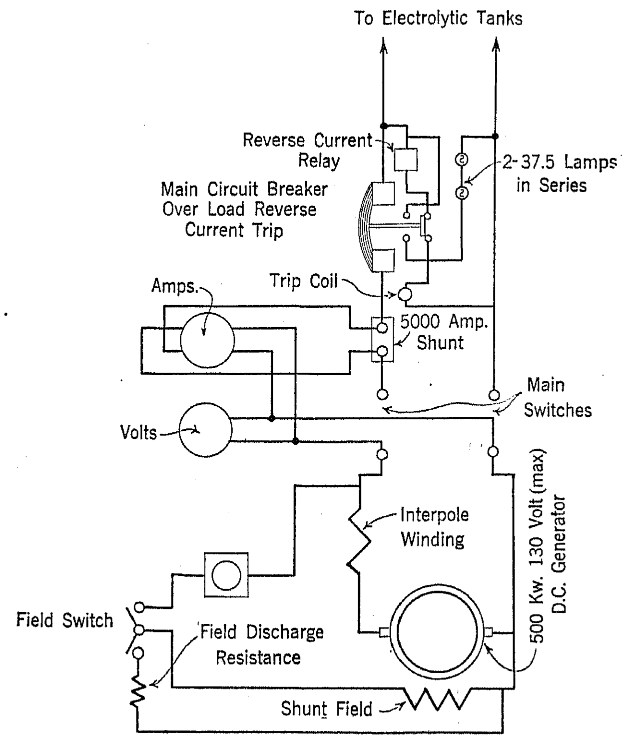
A noteworthy feature during construction was the ease with which the d-c. generators were artificially loaded before going into service, this being done principally for seasoning the commutators. It was only necessary to insert jumpers connecting the bus bars of each generator in multiple and apply the loading back test, commonly known as the "Hopkinson" test. The current taken by the motor being only that required to overcome the losses of the set.

The Auxiliary Exciter

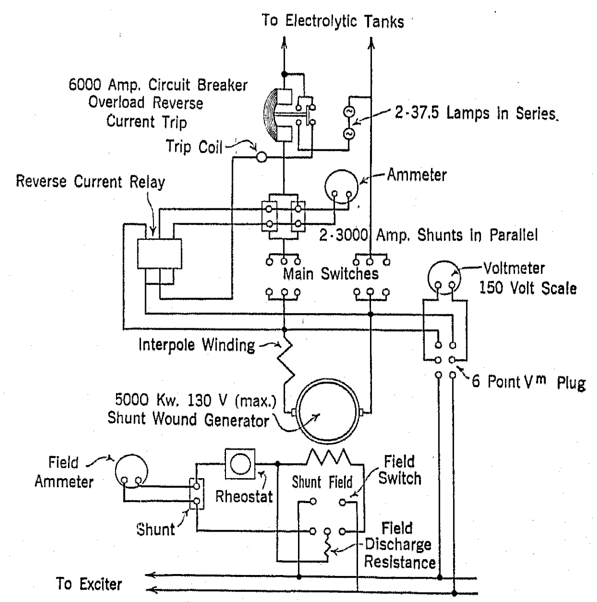
The auxiliary exciter consists of a motor generator set. The motor is of 40 h. p. and is 2200-volt type C. C. L. machine. The generator is rated at 25 kw. and 125 volts. This set not only serves as an auxiliary exciter but also as a source of supply for the cranes in the generator rooms and tank rooms as well as a source of power for a research laboratory. This set is provided with a suitable black marble switchboard on which is mounted the necessary instruments.

Ventilation

The frames of the generator sets and the neutral connections of all the instrument transformers, are securely grounded to a 250,000 cm. ground bus which uns the full length of the generator room. This bus is located in a tunnel under the floor space between the machines and the switchboard. It is 4 feet (1.22 m.) high and 4 feet (1.22 m.) wide, and serves for two purposes. One of these is that it contains the auxiliary exciter bus as well as a 3-phase, 110-volt circuit for the



Canadian General Electric Wiring Diagram



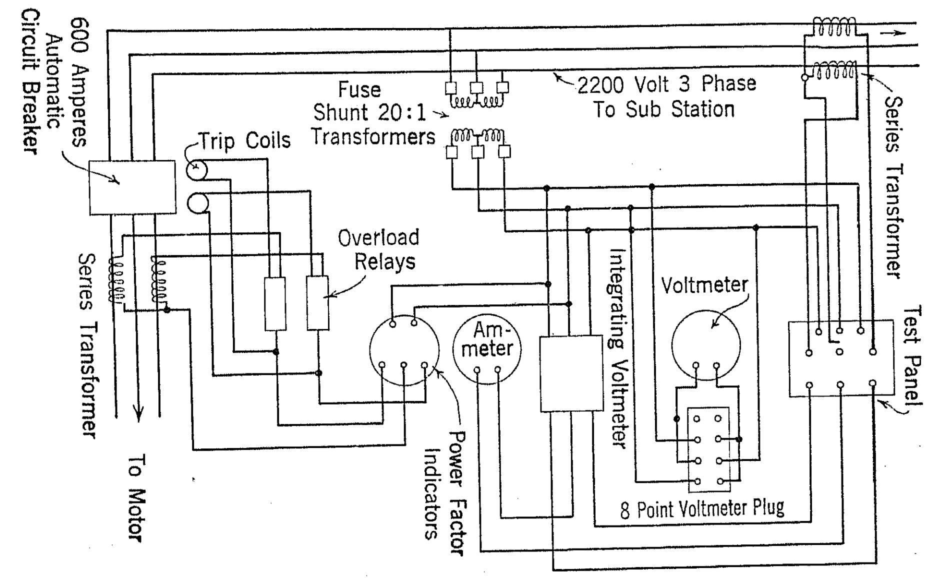
Canadian Westinhgouse Wiring Diagram

Westinghouse oil pumps, that it also contains the station lighting circuits.

For the purpose of ventilating the machines, air is drawn in through ducts connected to the tunnel; each motor and generator having its own duct, and the warm air is exhausted through cupolas on the roof.

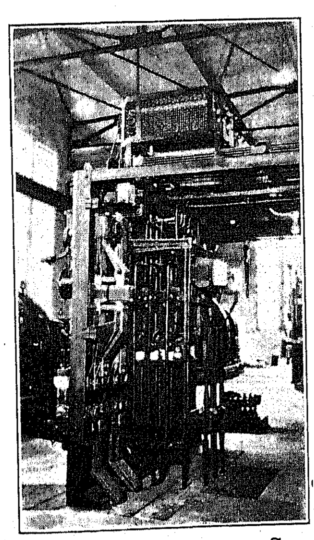
Switchboards

The switchboards are of the standard three-panel type on which is mounted the complete apparatus for the control of the sets. On the generator panel is mounted an ammeter which is connected in the tank circuit. These panels are equipped with a reverse current feature adjusted so that in case of power failure or the motor dropping off the line, the counter e. m. f. of the cells would not motor the set by acting as a primary battery. This counter e. m. f. is made use of as an auxiliary lighting source, each switchboard being equipped with lights, receiving current from the tanks

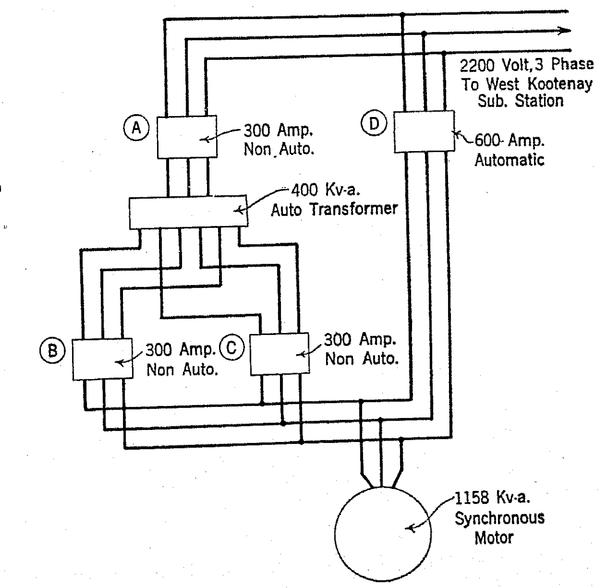


Instrument Wiring, Canadian Westinghouse Switchboard. Motor Panel

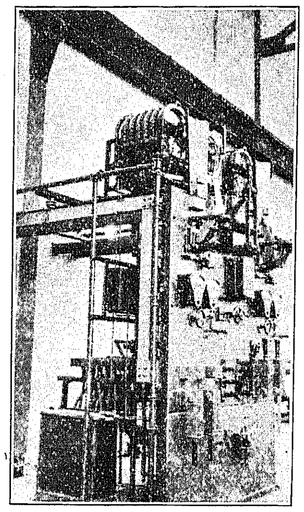
they supply. This is accomplished through a small automatic switch mechanically connected to the d-c. breakers which in turn are controlled from the reverse current relays. The a-c. or synchronous motor panel is marked by its simplicity; in fact, simplicity is one of the outstanding features of the whole plant. On the upper portion of the panels are mounted the indicating instruments. Test blocks have been installed, thus permitting the checking and testing of instruments under load. The motor is protected by inverse time limit alternating-current overload relays. The motor panels of the two manufacturers differ in some respects. With the Westinghouse panel the switches are mounted directly behind, one a Type B-non-automatic, 2500-volt, 300-ampere and the other a type B automatic oil circuit breaker of 600 amperes at 2500 volts. Two type *B* non-automatic, 300-ampere, 2500-volt oil circuit breakers are mounted on the wall directly at the rear of the switchboard over the auto-transformers and are mechanically connected with operating handles on the front of the board by bell



Rear Canadian Westinghouse Switchboard

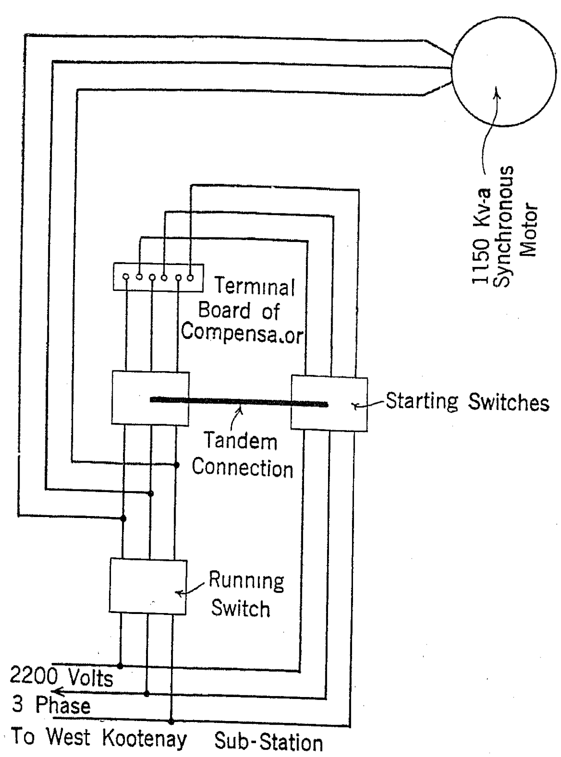


cranks and connecting rods. The 300-ampere non-automatic switch mounted directly at the rear of the panel is the magnetizing switch for the primary of the auto-transformer and is only in service during the period of starting. The next adjacent handle is the



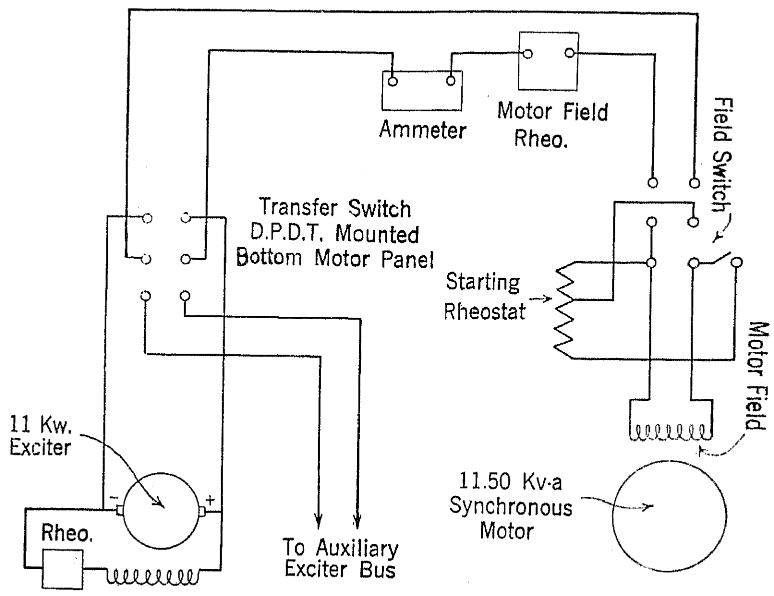
Canadian General Electric Switchboard

first or 50 per cent tap, *i. e.*, 1100 volts. The next handle is the 70 per cent tap or 1540 volts when 2200 volts is impressed on the primary. These switches are all mechanically interlocked to permit the proper sequence of operation. The auto-trans-



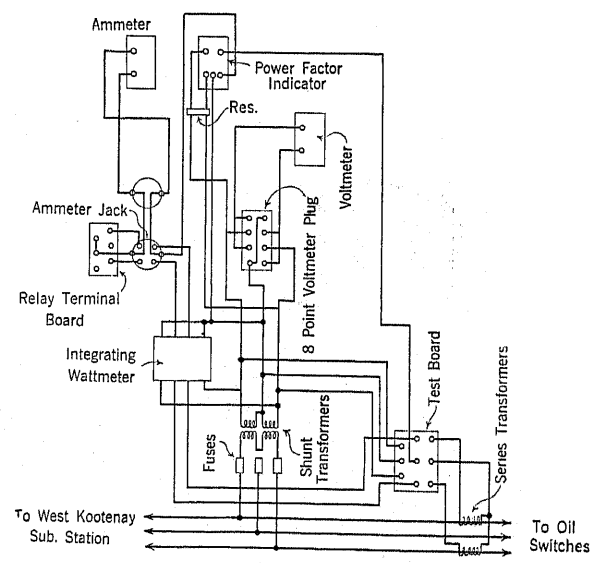
former, capacity 400 kw. is a self-contained, 3-phase oil cooled transformer with various taps having been brought out so that the following voltages may be obtained, 330, 485, 595, 770, 1100 and 1540.

The procedure of starting the sets is very simple. The motor being started as an induction motor, the rotor being equipped with an interconnected pole-face winding. After the machine has attained synchronous speed this winding acts as a damper to retard any



tendency to hunt. The revolving field is shunted through a 3.1-ohm resistance to decrease the induced voltage in the field at the start to 85 volts.

The Canadian General Electric switchboard is very similar to the Westinghouse with the exception of the



Instrument Wiring, Canadian General Electric Switchboard

motor panel. A unique feature of this board is the carbon break field switch mounted at the rear of the panel and operated from the front by means of spade handle and connecting rod. Only three oil switches are required; the magnetizing and starting switch are

mechanically connected in tandem, *i. e.*, they operate simultaneously. The method of starting is practically similar to that of the Westinghouse set. The motor being started as an induction motor during which time the rotating field is shunted through a resistance of 35 ohms. This reduces the induced voltage, which is due to the transformer action, to 850 volts at the moment of starting. On the motor reaching full speed, the revolving field is energized to full strength, *i. e.*, the field current required to maintain unity power factor at no load. When this is accomplished the motor is connected to the line. The motor attains synchronous speed in approximately sixty seconds. The switches are mechanically interlocked making the board as fool-proof as possible. The motor is protected through a double pole, overload inverse time limit relay operating a d-c. tripping coil.

Power Cables

All the power cables run from the Power Company's switches to the motor generators. They supply through 4-in. (10.1 cm.) "Orangeburgh" fiber ducts embedded in concrete under the floor. These cables are of 300,000 cm. and are insulated with varnished cambric which in turn is protected with a heavy braid impregnated with a moisture-repelling compound.

Load Characteristics

The load, which is wholly a synchronous motor load, is most desirable on account of its great flexibility as a power-factor corrector. This load has been a great help to the power house, cutting down the lagging kv-a. at the generators, which is mostly caused by the rest of the load on the power company's system being inductive. The average power factor at the power house which is 32 miles (51.2 km.) away is 0.98. Excellent voltage regulation is obtained at the power company's substation bus due to this synchronous motor capacity; the voltage never varying more than 2.5 per cent of the normal voltage.

The synchronous motors can be operated as synchronous condensers so long as the armature current does not exceed 15 per cent of full load current and the temperature rise does not exceed 40 deg. cent. If the temperature rise does not come up to 40 deg. cent. 25 per cent increase in armature current is possible.

For electrolytic purposes, advocates of the rotary converter are to be found; their main point of argument being their higher efficiency. They recommend the use of single units of about 5000 kw. capacity. However smaller units in d-c. generators have many advantages over the rotary converter; one of these being the ease with which the d-c. voltage can be regulated. The rotary converter requires expensive inductive regulators or synchronous boosters on the a-c. side also expensive starting equipment when compared with that of the synchronous motor.

With the large units, they are usually operated at about 500 volts on the d-c. side, which of course, means a large number of tanks in series. In the event of a breakdown, in either the tank system or the rotary, a much larger section of the plant is affected than would have been the case had smaller direct-current generators been used. Where a large corrective effect for low power-factor is desired, the rotary converter should not be used as a synchronous condenser, nor is it possible to obtain absolutely smooth operation from a rotary at the end of a long line having a high ohmic resistance. The rotary even with all its latest improvements is still a trouble maker at times and it is a question whether the saving in power brought about by its use will offset the cost of repairs and general up-keep when compared to a direct-current generator driven by a synchronous motor.

In one large plant it has been found necessary to install motor generators of sufficient capacity to keep the zinc from redissolving back into the solution when the rotary converters are down for repairs. To circulate a current to prevent the zinc dissolving, the motor generator would have to be approximately half the capacity of the rotary-converter. This greatly increases the electrical investment with accompanying decrease in earnings per kw. of generating equipment installed.

In the plant under discussion, this protection could be brought about by installing a transfer bus, when the unit shutdown could be transferred over to another generator, thereby not interfering with the operation of the plant to any great extent but as already mentioned it was not considered that the large investment in copper bus would be warranted.

Air Compressors

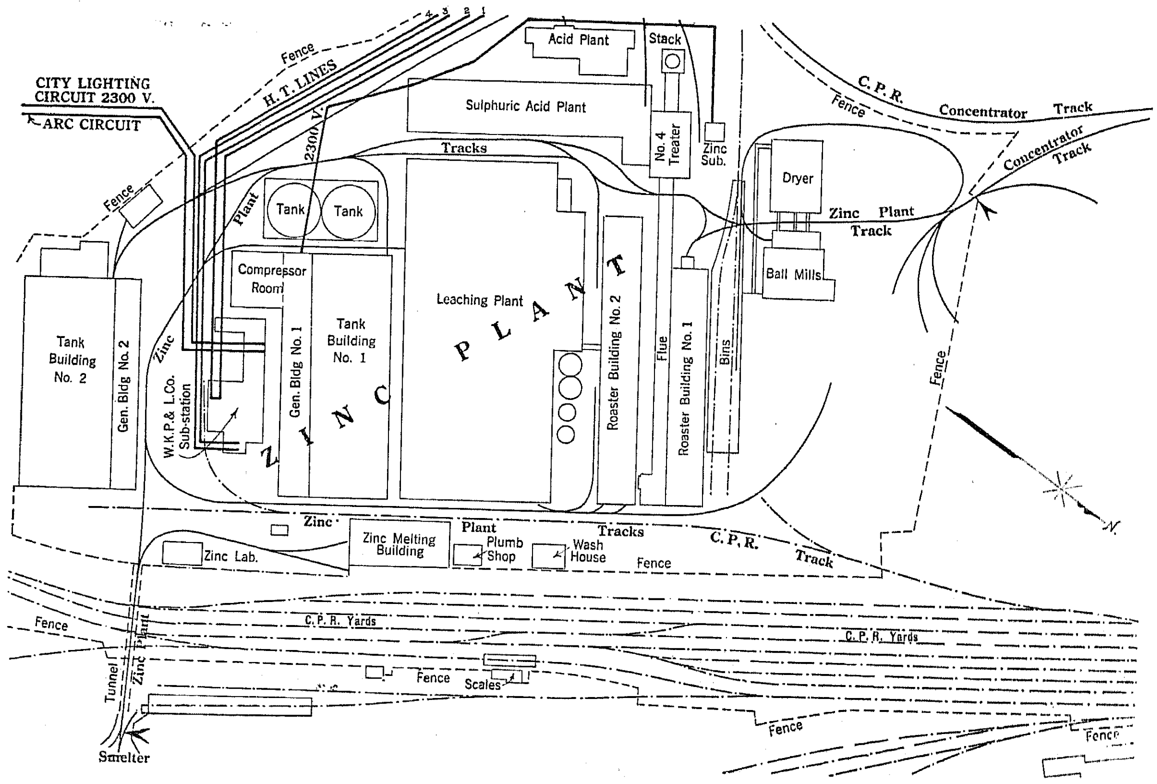
We will now turn our attention to the air compressors which are located at the far end of No. 1 generator room. This wing is of similar construction to that of the generator room. The compressors are operating at an elevation of 1558 ft. (475 m.) above sea level under an atmospheric pressure of 13.9 lb. per sq. in. (978 kg. per sq. cm.) barometer 28.3 in. (717.5 mm.) mercury. These compressors are a very vital part of the zinc plant, as air is used wholly for agitation, and the circulating of the different acid solutions. When the plant was first put into operation, the agitating of the solutions was done mechanically and the solutions were circulated by means of pumps. These pumps soon gave a great deal of trouble on account of the very severe operating conditions.

The first compressor installed was a Rand Ingersoll, with a capacity of 1650 cu. ft. (49.7 cm.) of free air per minute at a pressure of 35 pounds (15.9 kg.) speed 125 rev. per min. and belt-driven from a 200 h. p., 2200 volt, form "*L*" (internal resistance) Canadian General Electric induction motor. As the size of the plant increased, and the demand for air became greater, it became evident that the compressor plant was inade-

quate to cope with the increased demands and therefore it became necessary to install additional units. In the end, the capacity of the first compressor was increased by the addition of an additional cylinder which doubled its capacity.

This compressor has an automatic unloader working on both cylinders; in fact, when the other units are working, this unloader regulates the whole system. This compressor is now driven with a Canadian Westinghouse 300-h. p. type "C. C. L." 2200-volt, 490 rev. per min. induction motor. The motor is controlled from a panel on which are mounted, the starting switches, instruments, relays and low-voltage release.

The second compressor is of particular interest as this machine has been practically rebuilt, being taken from one of the company's mining properties where it had been operating as a steam unit for a number of years. It is a two-cylinder unit and by various valve arrangements can be operated; compounded, two cylinders in parallel or each cylinder separately. Usually it is operated compounded with a capacity of 3200 cu. ft. (90.5 cu. m.) of free air per minute, at a gage pressure of 80 lb. (36.3 kg.). With the two cylinders in parallel, the capacity is 4800 cu. ft. (136 cu. m.) at a pressure of 35 lb. (15.9 kg.) speed 67 rev. per min. This compressor is now electrically driven; this being made possible by installing a herring-bone gear on the crank shaft next to the fly wheel. The gear is driven from a pinion shaft connected to the motor through a flexible steel link coupling. The pinion shaft and pinion are in one piece having been machined from a solid steel forging. This unit is driven by a Canadian Westinghouse 600 h. p., 400 rev. per min., 60-cycle, 2200-volt, 144 amperes per terminal, squirrel-cage induction motor. The motor is controlled by a switchboard panel and a 1000 kw. auto-transformer with taps brought out by which the following voltages may be obtained: 650, 935, 1150, 1400, 1700 and 1900. That is when 2200 volts is applied to the primary. The motor is started on the 1400-volt tap taking 200 per cent full-load current and requiring from 50 to 70 seconds to attain full speed.



General Plan. Zinc Plant

No. 3 compressor has a capacity of 2000 cu. ft. (56.5 cu. m.) of free air per minute, speed 150 strokes per minute. This compressor only operates on the high-pressure system at an average pressure of 80 pounds per sq. in. (5.62 kg. per sq. cm.). Like No. 2 compressor, this machine came from one of the company's mining properties; the only change being found necessary was in the remodeling of the valve gear.

A 400-h. p. 2200-volt, wound-rotor Allis-Chalmers induction motor supplies the motive power. The motor is controlled from a suitable grey marble switchboard on which is mounted an oil circuit breaker and a six point Cutler Hammer drum controller, cutting out the different steps of resistance. On attaining full speed, the slip rings of the rotor are short-circuited. The motor has a full speed of 300 rev. per min. The starter being equipped with a "no-voltage" feature.

This compressor is rope-driven, the idlers and the tightning devices being fastened to the roof structure.

The three compressors are on one power feeder from the power company's bus. Each compressor has disconnecting switches connected ahead of the oil switches in order that the switches and starting equipment can be readily inspected.

Industrial Motors

In the rest of the plant there are practically only 550 volts induction motors varying from 5 to 200 h. p.

The 550-volt service is derived from a local substation which is within close proximity of the points of supply. The maximum capacity of this station is 1200 kv-a., there being 400 kv-a. water-cooled, single-phase transformers connected delta-delta. The primary voltage being 2200 and secondary 605. The primary has also a 1990 volt tap. Power is fed to this station over a 500,000 cm. line consisting of two circuits of 250,000 cm. This line is protected with a set of Canadian General Electric aluminum lightning arresters at each end. A three-panel switchboard controls the outgoing feeder circuits supplying, namely, a 1000-ampere circuit to the ball mills, a 600-ampere circuit to the roaster building and a 600-ampere circuit to the leaching plant. Practically all apparatus are individually driven, thereby the operation as a whole is not materially affected by the shutting down of any one machine.

The same reasons that hold for the preference of a-c. to d-c. motors in general industrial work make the a-c. motor more desirable for the zinc plant operation. There being two reasons for this: First, the relatively higher alternating voltage that can be used, *i. e.*, 500 or even 2200 volts in dry places, and second, the greater mechanical simplicity of the a-c. motors, particularly that of the squirrel-cage type which is very rugged and its initial cost, together with maintenance, being low. The operating conditions that exist in a cement mill are practically duplicated in the plant which is being described (see "Motors on Cement Industry" by R. B. Williamson, TRANS. A. I. E. E., Vol. XXXVLL, 1918, page 1241.)

On account of the heavy accumulation of dust in the motor windings which interfere with the ventilation, the machines have to be frequently blown out and cleaned off. It is the writer's opinion that in such places where the dust accumulations are heavy, at times plugging the air-gaps, a motor designed with a wide air-gap would be more suitable. Of course, a motor having this characteristic has a poor power factor, but this could be improved if the correction warranted the investment by connecting a synchronous or static condenser to the feeders supplying the induction motors.

This plant is especially well adapted to take care of power factor correction on account of the large capacity installed in synchronous motors.

Probably the most desirable motor for this class of work would be that of the enclosed type, which would permit a very close air-gap and consequently high power factor. Motors of this type are extensively used in the anthracite coal fields of Pennsylvania.

The argument generally advanced against the enclosed motor is that of the high initial cost, on account of the designer having to be more liberal with iron and copper. If, however, the enclosed motor were equipped with ball bearings, it seems only reasonable that the extra cost would be more than offset by the saving brought about in maintenance.

The roasters are arranged in two parallel lines, seven in one and six in the other. The roasters are of the wedge type; having seven hearths, each hearth having four sets of rabbles operated from the bottom by means of a bevel gear driven from a Westinghouse back geared motor. Coal is used as fuel and the roasters are fired by hand.

The gases issuing from the thirteen roasters feed into a general flue which in turn passes through the Cottrell plant (No. 4 treater). The elementary principles of the Cottrell system of dust precipitation are now generally known so that an extended theoretical discussion would be superfluous. The treater operates upon unipulsating direct current which is supplied from the rectifier room at a potential of 60 kv. The power consumption is 28.5 kw.

The electrical equipment consists of an Allis-Chalmers 38.5 h. p., 3-phase, 550-volt induction motor, a 28-kw. 220-volt, single-phase generator and a high-tension rectifier; all direct-connected so as to operate in synchronism, and an Allis-Chalmers single-phase, 220-volt to 150 kv. secondary connected to operate at 75 kv. Low-reactance transformer capacity 25 kv-a. The transformer is of special design and is constructed in such a manner as to be amply protected against all excessive strains placed upon the insulation due to the electrical surges arising at times from momentary short circuits, or arcing in the treater, as arise continuously from the use of the mechanical rectifier, which makes and breaks contact in the high-tension circuit.

The voltage in the treater is controlled from the switchboard through resistance control by means of which the field excitation in the generator can be varied over a wide range. This controls the generator potential which in turn varies the voltage impressed upon the treater. The voltage in the treater can also be regulated by shifting the position of the stationary contacts of the rectifier relative to the poles of the generator by which the proportion of the current wave can be controlled. This method of regulation, however, is only used for the making of general adjustments and is not resorted to in the course of ordinary operation.

The rectifiers are usually set once and for all in such a manner as to give contact to that part of the wave which will assure smoothest operation when the treater is operating under normal conditions. But when the conductivity of the gases varies radically, it becomes

desirable at times to change the position of the rectifier contacts.

The electrical equipment in connection with the concentrator consists of:

No. of Motors	H. P.	Type	Make	Speed	Motor Driving

The above motors are 550-volt machines with the exception of those marked "X" which are 2200-volt.

The equipment also included two Ding magnetic separators, speed 440, operating on 110 volts d-c. The 550-volt service is obtained from two 30-kv-a., 2200-550 volts (pole type) Canadian General Electric transformers connected in open delta. At the time of writing, a mineral separator consisting of a battery of flotation machines was being installed in direct connection with the leaching plant. This installation will require approximately 200 h. p. in 550-volt induction motors.

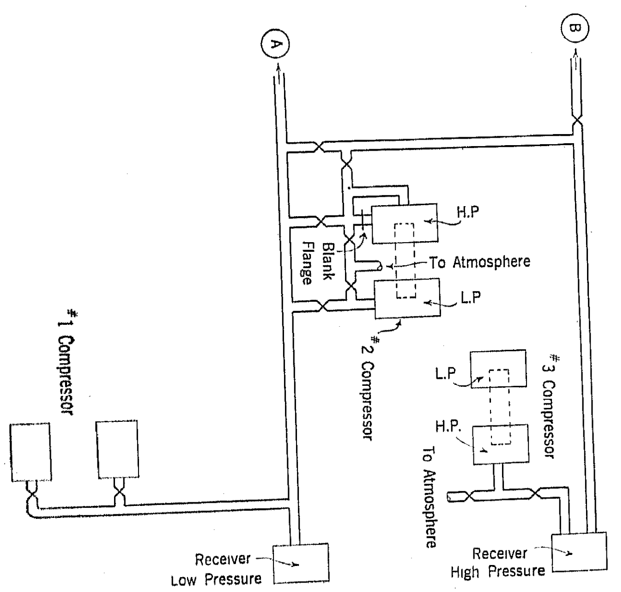
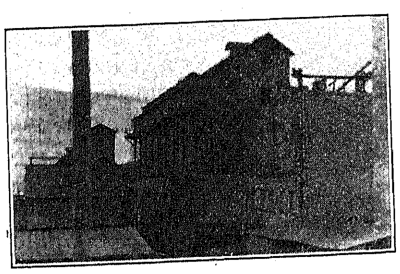
Total	120	22692	186	12609.6 kw.	74.25

The total horse power in motors installed per ton (916 kg.). Zinc is 215.8 h. p., this being figured from the theoretical daily capacity at 100 per cent efficiency, of the plant which would be 105.6 tons. (95,800 kg.). The theoretical capacity is computed from the total ampere-hour capacity for 24 hours of the generator equipment: this being 2,496,000 ampere-hours. Horse power in-



Air Compressor Layout



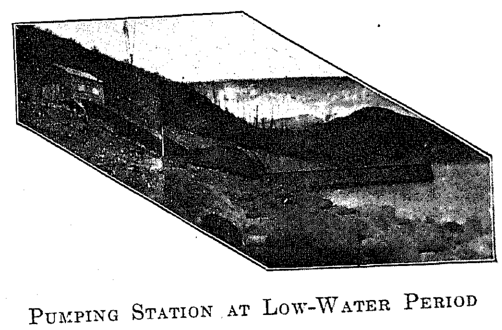
Cottrell Plant

stalled per ton figuring on the actual output of 85 tons (77,100 kg.) would be 266.9.

Water Supply

A very interesting development of vital importance to the continuous and successful operation of the reduction plant is the water supply system, this being of the most modern nature. After having experienced practically a total shut down one very severe winter due to a water shortage, plans were immediately made for the construction of a modern pumping station by which the plant as a whole would always be assured of an ample supply of water. In such a plant as is under discussion, there are very few departments that do not use water.

The pumping station is located about a mile (1.61 km.) up the Columbia River from the reduction plant; this point having been chosen on account of the water there being pure and free from sediment or taint which would make it unfit for domestic or other purposes. Also it is not affected by the drainage or seepage from the plant. The flat or bench on which the plant is situated is about 250 ft. (76 m.) higher than the average water surface in the river. The greatest obstacle to

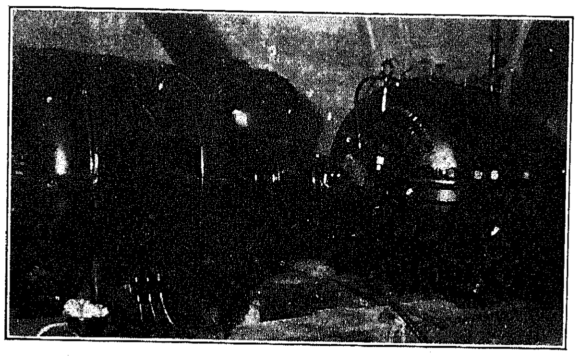


Pumping Station at Low-Water Period

be overcome was the great rise and fall of the water in the river due to the change of seasons and which at this point amounts to about 50 ft. (15.75 m.). The company's engineers overcame all these difficulties and have constructed a pumping station of large size and great strength at a point low enough to draw up the water when the river is at its lowest stage. With a sloping tunnel entrance running from a point up the river bank well above the highest known water mark, the whole has been covered and made absolutely water tight. This tunnel is 82 ft. (25 m.) in length. The pumps are housed in an arched concrete house of extremely heavy construction, being designed so that the total weight of the building and machinery overcomes the tendency of the structure to float at high water and at the same time to safely withstand the great pressure of water when the river is in flood. At

this time there is 30 (9.15 m.) or 40 feet (12.2 m.) of water over the roof of the pump house.

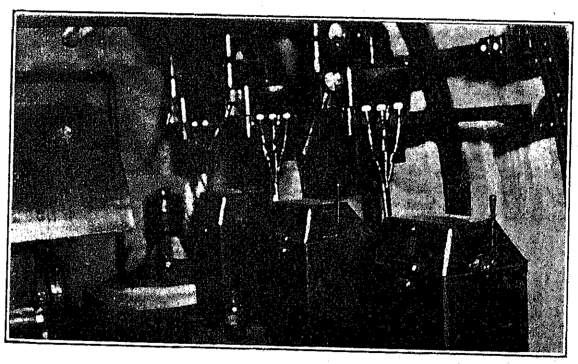
The floor of the pump house is 1350 feet (412 m.) above sea level. The building is 30 feet (9.15 m.) long and 20 feet (6.1 m.) wide with an arched roof 14 feet (4.27 m.) in height and 18 in. (35.8 cm.) in thickness. Through the bottom of the pump house three 10-inch (25.6 cm.) steel pipes lead downward to a covered suction forebay from which the supply is drawn. The



PUMPING UNIT

pumping equipment consists of three 4-stage turbo pumps manufactured by Goldie and McCulloch, Galt, Ontario. These pumps have a capacity of 1500 gal. (5675 liters) per minute against a maximum lead of 337 feet (102.6 m.) Each pump has a 10-inch (25.6 cm.) delivery connected to the 16 inch (40.7 cm.) main which runs up through the tunnel and is connected to the old system.

The pipe lines are built for two pumps, to be operating continuously, the third to act as an auxiliary. Under such conditions the plant has a capacity of over 4,000,000 gal. (15,130,000 liters) every 24 hours, or approxi-



STARTING EQUIPMENT FOR PUMP MOTORS

mately a sufficient supply for a city of 30,000 people.

The pumps are direct-connected to Canadian Westinghouse type *"H S"* induction motors operating at 1150 rev. per min. These motors are rated at 200 h. p. but will deliver 250 h. p. continuously with a rise in temperature of 55 deg. cent. They are started through auto-transformers which are mounted on the floor directly under an oil circuit breaker. The breakers are for motor protection and are equipped with overload tripping coils. An ammeter has been mounted on the lid of each switch. For taking care of all seepage and leakage a 3-inch (7.6 cm.) vertical sump pump is provided; having a capacity of 180 gal. (681 liters) per minute against a maximum lead of 50 ft. (15.25 m.). The pump is driven by a 5-h. p. 550-volt type C. C. L. Westinghouse induction motor and has a speed of 1750 rev. per min. The motor is controlled by an automatic float switch.

For priming purposes when the river is below the level of the pumps, two vacuum pumps are provided, being located on the landing at the entrance of the tunnel. These are shut down from the pump room by push buttons connected to solenoids in connection with the starting switches.

Power is derived from a bank of stepdown transformers, immediately outside the building consisting of three 125 kv-a. single-phase transformers connected delta. This bank is fed from a 2200-volt line running from the power company's substation, a distance of about a mile (1.61 km.). An outdoor type oxide film lightning arrester has been installed to further insure the station against a shut down.

Discussion

W. S. Peterson: I was employed at the plant referred to in this paper, which has rotary converters for its source of direct current. My experience at that plant, was that the rotary converters justify themselves in every way. The losses saved were roughly 5 per cent or 6 per cent of the total power used. The total power was 35,000 kw., which was maintained for 24 hours per day. You can understand that the power saved more than makes up for the increased maintenance of the rotary converter. The final result is greater economy.

I will now explain the use of the motor-generator set to hold the zinc from redissolving into the solution, when the rotary converters were off the electrolyzing tanks. The plant was originally laid out for five tank circuits, with six rotary converters, thus allowing one spare. Due to the necessity for greater production at one time, the plant was operated with six sets of tanks on the six converters, with no spare. The company had some motor-generator sets from an electrolytic copper refinery, which they were not using, and therefore installed them to use temporarily on a tank circuit while a rotary converter was down for repair work. This change probably worked out better than to have another rotary converter, due to the fact that the rotary converters in actual operation were down for repairs and maintenance not much over 1 per cent and certainly less than 1½ per cent of the total time. The main loss in a shutdown was not only the loss of production but the loss due to redissolving of the zinc. By having the motor generator carry one-third to one-half of the normal tank load, this latter loss could be avoided.

In the early years of the operation of this plant there was considerable trouble with the converters due largely to the lack of experience of the operators. For the past three years, I am told, the operation has been such as to give nearly 99 per cent availability per machine which seems remarkably good. Some may feel inclined to disbelieve this, but this record is taken over periods of nine or ten months continuous running at a time when there are no spare machines due to full production being required. A converter would be taken down once every week or ten days for cleaning and overhauling the brushes.

I would say from my experience with this kind of a plant, that the synchronous converter certainly deserves its place there due to its economical operation and is to be considered far superior to the motor generator for that work.

Electrometallurgical Applications

BY J. L. McK. YARDLEY
Fellow, A. I. E. E.
General Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa

Review of the Subject.—*This paper deals with a field of engineering in which electrical, chemical and metallurgical engineers are all interested, and have responsibilities. It contains a discussion of electrical power utilization developments, which are based upon fundamental principles of physical chemistry and electrochemistry. It outlines the particular function of the electrical engineer and indicates his close co-relationship with the chemist and metallurgist in the solution of such industrial problems. It deals only with metals which are ordinarily employed in construction or manufacture and in the production of which large quantities of electrical power are employed. Smelting and electrolytic methods are compared; data and illustrations on plants and equipment for the production of iron, zinc, copper, nickel, aluminum, etc., are included.*

ELECTRICAL engineers may perhaps be said to be inclined to confine themselves to that engineering function which consists of taking power generated by some natural resource and putting it in the form desired for some domestic or industrial use at some location. On the one hand, they are in contact with the mechanical, hydraulic and civil engineers and on the other, with the mechanical, chemical and metallurgical engineers. They are a sort of intermediary and as such, of course, perform an essential service. They are less likely to initiate than the one group and less likely to carry through to ultimate consummation than the other group, power utilization projects. From the one hand, they must take what is given and with the other, they do not equally join in reaping the final rewards.

It is an interesting thing to observe how regularly the electrical engineering student at college studies and absorbs all those laws that have been observed and formulated regarding electricity and then shortly thereafter, deliberately throws many of them away and thenceforth, speaks only in terms of the volt, ampere, ohm, henry, farad, gauss and gilbert, which, indeed, he pursues with relish in devious ways with all the mathematical weapons at his command. It is true that he joins with the mechanical engineer in taking interest in the laws for the conversion of electrical energy into mechanical form and vice versa. Daily, in industrial engineering applications, he converts kilowatts into horse power and horse power into kilowatts.

When considering energy, the electrical engineer seldom takes occasion to go back of the kilowatt hours. Having departed the alma mater, he never speaks more of the unit of energy, the Joule, nor of those electrical units of quantity, the Coulomb, and Faraday. He is not interested in those laws of Gibbs-Hemholtz and Faraday which give the relationship between heat of chemical combination and electricity and connect quantity of electricity with electrolytic production.

Those laws have been abandoned; but let us not think they have fallen upon stony ground or in barren places. Not at all! They are in the arms of the electrochemist and electrometallurgist who esteem them highly and regard them as their very own, the foundation stones of the arts and industries which they have fostered and developed.

It would seem that if he desired, the electrical engineer might have a more equal share with the chemist and metallurgist in those power utilization developments which are based upon the fundamental principles of physical chemistry and electrochemistry. What actually happens, however, frequently, is that the chemist or metallurgist is discovered to know far more about electrical engineering than the electrical engineer does about chemistry or metallurgy, so that he gets charge of the whole undertaking and the electrical engineer is in the position of subordinate.

Inasmuch as the electrical engineer should and must meet with the chemist and metallurgist on a common ground, in those industries based upon physical chemistry and electrochemistry, it is proposed to state and briefly discuss some of the more elemental things, in which electrical engineers as well as chemists and metallurgists are vitally interested, because they constitute starting points in the economic industrial utilization of power.

1. Every chemical combination or dissociation absorbs or gives out a certain definite amount of heat and takes place at either a definite temperature or within a certain temperature range.

2. Some chemical combinations in aqueous or molten solutions are capable of being dissociated or produced by the action of electric current flowing through them.

Upon the first statement is based the practise of smelting; and upon the first and second, the practise of electrolysis. In smelting, energy, whether in electrical form or otherwise, applied in producing the chemical combination or dissociation, must supply that quantity of heat and at that temperature. In electrolysis, the energy required or absorbed is not only determined as in smelting, by the heat of chemical formation, but it is also determined by a fact established by Faraday, that the number of grams of any metal which would take the place of one gram of hydrogen in a chemical combination will be deposited by a

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

definite quantity of electricity called one Faraday (F), in amount equal to 96,540 Coulombs.

The electrical energy absorbed or produced in electrolysis, in volt Coulombs or watt seconds, for the number of grams of the metal in the chemical combination, which is equal to its atomic weight, is $e \times n \times 96{,}540$, where e is the electromotive force absorbed or produced in the electrochemical process and n is the valence or number of bonds uniting the metal with the other elements in the chemical compound. Thus: if electric current be passed through a pure solution of copper sulphate, $CuSO_4$, in water from an insoluble anode to a copper cathode, copper, Cu, is deposited at the cathode and oxygen, O, is liberated and sulphuric acid, H_2SO_4, is formed at the anode. $e = 1.22$ volts; $n = 2$; atomic weight of Cu = 63.57. Then, 63.57 grams of Cu are deposited by $1.22 \times 2 \times 96.540 = 235{,}500$ volt Coulombs, or watt seconds; or, converting to pounds per kw-hr., 1 kw-hr. theoretically deposits

$$\frac{3600 \times 1000 \times 2.2 \times 63.57}{235{,}500 \times 1000} = 2.135 \text{ lb. of Cu}$$

The Gibbs-Hemholtz equation definitely connects electrical energy absorbed or produced in electrolysis with heat of chemical formation and temperature of operation. According to it; $e\,n\,F_{(at\ temp.\ T)}$

$$= 4.187\,Q_{(at\ temp.\ T)} + n\,F\,T\,\frac{d\,e}{d\,T}\;; \quad \text{where } T$$

equals absolute temperature, Q equals heat of formation in gram calories and, since one gram calory = 4.187 Joules, $4.187 \times$ number of gram calorie = number of Joules, or watt seconds, corresponding. From this equation e the theoretical voltage absorbed or produced in electrolysis, may be obtained; thus $e = \dfrac{4.187\,Q}{n\,F} + T\dfrac{d\,e}{d\,T}$. The second term at the right is the temperature coefficient of the electromotive force multiplied by the absolute temperature. It may be considered as a term of correction or refinement and since it is small at ordinary temperatures, the approximate result obtained by using only the first term is sufficiently accurate. For example, with the aid of this equation, the decomposition voltage for copper sulphate, used above, may be obtained. As shown by the following equations, when an electric current is passed through a solution of copper sulphate, both $CuSO_4$ and H_2O are dissociated and H_2SO_4 is formed.

$CuSO_4 + H_2O$ + electrolysis

$= Cu_{(at\ cathode)} + H_2SO_4 + O_{(at\ anode)}$

Molecular weight:

$(63.6 + 32 + 4 \times 16) + (2 \times 1 + 16)$

$= 63.6 + (2 \times 1 + 32 + 4 \times 16) + 16$

Gram, kilogram or pound equivalent:

$159.6 + 18 = 63.6 + 98 + 16$

Heat of formation or dissociation—gram calories:

$197{,}500 + 69{,}000$ = heat of electrolysis $+ 210{,}200$.

Then heat of electrolysis $= 197{,}500 + 69{,}000 - 210{,}200$

$= 56{,}300$ gram calories; and $e = \dfrac{56{,}300 \times 4.187}{96{,}540 \times 2}$

$= 1.22$ volts.

So much for fundamental theory; but very frequently, the heat of formation of the material smelted or electrolyzed which, in any smelting or electrolytic operation, is the primary thing determining the amount of energy required is so masked by other factors that in calculating the final or overall efficiency or economy of a process, the initial starting point is either not determined accurately at all or is practically lost from sight. In the smelting process, heat is absorbed or is obtained from:

1. The various heats of combinations or dissociation that are operative in the rearrangements of chemical combinations which take place at or before reaching the smelting temperature.
2. Raising the valuable chemical combination and such other chemical combinations as are necessary to the requisite reactions, and the furnace to the smelting temperature.
3. Radiation, convection, conduction heat losses.
4. Electrical supply equipment.

In the electrolytic process, heat is absorbed or is obtained from:

1. The heat of formation or dissociation active in the main reaction.
2. The heats of formation or dissociation in the various secondary reactions that go on in commercial electrolytes at or near the anode or cathode.
3. Raising the electrolyte and electrodes to operating temperature.
4. Radiation, convection, conduction, heat losses.
5. Electrical loss in the form of or equivalent to leakage, thus reducing the ampere efficiency, that is, the number of grams of metal deposited per Faraday from the theoretical 100 per cent, which is as previously stated.
6. Electrical supply $C^2 R$ losses, which show up in voltage drop in the various component parts of the electrical circuit such as the electrolyte, the anode, cathode, contacts, bus leads or conductors and the electrical supply equipment itself and result in a total impressed voltage, E, being required, which is much larger than e. If no other external heat is provided, it is obvious that ampere efficiency (No. 5 above) $\times\, e/E$ is a measure of the inherent efficiency of the electrochemical process at a particular plant.

The electrical losses mentioned just above are all perhaps of a nature with which electrical engineers are generally acquainted, except those taking place in the electrolyte itself and these, accordingly, require special study to determine variations due to variations in temperature, acidity, current density and other factors.

For example, the copper sulphate solution of composition ordinarily employed in copper refineries has a negative temperature coefficient of approximately 0.5 per cent per degree fahrenheit within the range of temperature ordinarily employed; so that appreciable saving of power results from operating at the highest practicable electrolyte temperature, that is, around 150 deg. fahr. Other ohmic losses being small compared to the electrolyte loss, a power saving of 15 per cent results as compared to operation at 120 deg. fahr. This partly accounts for the economy of copper refineries which generate their own power from steam and operate in the neighborhood of 20 per cent non-condensing, so as to provide steam for electrolyte heating, and experience as a result a net saving somewhat more than 10 per cent. Mention should, perhaps, be made also at this point of the fact that in the electrolytic refinery the opposite reaction is going on at the anode to that taking place at the cathode, so that the resultant e is zero and E is the result of resistance drop purely. As a further example, the acidity of the zinc sulphate ($ZnSO_4$) solution at one of the largest electrolytic zinc reduction plants ranges between 5 and 9 per cent. With constant voltage applied, a change of one per cent in the acidity of the solution changes the resistance so as to produce about a 15 per cent change in current density. This is of importance because it is indicative of the fact that control of the electrolytic cell room conditions can readily be at least partially obtained through variations in acidity, thus relieving the electrical supply equipment and rendering it unnecessary that that equipment be provided inherently with an impracticable amount of voltage varying capability.

From a consideration of the various items of the total heat appearing in the smelting or the electrolytic process, it is apparent that the only really useful energy is that taking part in the final or main reaction or that energy anywhere else in the process that tends to reduce the amount required in the main reaction. The useful heat is a small part of the whole and all the various losses and secondary reactions must be taken into account in determining the overall economy. Where possible, the secondary reactions should be made to work in favor of, rather than against, the process and where external heat can be supplied more cheaply, as it has been shown can be done by steam in the copper refinery, than from electrical energy, this should be done. In smelting, the largest quantities of heat appear or are absorbed under headings 1, 2 and 3, above. In electrolysis, the quantities of heat involved under 1, 2 and 3 also constitute by far the major part. The radiation, etc., losses under 4, for electrolysis are so much less than under 3, for smelting, owing to the lower temperature of operation that this partly accounts for the comparative economy usually to be obtained.

To state the case briefly, the energy required for electric smelting is a function of the amount of furnace charge, whereas, the energy required for electrolysis is a function of the amount of metal deposited. This is the fundamental difference between the two processes and the one which determines the economic success of either in any application. It is not an appreciable disadvantage so far as efficiency is concerned in the electrolytic process, at least in aqueous solutions, to have large quantities of the materials in process. For example, in the case of a large electrolytic copper reduction works more than one-half month's production would be tied up in the electrolyte alone and for a daily production of 60 tons of copper there would be in the neighborhood of 30,000 tons of electrolyte. This large body of electrolyte, flowing in cycle, contains only about three per cent of copper when it enters the electrolytic cell room and still contains about two and one-half per cent of copper when it leaves it. For economic smelting, on the other hand, of the more common metals, it is essential that only small quantities of material in proportion to recoverable metal be in process. Low priced electric energy in conjunction with high priced fuel is a favorable condition for economic electric smelting, but high grade, concentrated materials in process are also essential.

In Norway and Sweden, particularly, there are large economic electric smelters producing pig iron from iron ore. A type of furnace, such as shown in Fig. 1 is employed, which is similar to the blast furnace. The gases are recirculated but there is no blast and external heat to produce the temperature necessary for the reaction is introduced through 6 electrodes from 3000-kw. transformers. The energy consumption is in the neighborhood of 2400 kw-hr. per long ton, or 1.09 kw-hr. per pound of pig iron.

It is of particular interest that the product equals 47.5 per cent of the furnace charge. The charge per ton of product is approximately, 3680 lb. of iron ore containing 61.5 per cent of iron, 132 lb. of lime stone, 815 lb. of charcoal and 17.5 lb. of electrode consumed, or a total of 4645 lb. The ore consists of 20.64 per cent Fe_2O_3 and 64.96 per cent Fe_3O_4, or 760 lb. and 2385 lb., respectively, per ton of pig iron produced. It is, of course, understood, that electric smelting, as fuel smelting, requires fluxes and reagents to produce chemical reactions at the smelting temperature. Hence, the amounts of limestone and charcoal stated above. In view of the high percentage of the final product in the initial furnace charge, owing to the high grade iron ore employed, an analysis of the way heat is absorbed or produced, in the main reactions at least, will be of interest as indicative of the efficiency and economic possibilities not only of this particular electric smelting operation but of other similar operations.

1. Reduction temperature 900 deg. cent.—probable equation:

$$Fe_3O_4 + 3C = 3\,Fe + 2\,CO + CO_2$$

Molecular weight—weight equivalent:

$$231.5 + 36 = 167.5 + 2\ (28) + 44$$

Heat of formation or dissociation—gram calories:

$$270{,}800 = 2\ (29{,}160) + 97{,}200 + \text{electric heat.}$$

$$\text{Then, electric heat} = \frac{115{,}280 \times 3.968 \times 1{,}000}{167.5 \times 3412} = 800$$

kw-hr. per long ton. As there are $\dfrac{2385 \times 167.5}{231.5}$ = 1725 lb. of Fe produced from Fe_3O_4, 627 kw-hr. will be required.

2. Reduction temperature 800 deg. cent.—probable equation:

$$2\,FeO + 2\,C = 2\,Fe + 2\,CO$$

Reduction temperature 700 deg. cent.—probable equation:

$$Fe_2O_3 + 2\,CO = 2\,FeO + CO + CO_2$$

Combining:

$$Fe_2O_3 + 2\,C = 2\,Fe + CO + CO_2$$
$$159.7 + 24 = 111.7 + 28 + 44$$
$$197{,}700 = 29{,}160 + 97{,}200 + \text{electric heat}$$

$$\text{Then, electric heat} = \frac{71{,}340 \times 3.968 \times 1000}{111.7 \times 3412} = 742$$

kw-hr. per long ton.

Then, the 535 lb. of Fe produced from Fe_2O_3 will require 181 kw-hr. Then, the total 2260 lb. of Fe (including 3 per cent loss) produced will require 808 kw-hr. theoretically.

3. The ore carrying the reduced Fe is raised to a much higher temperature 1400 deg. or 1500 deg. cent. in the crucible of the furnace by the addition of about 342 kw-hr. per ton of Fe where the Fe melts, uniting with 3 or 4 per cent of carbon and a fractional percentage of silicon to form the fusible product known as pig iron. There are several minor reactions in the reduction of the silicious gangue, in this case 14.4 per cent of the ore, and in the decomposition of the limestone, which fluxes the gangue and the ash of the reducing agent, if any, to form a fusible slag floating on top of the iron which is tapped and thrown away. These reactions do not materially affect the total electric heat required which, therefore, is approximately 1150 kw-hr. per long ton of white low silicon iron suitable for making steel.

Accordingly, the inherent efficiency of the process comparable to the energy efficiency, $e/E \times$ ampere efficiency, for electrolytic processes, is 1150/2400 = 48 per cent. Whereas, the furnace operating voltage is usually from 70 to 80 volts, equipment having a range of from 60 to 120 volts is required.

In Norway and Sweden also, there has been extensive economic electric smelting of zinc. Here the raw material employed has been high in the values produced. It has consisted largely of cheap, slagging lead zinc say 35 per cent zinc and 10 per cent lead ores, making beside metallic zinc, lead bullion and copper matte. In other words, it is really a separating process, each of the three products requiring further working to place it in marketable form. The power consumed is from 2 to 2½ kw-hr. per lb. of zinc pro-

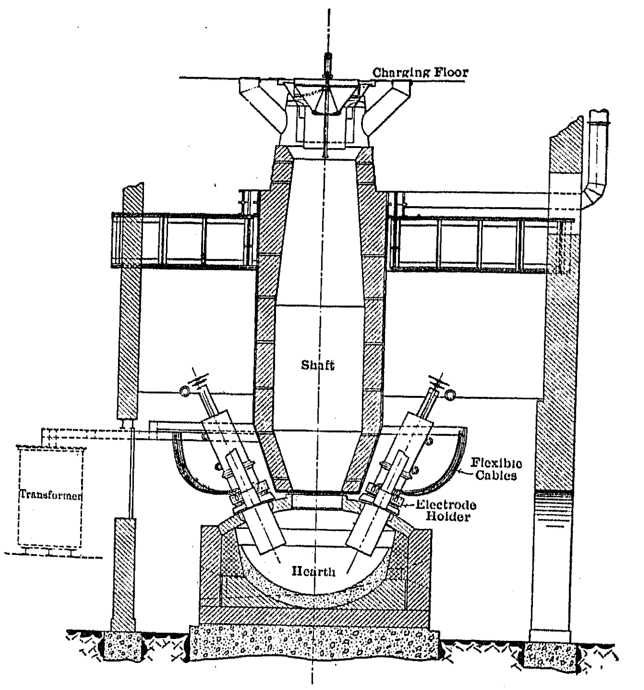


FIG. 1—SHAFT TYPE, ELECTRIC SMELTING FURNACE FOR PIG IRON

This type of furnace allows for circulation of gas so that about 25 per cent of the heat value of the gas formed is utilized within the furnace. Of the total kw-hr. supplied about 6½ to 7 per cent is lost in the cooling water and 20 to 25 per cent by radiation. There are reported to be about 30 electric smelting pig iron furnaces in the world, 21 of which are located in Sweden and Norway. The furnaces are mostly of 3000-kw. capacity, although several of 4500 kw. and 5000 kw. have been built.

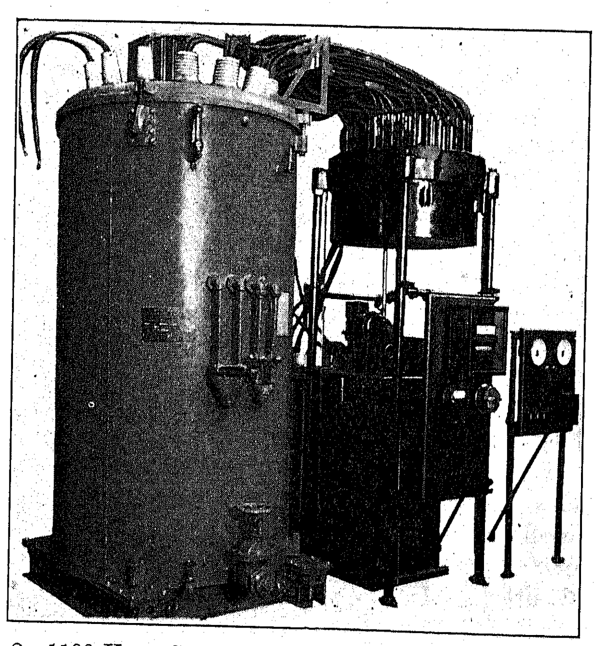

FIG. 2—1100-KV-A. STEP INDUCTION REGULATOR TRANSFORMER EQUIPMENT FOR ELECTRIC SMELTING FURNACE

This view shows control panel containing feeder type constant current automatic control.

duced. Electrical units of about 1000 kw. each have been largely employed. Equipment having a voltage range for the furnace of from 50 to 180 volts, or 90 to 180 volts, is required.

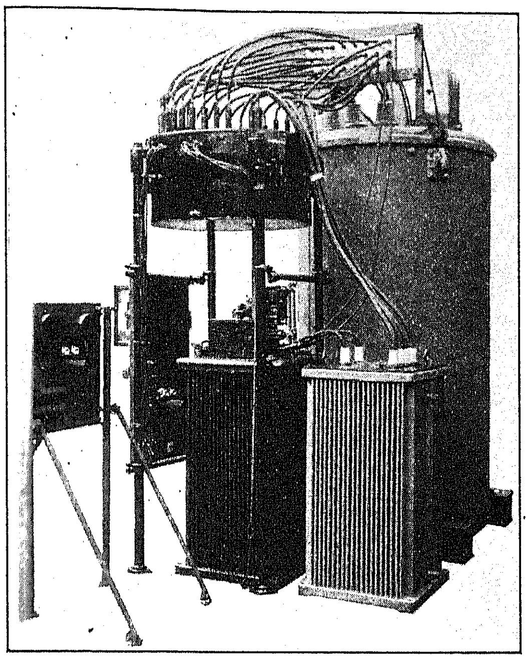

FIG. 3—VIEW OF 1100-KV-A. STEP INDUCTION REGULATOR TRANSFORMER EQUIPMENT FOR ELECTRIC SMELTING FURNACE WHICH SHOWS PARTICULARLY THE SMALL INDUCTION REGULATOR SERIES TRANSFORMER, TANK CONTAINING SELECTOR SWITCHES AND REAR OF CONTROL PANELS

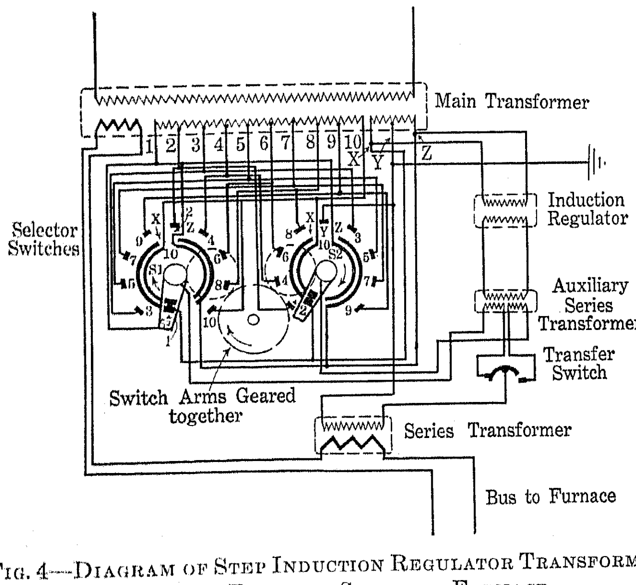

FIG. 4—DIAGRAM OF STEP INDUCTION REGULATOR TRANSFORMER UNIT FOR ELECTRIC SMELTING FURNACE

This diagram shows the scheme so clearly that taken together with descriptions with Figs. 5 and 6, further detail description is unnecessary. When the primary supply voltage is very high it is desirable to have a separate winding on the transformer of moderate voltage upon which the auxiliary control apparatus will operate. By this means, it will be obvious that the electrical apparatus such as selector switches, induction regulator, etc., will be of comparatively small capacity.

Figs. 2 and 3 show the type of step induction regulator transformer unit, which has been largely employed in the economic electric smelting of zinc. It is also the preferable type of unit for use in the economic electric smelting of pig iron. About 22 or more of these units have been installed, and a considerable number, 10 or so, of smaller units of 550 kv-a. capacity of a similar type. This type of control, as developed particularly for electric smelting, is shown in the diagrams, Figs. 4, 5 and 6, for the different electrical conditions usually met with in practise. The details of this are instructive, particularly to electrical engineers. Fig. 7 is a plan or layout of the first complete commercial electric steel smelter and rolling mill established in the Western Hemisphere. This is the plant of the Compana Electro Metallurgica Brazileria,

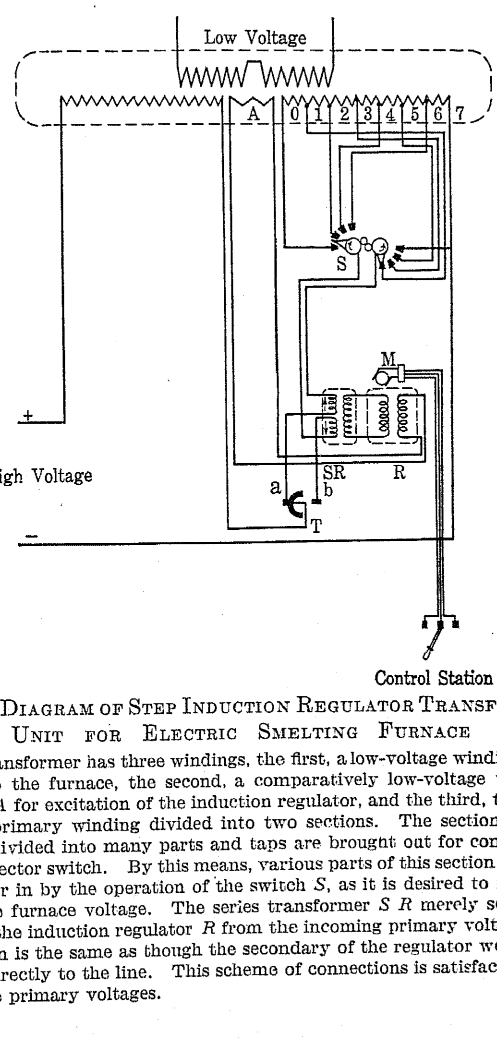

FIG. 5—DIAGRAM OF STEP INDUCTION REGULATOR TRANSFORMER UNIT FOR ELECTRIC SMELTING FURNACE

The transformer has three windings, the first, a low-voltage winding connected to the furnace, the second, a comparatively low-voltage winding marked *A* for excitation of the induction regulator, and the third, the high voltage primary winding divided into two sections. The section to the right is divided into many parts and taps are brought out for connection to the selector switch. By this means, various parts of this section may be cut out or in by the operation of the switch *S*, as it is desired to raise or lower the furnace voltage. The series transformer *S R* merely serves to insulate the induction regulator *R* from the incoming primary voltage and the action is the same as though the secondary of the regulator were connected directly to the line. This scheme of connections is satisfactory for moderate primary voltages.

with a capacity of 30 tons of steel per 24 hours. The equipment consists of:

Two shaft type furnaces (1 as standby), voltage range 60 to 120	3000 kv-a. each
Two 6-ton Bessemer converters (blowing engine for 1)	700 kv-a. "
One 6-ton Ludlum electric steel refining furnace	1500 kv-a. "
One 16-inch rolling mill	500 kv-a. "
One 10-inch rolling mill	500 kv-a. "
Miscellaneous 220-volt power for motors, cranes, shops and lighting	400 kv-a. "
Total Installation	6600 kv-a. "

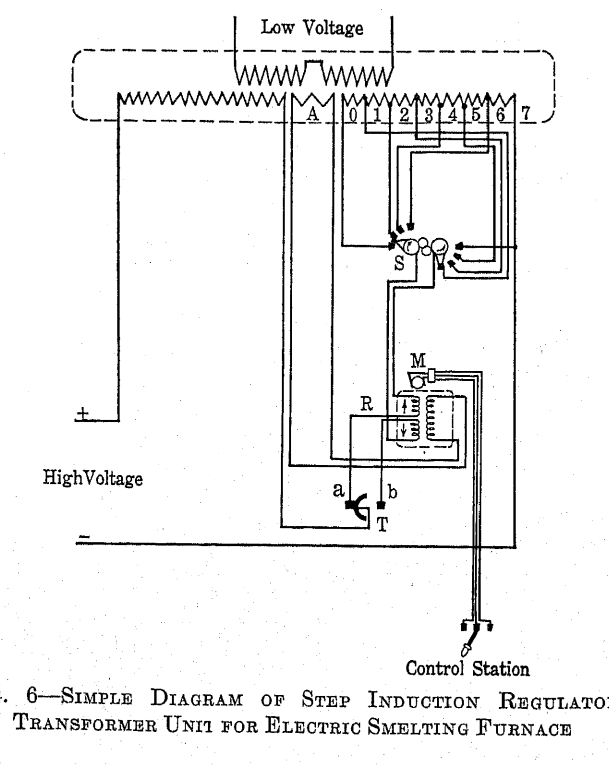

FIG. 6—SIMPLE DIAGRAM OF STEP INDUCTION REGULATOR TRANSFORMER UNIT FOR ELECTRIC SMELTING FURNACE

This is used when the primary voltage supply to the furnace unit is comparatively low so that it is unnecessary for the sake of economy to insulate either the induction regulator or the selector switches. The "buck" or "boost" of the induction regulator is equal to one-half the voltage existing between adjacent transformer taps. When it is desired to vary the furnace voltage, it is merely necessary to start the operating motor M of the regulator and if the regulator has been in neutral position, immediately a voltage is induced in the secondary of the regulator. In raising furnace voltage, this induced voltage would add to the supply voltage. With the regulator continuing to revolve, the induced voltage reaches its maximum which is one-half the voltage between adjacent transformer taps. At this point, the selector switch S being geared to the regulator, operates so as to connect the next transformer tap to the supply. At the same point, the transfer switch T also geared to the regulator, operates so that the induced voltage in the regulator subtracts from, rather than adds to, the supply voltage. This last operation is secured by having the secondary of the regulator made up of two windings, so that the reversal from boost to buck can be made through the transfer switch by reversing one of these windings. This feature allows the induction regulator to be rotated continuously in one direction for either raising or lowering the furnace voltage. It is obvious that this equipment may be controlled entirely automatically by a constant current regulator or a constant energy regulator.

Fig. 8 is a cross sectional view of the smelting furnace showing particularly details of the gas recirculating system and giving a good idea of the two parts of the furnace, the shaft in which the reduction of the ore takes place and the crucible in which the pig iron is formed at high temperature. Fig. 9 shows the layout of electrical connections between the regulator transformer and

smelting furnace electrodes. Provision is made by mounting the regulator transformer units on trucks traveling on tracks so that the electrical equipment can be shifted quickly from one smelting furnace to the other.

In Norway also, we have had the electric smelting of copper in large scale tests at an expenditure of 700 kw-hr. per long ton of charge containing 6 per cent or 132 lb. of metal and producing a 30 to 40 per cent copper matte. In other words, it has practically been merely a concentrating operation at an expenditure of 5.3 kw-hr. per pound of copper contained in the matte. It has been calculated that the concentrates from one of our western mines containing about 32 per cent Cu could be smelted by electricity, producing a matte of from 53 to 68 per cent Cu at an expenditure of approximately one kw-hr. per pound of Cu contained. This product would, of course, still require additional expensive treatment. By the electrolytic process, 700 kw-hr. will produce 700 lb., or one lb. per kw-hr. of high grade copper, requiring very little further treatment to be in merchantable form; and this is produced from a solution or electrolyte containing only a few per cent of Cu obtained by the action of dilute H_2SO_4 upon raw low grade oxidized ore containing only around one and one-half per cent Cu. The electrolyte may, of course, also be obtained by the action of H_2SO_4 upon concentrates of sulphid ores which have been oxidized by roasting.

Turning to the electrolytic processes, voltage, rather than temperature (at least usually) induces dissociation and, owing to the low temperature at which these processes (usually) may be conducted, efficiency, as has been stated, is not a function of the quantity of charge that is, the quantity of material in course of treatment, but is a function of the amount of metal deposited. In view of the growth and future prospects of electrolytic processes in the production of metals commonly used in construction and manufacture, electrical engineers must take more than a detached or theoretical interest in the subject. Table I shows considerable data with relation to the status of electrolysis as applied to the production of metals at the present time, particularly in the Western Hemisphere. Where not obtained from published sources, these data are only approximate, but a study of it will

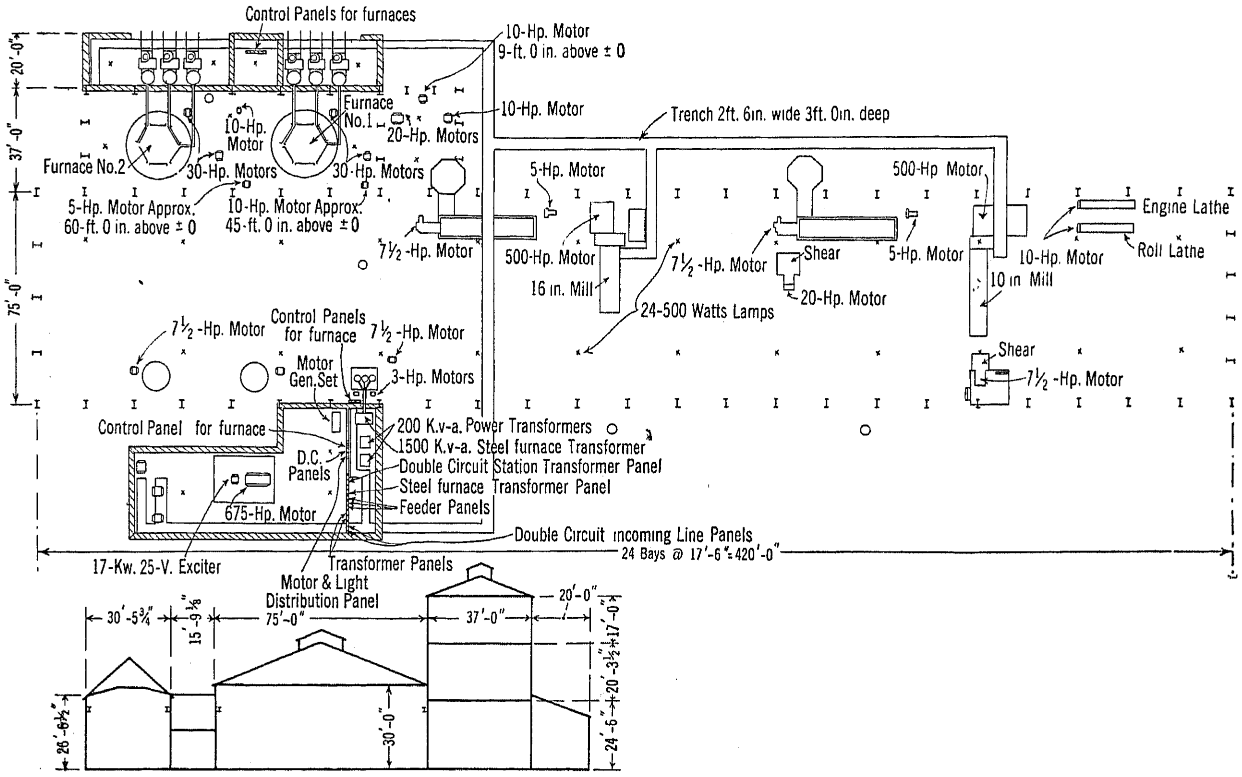

FIG. 7—ELECTRIC STEEL SMELTER AND ROLLING MILL—COMPANA ELECTRO METALLURGICA BRAZILERIA—30 TONS CAPACITY PER 24 HOURS. THE EQUIPMENT CONSISTS OF:

Miscellaneous 220-volt power for motor, cranes, shops and lighting	400 kv-a.
Total installation	6600 kv-a.

indicate the correctness of many of the statements made.

The chart, Table I, shows how the problem in the metallurgical plant passes from the physical and chemical to the electrochemical and electrometallurgical and on to the purely electrical. Perhaps of all the columns, the electrical engineer is most interested in one near the center showing the overall efficiency of the electrochemical process and one to the right showing the efficiency of the purely electrical part of the installation. It is assumed that power is delivered at the electrochemical substation from the company's own power plant, or purchased from an external power plant in the form of alternating current; and the electrical efficiency given represents the efficiency of the electrical circuit from that point to the busses on top of the cells upon which the anodes and cathodes rest. The particularly interesting point is that in the relatively modern and efficient installation from 7.5 to 15 per cent of the power received at the electrolytic substation is lost before the current reaches the cells and that the cells themselves in a commercial economic plant are, in general, no more than 50 per cent efficient,

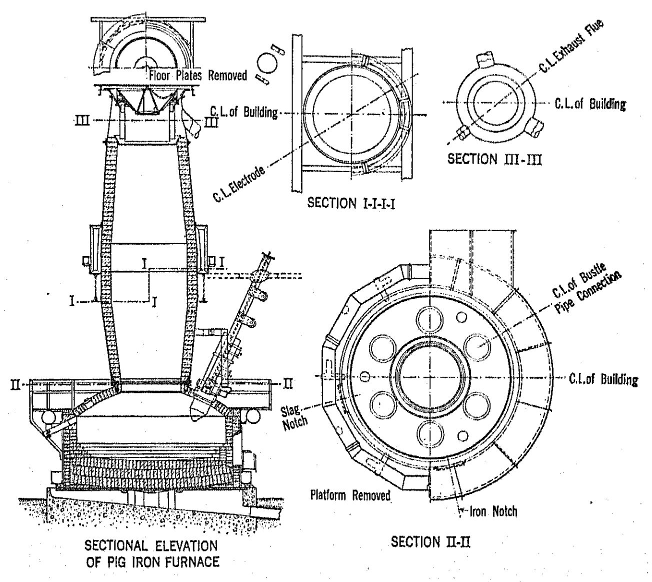

FIG. 8—CROSS SECTION OF 3000-KV-A. ELECTRIC SMELTING FURNACE FOR PIG IRON—COMPANA ELECTRO METALLURGICA BRAZILERIA

that is, they use upward of 100 per cent more power per pound of metal produced than would be calculated

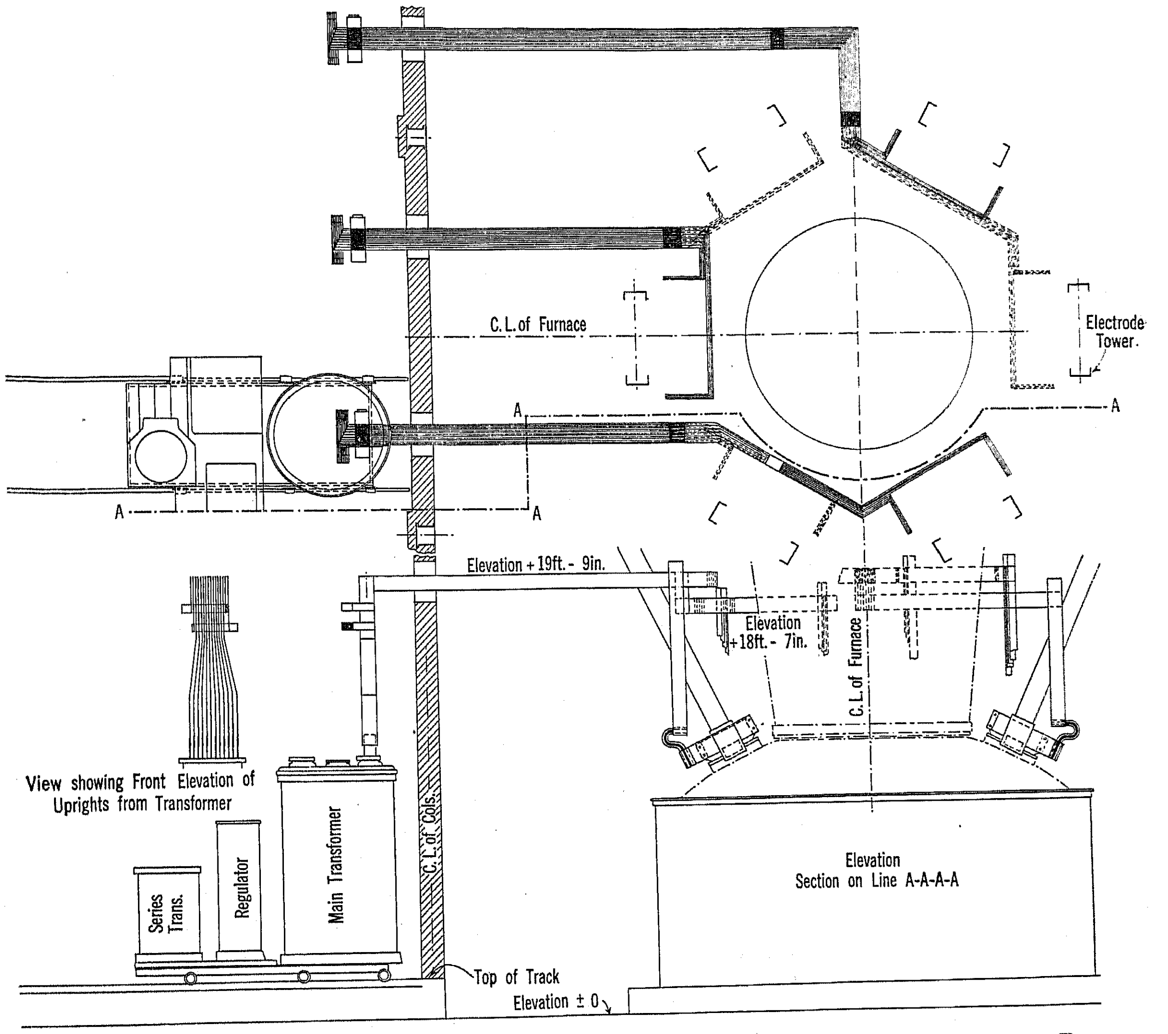

Fig. 9—Electrical Layout, 3000-Kv-a. Electric Smelting Furnace Showing Connections Between Transformers and Electrode Holders—Compana Electro Metallurgica Brazileria

by the theoretical Faraday and Gibbs-Hemholtz laws. This is well known to those chemists and metallurgists who are closely associated with this field of engineering, but it is being mentioned because it is not so familiar to electrical engineers. It may be said that the present day solution of the electrochemical problem gives an efficiency in the neighborhood of only 50 per cent of the theoretically possible, or rather impossible.

As the electrical problem was rather fully covered in my paper before the American Electrochemical Society, "The Substation Problem of the Electrochemical Plant," Volume 32 of *Transactions*, and in my discussion before the American Institute of Mining and Metallurgical Engineers, September, 1918, on "Electrolytic Zinc," further consideration at this time will be confined especially to features directly affecting efficiency.

Certain conclusions seem to have been borne out by accumulated experience. In general, it is not necessary or advisable to have great voltage range in the electrical supply apparatus. Great voltage range introduces costs and inefficiencies in the electrical equipment

*Based on 5000 tons per 24 hours requiring approx. 4560 kw. d-c. capacity.

†Based on normal capacity at max. boost. voltage including cost for spare equipment.

The cost figures above are relative merely in an approximate way and should not be interpreted as indicative of present day prices.

which offset advantages gained in the cell room. The most economic all around installation is one in which the cell or tank room layout is designed with sufficient flexibility to demand comparatively small flexibility or voltage range in the electrical apparatus. Except that for all service of 125 volts d-c. and lower, the motor-generator set is the better application; Table I shows that the electrical efficiency is much greater for the higher voltage tank rooms (greater for 500 volts than 250 or 125 volts and greater for 250 than 125 volts) and when synchronous converters are employed rather than motor-generator sets. Synchronous booster converters with about a 12 per cent $\pm$ voltage range seem adequate, that is, say from 220 to 280 volts, or from 240 to 300 volts, or from 485 to 615 volts. In fact, in the aluminum and zinc industries which operate lines of cells at 500 volts and higher, the cells are so manipulated as to require very little voltage variation from the electrical equipment. A large part of the production of aluminum is accomplished by means of straight synchronous converters without boosters.

Fortunately, the synchronous booster converter is an economical machine to build and an efficient one to operate over the range which has been indicated. Sometime ago I made an analysis to determine the best electrical plant for an electrolytic copper reduction works, the data of which are typical and illustrative as well as anything could be, that the voltage should be as high as practicable and that unless external conditions, due to transmitted power, are too unfavorable, synchronous booster converters or straight synchronous converters should be used in preference to motor-generator sets. This analysis was made because it was known from data such as given in Table I, that some modern commercial plants have 100 per cent higher efficiency in the purely electrical part of the plant than do others. The curves in Figs. 10 and 11 show the efficiencies of a number of electrolytic units, that is, actual combinations of equipment, transformer and synchronous converters, which might be employed. While the service is a constant-current service at practically full load, it is noteworthy that high efficiency is obtainable over a considerable range of load and over the entire range of voltage. Indications were that for an electrolytic copper reduction works treating 5000 tons of ore, or more, per day, that the necessary electrical substation equipment would cost in the neighborhood of $22 per kw. of continuous supply to the tank room and $20 per ton of ore treated and that the cost of the electrical substation, building and equipment, would be from 15 per cent to 20 per cent

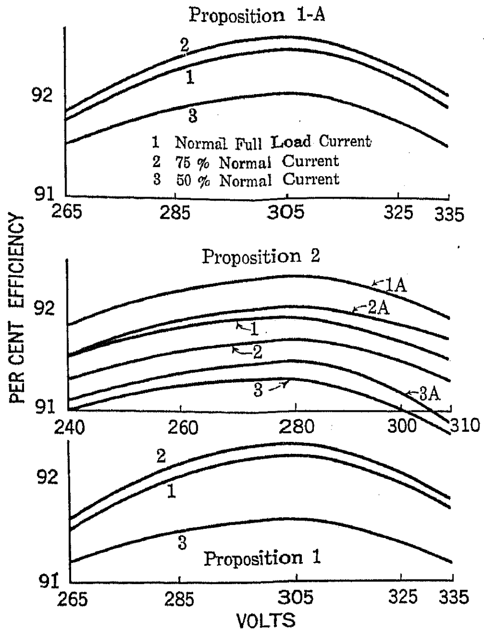

FIG. 11—CURVES SHOWING APPROXIMATE EFFICIENCIES OF ELECTROLYTIC UNITS CONSISTING OF SYNCHRONOUS BOOSTER CONVERTERS AND TRANSFORMERS. THESE CURVES SHOW EFFICIENCIES FROM MINIMUM VOLTAGE TO MAXIMUM VOLTAGE OF RANGE

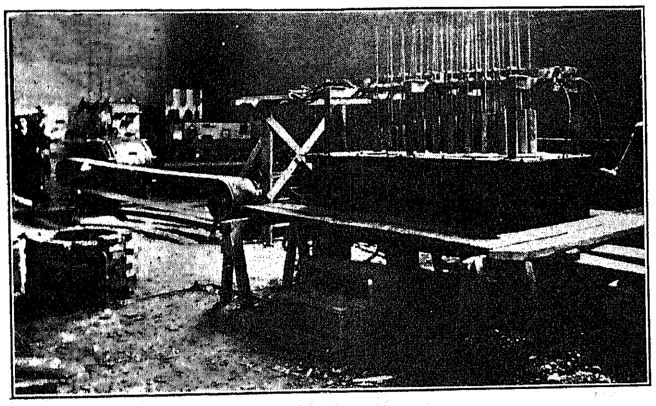

FIG. 12—EXPERIMENTAL PLANT FOR OBTAINING ELECTROMETALLURGICAL DATA ON ALUMINUM, SHOWING ELECTROLYTIC ALUMINUM CELL AND LOW-VOLTAGE D-C. GENERATOR, BELT DRIVEN BY INDUCTION MOTOR AND MEASURING INSTRUMENTS

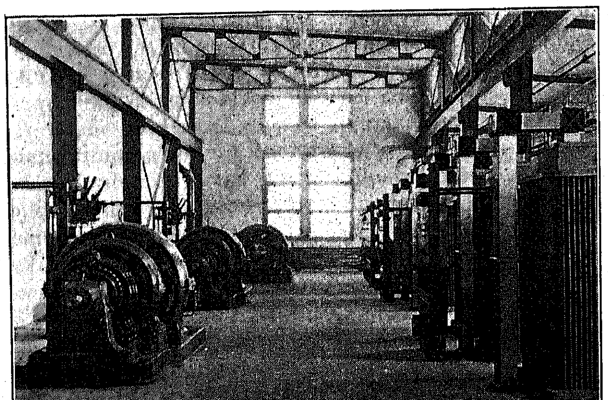

FIG. 13—SUBSTATION FOR ELECTROLYTIC NICKEL AND COPPER PRODUCTION

There are five synchronous booster converters, 4000-ampere capacity each, maximum volts 290. The booster gives a range of 30 volts ± and by a number of taps and switches on the secondary of the transformer any operating voltage down to 100 or less is obtainable. Wiring diagram which is typical of a station of this type is shown by Fig. 14.

of the cost of the tank house. (The ratio of cost of electrical substation to tank house for electrolytic zinc would be higher than this owing to the larger kw-hr. per pound taken by zinc and the greater current densities employed; refer to Table I.) A tabulation

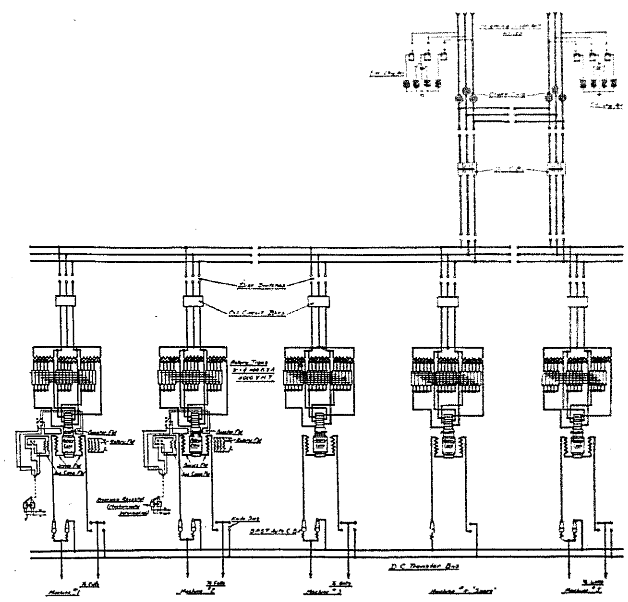

FIG. 14—ELECTRICAL CIRCUIT DIAGRAM FOR ELECTROLYTIC SUBSTATIONS FOR NICKEL AND COPPER HAVING 4 ACTIVE UNITS AND 1 SPARE

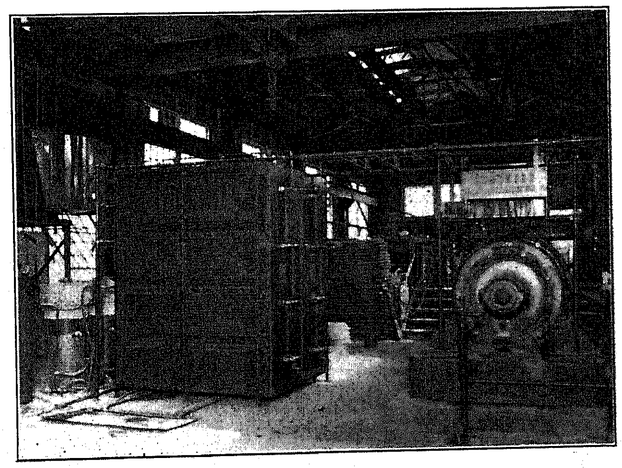

FIG. 15—ELECTROLYTIC IRON REFINERY, CAPACITY 15 TONS PER MONTH

To the rear, at the center, may be seen the electrolytic tanks and in front of them a pile of Armco iron anodes ready for use. To the right at the front may be seen a 100-kv-a. 5000-cycle alternator, which, together with the banks of condensers, shown to the left, form a power supply for high-frequency inductive melting furnaces, shown to the left of the condensers. At the extreme left is a hydrogen tank for the purpose of insuring a non-oxidizing atmosphere in the furnaces. The electroltyic iron is here melted together with other materials in the manufacture of high grade iron alloys. Power for the electrolytic cells is obtained from a 2000-ampere 20-volt motor-generator set which is not shown in the view.

of the equipment considered in the analysis above referred to, is shown in Table II. This shows first cost very much in favor of higher voltage and, considering the matter of efficiency of conversion once more, let us assume that the electrolytic copper plant

has an output of 60,000,000 lb. of copper per year at a cost of 10 cents per pound. Then, the difference in conversion of between 86 per cent and 91 per cent, that is, 5 per cent will mean something in the neighborhood of 0.8 per cent of the total production cost of the copper with power at one and one-half cents per kw-hr., or more than $45,000 per year, which is about one third of the cost of the electrical substation equipment.

It would be impossible to cover the relationship of the electrical engineer to the commercial development of economic electrometallurgical processes within the reasonable scope of an American Institute of Electrical Engineers' paper. It was merely desired to indicate his correlationship with the chemist and metallurgist in working out these problems. By a survey of the field, without being critical, it was hoped to be stimulating. Discussion has purposely been confined to the more common metals. Consideration of the electrolytic treatment of precious metals has been purposely omitted since the quantity of power involved is small. No reference has also been made to the electric smelting of metals such as chromium, tungsten, molybdenum, etc., which are used in the production of alloyed steel. Fig. 12 is a view of an experimental plant for the purpose of determining electrometallurgical data in the production of aluminum, which, perhaps, it should be mentioned can only be produced electrolytically at high temperature. Fig. 13 is a substation of synchronous booster converter transformer units employed in the electrolytic production of nickel and copper. Fig. 14 is a typical diagram of electrical circuits for such an installation. Fig. 15 is a small commercial electrolytic iron refinery.

Discussion

C. J. Russell: Mr. Yardley's paper is timely and the present speaker desires to call attention to the importance of the subject of electrolytic and electrometallurgical processes to electrical engineers—particularly to those who are connected with public utilities. Entirely aside from the fields in which such processes are found, we are just on the threshold of tremendous developments along the lines of industrial heating by electricity. The question of the relation of the electrical engineer to all these applications is important because he must pass upon many points which may be decisive as to the commercial success of any undertaking. There have been many failures due to the applications of electricity for the accomplishment of some process which would never have been undertaken, if proper advice had been tendered or accepted. The application of electricity to meritorious processes has been seriously retarded by these failures. As against that, we find in France, Norway and Sweden a very large number of highly successful processes along the lines of electric-furnace operations which cover a field from electrometallurgical work to the manufacture of calcium cyanamid and nitrogen fixation.

This paper should result, particularly on the Coast, in a very active interest, on the part of electrical engineers, in the consideration of electrochemical and electrometallurgical applications along the lines of electrolytic and electric furnace processes.

Carl Hering (by letter): In referring to the very important matter of the energy which is set free or absorbed in nearly every chemical reaction, the author still repeatedly uses the

old term "heat." These energies have for many years been called "heats of combination" because in the older, simple, purely chemical reactions this energy always appears as heat or cold. But in many electrochemical processes this energy does not appear as heat, and it is confusing to the student to call it so. It appears as electrical energy, being set free as in batteries, or absorbed, as in electrolytic reduction processes. It is therefore not up-to-date in this electrical era still to refer to this energy as heat. It should be called the *energy* of combination, even though in books, the data are still always given in calories,—one of the units in which energy may be measured.

In stating the elementary principles near the beginning, the author should have added to his statement (1) the words "and pressure." Pressures are quite as important as temperatures in some chemical reactions, hence the useful autoclave. In his next paragraph, (2) it would have been more clarifying to have added that the action takes place only at the electrodes. None but secondary reactions can occur in any other parts of the electrolyte, and the energy of these secondary reactions may be entirely foreign to the electrical energy. Many years ago I suggested that the answer to the much-discussed question, as to whether a certain reaction is primary or secondary, might well be based on this distinction.

In the next paragraph of this paper, it might have been made clearer that Faraday's law does not refer to any energy. It is entirely independent of whether the energy involved is large or small. The voltage, with which Faraday's law is not in the least concerned, must be included to determine the electrical energy. Faraday's law deals only with ampere-hours or coulombs (ampere-seconds) and not with watt-hours. Like many others, the author omitted to say that this law applies directly only when there is but one atom to the molecule, and when the change of valence is unity. Serious mistakes may be made in some calculations by ignoring these limitations.

The latest and best value of the Faraday is 96,494, and not 96,540. A more convenient form is 26.804 ampere-hours, which divided by the atomic weight gives the quantity of electricity in ampere-hours per gram, or 12,158, which divided by the atomic weight gives the ampere-hours per pound, both for every unit change of valence. Faraday's[1] law, stated as usual in terms of valence (or worse yet, with that term omitted), fails to apply in some cases and is therefore not a universal law; using the term "change of valence" makes it a universal law.

In many of the kinds of electrochemical processes referred to by the author, the so-called "thermo-chemical" constants, or "heats of combination" (better called energies of combination) given in tables, are extremely important, as they may show that a proposed process will cost more in energy than the result is worth. I have repeatedly called attention to the fact that these constants as given in the tables, are in many cases the sum of two constants which ought to have been stated separately; they represent two radically different things, namely, the real chemical energy and the physical energy (temperature, pressure and change of state).

The reason for separating them is that the physical part, which may be quite large, might perhaps be reduced (by pressures and temperatures for instance) which the essentially chemical part, of course, cannot. The physical part of this energy may involve relatively large latent heats. Thus, when solid carbon is burned in gaseous oxygen, the end-product being a gas (CO or CO_2), the latent heats of liquefaction and vaporization of carbon have been absorbed or deducted from the chemical energy of the combination and only their difference appears. In the thermite process, the oxygen must be regarded as being solid to start with, and the end-product is solid, hence the high temperatures, there being no latent heat deductions. Or when solid magnesia (flash powder) is burned in air forming the solid oxide, the latent heats of liquefaction and vaporization of oxygen has been added to the chemical energy, hence the high temperature and bright light produced. If zinc can be reduced from its ore without vaporization (for instance by increased pressure or by electrolysis) its latent heat of vaporization, ordinarily lost, can be saved.

Electricity in Mines

BY F. L. STONE
Associate, A. I. E. E.
Industrial Engineering Dept., General Electric Co., Schenectady, N. Y

Review of the Subject.—*In the following paper, the author has given a fairly complete description of the various uses to which electric power is put in and around the mines, together with some interesting figures in regard to the amount of electric power now used and that which is still to be applied.*

* * * * *

A COMPLETE treatise on the subject of this paper namely, "Electricity in Mines" would be exceedingly voluminous. Neither time nor space will permit me to enter into a detailed discussion of all the applications of electric power in the mining industry.

In describing various applications of electricity to mining apparatus, I will endeavor to be as brief as possible, and further, keep away from any great amount of technical discussion. My desire is rather to show you the various ways in which electricity is used around the mines and to give you some impression of the extensive field of application offered by the mining industry.

Electricity as a medium for the transformation of power lends itself so well to practically all power applications in and around the mines that, notwithstanding the gratifying advances that have been made, it is a little surprising to one who has studied the subject, that this form of energy is not more universally used.

In the case of a small operator in a territory where purchased power is not available, it is always a question whether or not it is best to install an electric generating station. Local conditions incident to such an installation must be taken into account and the problem analyzed carefully before a decision can be made.

Fortunately, however, power lines from large power companies have penetrated the majority of the important mining fields. Equitable rates have been established whereby the prospect or operator can afford to purchase power. Large distributers of power are, I believe, well satisfied that mining load is very desirable and are soliciting it vigorously. This is quite in contrast with the policy of a few years ago. At that time very few power companies were anxious to have mining loads on their lines. This is easily explained by the fact that to take on such loads it would have been necessary to increase the size of their transmission lines and generating stations, all of which involve large capital expenditures. This inability to serve caused many mine operators to install generating stations of their own. Many of these stations have been abandoned and the operators changed over to purchased power as soon as the Public Utilities were ready to furnish it at a reasonable rate.

Serious power interruptions have always been the constant dread of a mine operator, particularly if his mine be gaseous or collects water rapidly. Some mines give off explosive gases so rapidly that an hour's shutdown of the ventilation system changes the mine from a comparatively safe thing to an exceedingly dangerous thing, waiting only for some half-wit to light a cigarette to send himself and his fellow workers into the great beyond and incidentally totally wrecking the property.

Power interruptions today are fortunately rather rare and of short duration. It is only in exceptional cases that a standby source of power is required. When such an expediency is resorted to it usually takes the form of a gas engine and generator just large enough to run the vital parts of the machinery such as the hoist, the fan, (both at reduced speeds) and some lights. Needless to say, continuity of service is the prime factor in the supply of power to mines.

In order to give you some idea of the magnitude of the mining industry the following figures should be of interest.

There are employed in and about the mines of the United States in round numbers one million men. They receive an annual wage of approximately one billion five hundred million dollars. Of these one million miners, thirty-five per cent work above ground and sixty-five per cent under ground. The mines require a total of approximately 6,800,000 h. p. in motive power. Of this only 1,603,000 h. p. or twenty-three per cent is connected to Public Service lines and 1,206,000 h. p. in motors or 17.7 per cent is run from privately owned electric plants.

Even with this small percentage of purchased power, the amount paid annually to power producing companies is about thirty million of dollars.

So there is still a very large field for the sale of power to the mining industry.

Now as to the nature of the load, it is not steady and the load factor is quite variable, seldom exceeding fifty per cent. By load factor I mean the ratio of the maximum 15-min. integrated peak to the average load over 24 hr.

In Fig. 1 is shown a typical 24-hr. chart from a group of anthracite mines. This chart is fairly typical of a large majority of coal properties. It has a load factor over 24-hr. of approximately 42 per cent calculated on the basis above described.

The individual drives will now be taken up and

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

discussed in as much detail as space and time will permit.

VENTILATION

The usual method of supplying air for the support of life and the rendering of the mine safe from dangerous gases is to install a fan at the top of an air shaft. The fan may be either of the exhaust type drawing air up the shaft or it may be of the blower type forcing air down the shaft, the former as an "up-cast shaft" and the latter as a "down-cast shaft." Frequently the doors of the fan house are so arranged that the fan can, by adjusting these doors, be operated either as an exhauster or a blower. Such equipments are known as reversible fans. Much discussion has taken place among mining engineers as to whether or not reversible fans should be permitted, the point being that in case of fire the air currents might and, in fact, have been reversed without proper knowledge of the inside conditions, thereby causing greater damage and loss of life

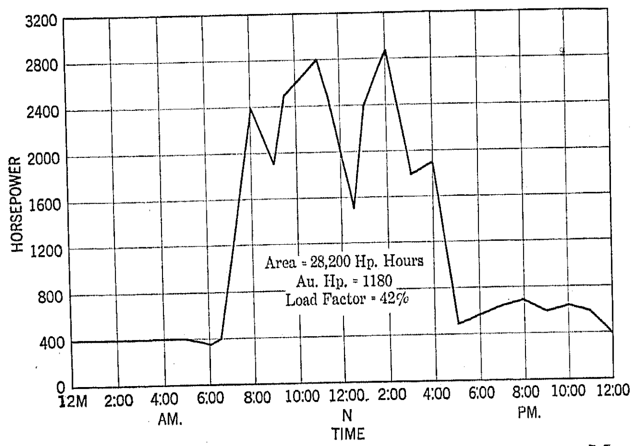

FIG. 1—24-HOUR LOAD CHART OF GROUP OF ANTHRACITE MINES

than would probably otherwise have resulted. This, however, is slightly aside from the electrical engineer's problem.

The load characteristics of the fan are similar to those of most centrifugal apparatus, the power required by a given mine fan being approximately proportional to the cube of the speed. The normal speed of large fans varies from 75 rev. per min. to 350 rev. per min. or even higher, depending on the size and design of the fan.

The starting load of large fans differs from most other loads in that the load on the driver increases very rapidly with the speed. Fans cannot to advantage be by-passed. It is impractical to close the intake or outlet because of the size and consequent pressure that would result. Furthermore, could either or both of these openings be closed, it would only reduce the load at full speed to about 75 per cent of full load. Many mines require variable speed fans as some operators feel that at times it might be necessary to increase the speed above normal and at other times advisable to drop it to some subnormal speed. I think, however, there are many more mines where fans are run at constant speed delivering sufficient air at all times to keep the mine free from dangerous gases than there are mines which require variable speed fans. Thus, it may be seen that the fan drive presents some interesting problems to the electrical engineer.

In the case of the constant speed fan, the problem is largely one of starting. The drive may be induction motor of the squirrel-cage type or slip-ring type geared, belted, or with chain drive. Due to the starting conditions, it would seem that the slip-ring motor has quite a decided advantage over the squirrel-cage motor. If the squirrel-cage motor be used, very high percentage taps must be resorted to in the starting compensator, otherwise the motor will be thrown across the line at a considerable percentage below full speed, thus putting an excessive stress on the apparatus and the system. With the slip-ring motor, the torque can be controlled nicely by the controller and increased gradually as required from zero to full-load speed.

Synchronous motors have been suggested for fan drive but the pull-in torque must be 100 per cent of full-load torque if the motor is just large enough to drive the fan. To meet this would be to impose design conditions, which, if met, would be very detrimental to other desirable characteristics in the motor. Synchronous motors have been installed, however, using a motor considerably larger than is actually necessary to drive the fan. This solves the pull-in problem, but on the other hand it gives the operator a motor of which only a part of the installed capacity is in use 99 per cent of the time. Synchronous motors have been successfully installed on fan drives using a clutch between the rotor and the load, bringing the motor to speed with the clutch disengaged and after the motor is in step bringing the load up on the clutch. Some installations as large as 750 h. p. have been so made.

To overcome the starting troubles on fans and other similar devices such as mills and crushers where there would be a decided advantage accruing from the use of a synchronous motor, one large manufacturing company has developed what it chooses to call a super-synchronous motor. This motor has, as far as the load is concerned, a starting torque equal to the break-down torque of the motor. This is accomplished by mounting both the stator and the rotor on bearings and placing a large brake around the outside of the stator. To start a fan with such a motor the brake is released and power is applied to the stator. This begins to revolve and comes to synchronous speed, no load. Field is then put on the rotor and the brake applied to the stator. When the braking effort is sufficient the stator begins to slow down, but simultaneously the rotor and load begin to accelerate, increasing in speed as the stator falls in speed. The sum of the two speeds is always equal to the synchronous speed of the motor. Finally, the stator is brought to rest and the rotor and load are at synchronous speed. I do not know of any

such installation having been made on a fan but some 50 of these machines have been installed on Ball and Tube mills in cement and metal mills with very excellent

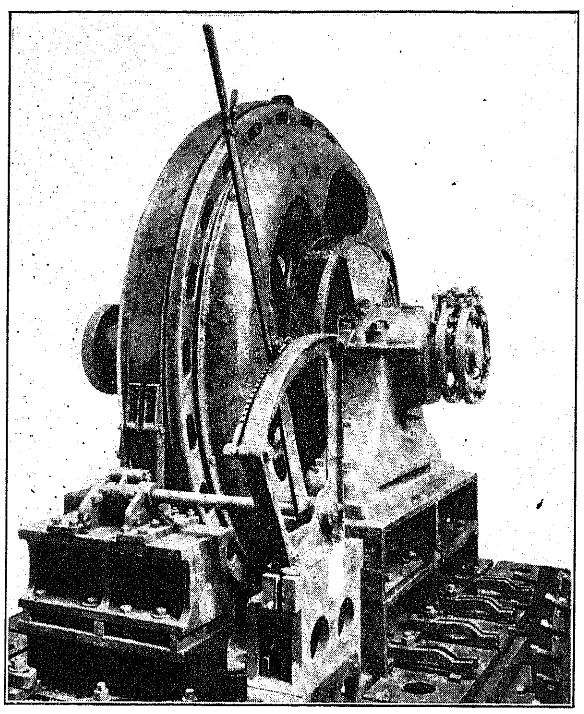

FIG. 2—SYNCHRONOUS MOTOR WITH REVOLVING STATOR SHOWING COLLECTOR RINGS AND BRAKE MECHANISM

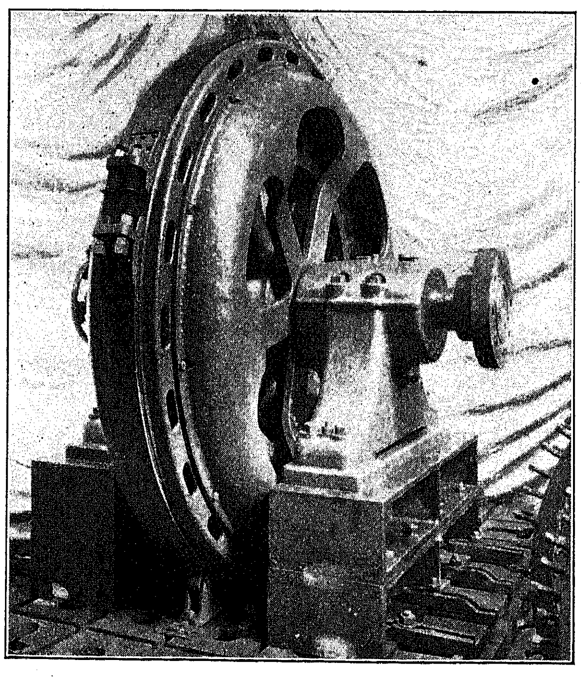

FIG. 3—SYNCHRONOUS MOTOR WITH REVOLVING STATOR SHOWING COUPLING END

450-H. P. 0.8-Power Factor 187.5-Rev. per Min. 3-Phase 60-Cycle 2200-Volt

results. Two views of one of these motors are shown in Figs. 2 and 3.

The synchronous motor also lends itself much better for direct connection to the fan than the induction motor on account of the poor power factor of the latter at slow speed that prevails with fan drives.

In view of the fact that high power factors are rewarded by many power companies, it would not be surprising to see many more synchronous motor drives for fans installed as the work of electrification proceeds.

Variable speed fans present an added problen. The starting conditions are similar to those of the constant speed fan but there is the additional problem of the variable speed control.

Where two or possibly three fixed speeds are sufficient and these speeds are some common fraction of full speed, such as one-half and three-quarters, a pole changing squirrel-cage induction motor has some field.

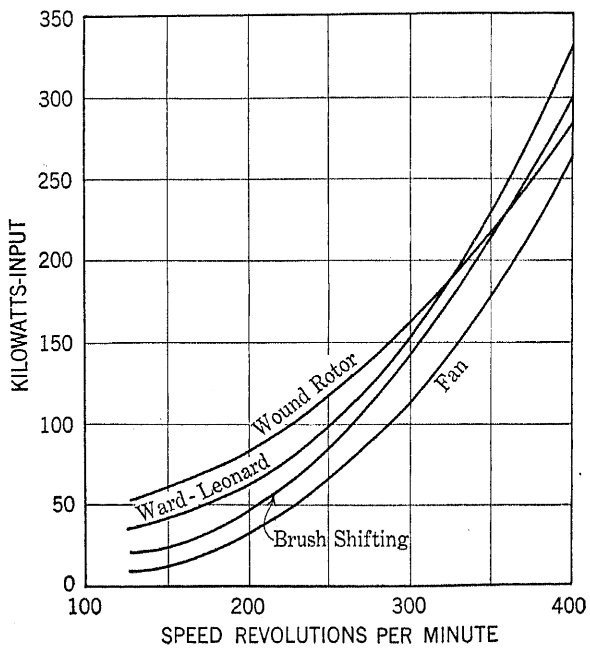

FIG. 4—SPEED KILOWATT INPUT CURVES OF MOTOR-DRIVEN FAN USING WOUND ROTOR INDUCTION MOTOR, BRUSH SHIFTING ALTERNATING-CURRENT MOTOR AND DIRECT-CURRENT MOTOR WITH WARD LEONARD CONTROL

On large drives, however, where variable speed is required intermediate speeds are usually necessary, which puts the application of the squirrel-cage motor out of the question.

For variable speed fan drives, we have left the slip-ring motor with controller and resistance, the brush-shifting a-c. motor, the Scherbius and Cramer systems of drive with various modifications and possibly to these might be added the Ward Leonard control system. (This latter has never as yet to the writer's knowledge been used for this work).

Fig. 4 shows the power required at the fan shaft for a given fan at various speeds from minimum to maximum. On the same sheet are shown the powers consumed to drive this fan at the various speeds using first the slip-ring induction motor, second the brush-shifting motor

and third the Ward Leonard system of control. Since the power factor of the slip-ring motor falls quite rapidly at light loads, curves are also shown in Fig. 5 giving the kilovolt-ampere input under the same conditions. Other sizes of fans and other speed variations may change the relative values of these curves. It is only necessary to capitalize the saving of one over the other to determine which is the cheapest form of drive.

Reliability is, in many installations (for reasons already referred to) the controlling factor in the choice. The slip-ring motor perhaps has a little the best of this argument, there being only one motor involved, and no commutators or other mechanism beyond the control and resistance. The other systems, however, are reliable and have been installed on a large number of fans.

The curves shown in Figs. 4 and 5 do not take into account the efficiency of the fan proper. This efficiency is just as important as the efficiency of the motor drive. For instance, the majority of fans will increase in

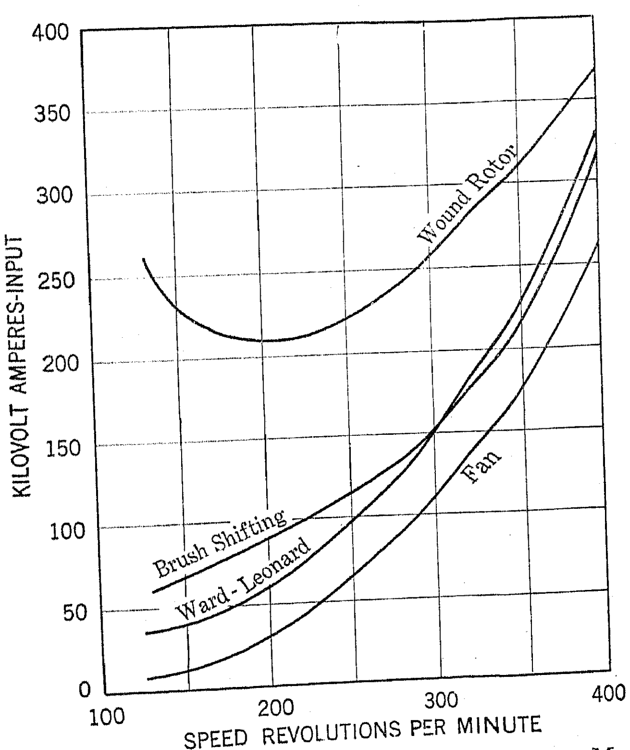

Fig. 5—Speed Kilovolt-ampere Curves of Motor-Driven Fan Using Wound Rotor Induction Motor, Brush Shifting Alternating-Current Motor and Direct-Current Motor with Ward Leonard Control

efficiency up to a certain speed and beyond this speed the efficiency falls off very rapidly. Thus, a most efficient motor drive might be selected, but on account of operating the fans at an inefficient point the overall efficiency of the installation might be low. The prospective purchaser is strongly urged to make a thorough analysis of his fan and drive before obligating himself beyond recall. A small percentage difference in efficiency is much more serious in the case of a fan than in almost any other motor application about the mine. The fan runs continuously and therefore the kilowatt-hours consumed pile up at an amazing rate so that a few per cent saved by improving the efficiency of this drive nets him a very large return over the year.

In this day of automatics, the fan drives have received their share of attention. They may now be built to start automatically upon the return of power after an interruption and to shut down and notify the officials in case of hot bearings or excessive temperatures in any part of the apparatus. They can be started and stopped by remote control.

Motor-driven fans, if properly designed and installed,

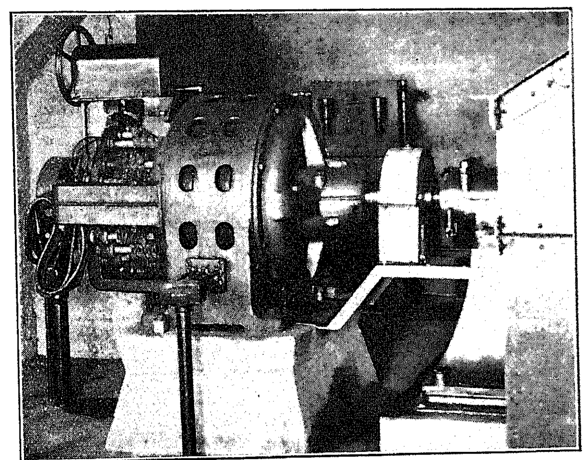

Fig. 6—Brush Shifting Variable Speed 150-H. P. Motor Direct-Connected to High Speed Fan

are thoroughly reliable and economical pieces of machinery.

The fan load is ideal from the power supply standpoint. It is usually steady for 24 hours a day and 7 days a week. From the operator's standpoint it helps materially to improve his load factor.

Fig. 6 shows a brush-shifting motor directly coupled to a high-speed fan. This does not happen to be a mine installation but is similar to the arrangement used for direct-connected fans.

Haulage

The installation of electric mine locomotives was the first achievement along the lines of economy in which electricity played the leading part. Long before power companies thought of supplying current to the mines, electric locomotives were busy underground hauling loaded cars from the working face and returning empties. Their power supply usually consisted of a small direct connected engine generator unit in sizes varying from one to three hundred kilowatts. The generators were generally very heavily over compounded to compensate for excessive line drop.

In this manner the early operators hoped to save expense in their copper line wire investments. Later experience, however, seems to indicate that it is better practise to maintain as high a voltage as practicable at

the substations and make a moderate investment in copper, thereby keeping the voltage up and the energy loss down.

The scheme of wiring and underground transmission varies considerably with local conditions. Sometimes cables are run down the main shaft, in other instances a borehole is put down as close as possible to the center of distribution and a feeder cable dropped through the borehole. Various parts of the mine wiring are usually sectionalized so that power may be cut off in any desired part of the mine. Since the early days the small engine generators have been shut down and modern substations installed.

The design of the locomotive has changed most materially as conditions surrounding its operation become more thoroughly understood by designing engineers.

Mine locomotives may be divided into two general classes namely; the main-line haulage locomotives and

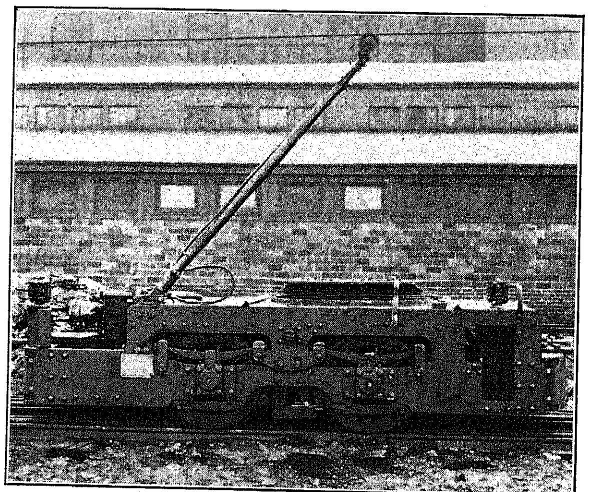

FIG. 7—FOUR TON GATHERING LOCOMOTIVE SHOWING EQUALIZING LEVERS AND CABLE REEL

the gathering locomotives, the former as their name indicates haul large strings of cars or "trips" from various central points to the foot of the shaft, while the gathering locomotives bring the loaded cars from the rooms to the central points where the trips are made up. The gathering locomotive differs from the main-line locomotive in that it is usually lighter, of shorter wheel base and carries with it a cable reel. The size of the gathering locomotives ordinarily used varies from three to eight tons. The cable reel is usually driven by a torque motor which when the reel is in action is left across the line permanently and continually exerts a torque against the reel. One end of the cable is electrically connected to the trolley or other source of power and when a locomotive enters the room the cable reel is unwound against the torque of the motor. When the locomotive comes out of the room, the torque developed by the motor is sufficient to reel up the cable as the locomotive returns. The action of this motor is very similar to that of an endless spring. Cable reels are built in two distinct forms, one a comparatively long drum of small diameter placed at one end of the locomotive and the other a large diameter drum with a very narrow face, placed on top of the locomotive with its axis vertical. The long-faced small-diameter reel referred to necessitates a mechanical guide to insure the proper coiling of the cable. The short-faced large-diameter reel requires no such device, but, on the other hand, usually adds a few inches to the overall height of the locomotive.

Cable reels of both types were originally mechanically driven from the locomotive axles but this was found decidedly unsatisfactory because in coming out of a room of any considerable pitch or grade the locomotive runner is very liable to lock the wheels which in the older style would stop the cable reel winding in and allow the locomotive to run over and destroy the cable. Gathering locomotives are usually designed to operate at a speed of from six to seven miles per hour at normal rated drawbar pull. Quite recently the question has come up as to whether it would not be better to drop this speed to approximately three or three and one-half miles per hour, it being found that very few gathering locomotives exceeded this speed and that the locomotive runners wasted a great deal of energy in the resistance, running the motors in parallel with a large quantity of resistance cut in series. A slow-speed gathering locomotive was designed and installed for one of the very large coal companies and it was found that a material saving resulted in kilowatt-hours per day with practically no reduction in tonnage. The question naturally suggests itself as to why (since the majority of locomotives have two motors and high speed is obtained by operating the motors in parallel) a series parallel controller could not be used, which would give practically half speed when operating the motors in series, and also give high speed with motors in parallel when desired. This scheme is entirely feasible and is open to but one criticism, namely, the locomotive runners will not operate their motors in series but prefer to run in parallel on resistance; this, notwithstanding all rules and instructions to the contrary.

The electrical equipment on the gathering locomotives generally consists of two motors totally enclosed and rated on a 75-deg. cent. rise full-load one hour. The design of the motor has been materially improved these past few years and today operates as far as commutation is concerned about as well as a standard industrial motor. It is equipped with interpoles and in the better designs with very liberally proportioned ball bearings. This latter feature alone has cut down the locomotive repair bill very materially. The old style bearings used to wear badly and since the inspection was not of the best, the locomotive would run until its armature struck the pole pieces which usually necessitated a complete rewinding. This complaint is practically unheard of with ball bearings.

Control

The majority of controllers is of the series parallel type, so wellknown that no description of them is necessary.

Within the past few years, however, one of the large manufacturing companies has built as a standard part of its line a controller of the series parallel type with an auxiliary cylinder, which, when moved into the proper position, gives the operator complete control of his trip by a dynamic brake action of the motors. This arrangement lightens the manual work of the mine locomotive runner and has proved very popular where installed.

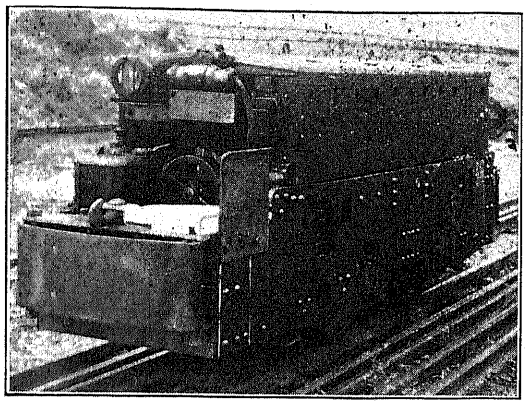

Fig. 8—Five-Ton Two-Motor Storage Battery Mine Locomotive Extensively Used in Metal Mines

Storage Battery Locomotives

The application of the storage battery locomotive is in the writer's opinion rather limited. At first thought, it would seem as though this type of locomotive would have a very wide application in mines. No trolley is necessary and the rails need not be bonded. The equipment could be made safe to enter gaseous places in the mine and altogether the outlook for this particular type seemed very bright. Several small manufacturers entered the field building locomotives equipped with storage batteries and turned their salesmen loose to secure business. A great many failures followed, due largely to improper application. Locomotives were put on long hauls that were designed only for short ones. The result was a very rapid battery deterioration and consequently very heavy renewal charges. From such information as I can gather the sales of storage battery mine locomotives have fallen off quite materially in the past year or year and a half and many instances are recorded where users have changed from the storage-battery type to the cable-reel type for gathering work. I do not mean to indicate by this that the storage battery locomotive has no field in the mine. In many cases it has a field but nothing like the general application as first anticipated. Properly designed and operated storage battery mine locomotives have a battery large enough to carry it through a day of normal operating conditions and after an all-night charge is ready for service the following morning. Batteries are usually mounted in a battery box which is easily removable from the locomotive and a new battery substituted when desired. The standard speeds of battery locomotives do not exceed four miles per hour at rated drawbar pull. The direct current for charging a storage battery is furnished usually from a motor generator set installed in the charging room and controller through a battery-charging panel.

Main-line locomotives are of the same general construction as the cable-reel locomotives. Their function as the name indicates is to operate along the main haulage ways carrying loaded cars to the foot of the shaft and empties to some central point. In sizes they run usually from 6 to 30 tons. The motors are rated on the same basis as the gathering locomotives and the control is of the series parallel type. One comparatively recent improvement has been developed for the haulage locomotives which is that in place of the ordinary series parallel controller, a master control and contactors have been substituted. The main-line currents are handled on contactors of the same general design as those used on street railway work. Locomotives so equipped have created a very favorable impression and this method of handling main-line currents on contactors will in all probability be adopted by all manufacturers of trolley-type locomotives.

Another important change of design in mine locomotives of all types is in the method of carrying the weight on the axles. Leaf springs with equalizing levers are arranged so that an equal weight is carried on each wheel irrespective of track conditions. This is obviously of great advantage when rough mine track conditions are considered. In the older types of locomotives when operating on uneven tracks, the weight on the wheels varied greatly, which in turn reacted upon the drawbar pull. The general arrangement of these levers and equalizing devices can be seen in the illustrations.

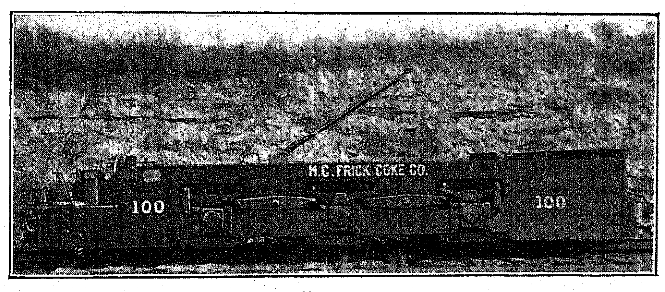

Fig. 9—Locomotive

The larger locomotives are equipped with air brakes and suitable compressor. The usual motor equipment on modern locomotives is of such capacity as to give approximately 10 h. p. per ton of weight on the drivers,

the rating being as before stated on a 75 deg. cent. rise at rated drawbar pull for one hour.

SUBSTATIONS

No practical mine locomotive has been built using a-c. motors. It, therefore, becomes necessary to equip the locomotives with d-c. motors.

Power is delivered to the mines in the form of high-voltage alternating current. This power must be transformed to a suitable voltage and then such amounts of it as are necessary must be converted to direct current for supplying the mine locomotives and in many coal mines the mining machines for undercutting the coal.

The step-down transformers are of the usual type transforming the transmission voltage to 2200 volts. The transformer end of the substation may be of the outdoor or indoor type and is designed along the same lines as similar step-down substations in other industrial work.

Conversion from alternating current to direct current is accomplished either through a motor-generator or a

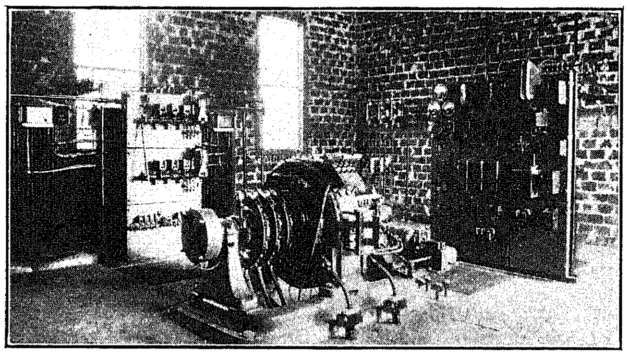

FIG. 10—AUTOMATIC ROTARY CONVERTER SUB-STATION

synchronous converter. If the synchronous converter is used, further transformation of a-c. voltage is necessary. If the motor generator is used, a motor can be operated directly from the 2200-volt bus.

The question as to the selection of a motor generator or synchronous converter seems to be quite badly misunderstood by many engineers. At first glance it would seem as though the synchronous converter on account of its higher efficiency should be used in all such places. It would seem to the writer that the determining factor in the choice lies largely in the nature of the power supply. If the operator is sure of a constant voltage supply and does not require any over compounding of the converter and is in no need of power-factor correction, then the indications point to a synchronous converter. If, however, the line voltage is variable, any percentage reduction in voltage on the a-c. side will produce a corresponding reduction on the d-c. side where a synchronous converter is used. This reduction in voltage means to the operator a reduction in speed of practically every piece of machinery operating on the d-c. system which reacts in practically the same percentage on his output. If he requires power-factor correction, standard mine motor-generators are designed to operate normally at full load with 80 per cent leading power-factor in the synchronous motor. Synchronous converters cannot be used for power-factor correction beyond operating them at unity power factor. The d-c. voltage of the motor-generator can be held constant irrespective of a-c. voltage fluctuations. The generators of the motor-generators can be readily compounded if it is so desired.

The load on the rotor or motor-generator is extremely variable and the set must be built to withstand and commutate satisfactorily 100 per cent over-load momentarily and should be capable of carrying 50 per cent over-load for two hours without any injurious temperatures resulting.

The control of these units and the units themselves must be capable of withstanding numerous short circuits. One side of the d-c. bus is always grounded. Consequently, the fall of a trolley wire in the mine, which is a very frequent occurrence due to faulty roof conditions, will cause a dead short circuit. The control must be capable of removing this short circuit from the generator as quickly as possible.

In large operations, particularly coal mines, it is very common to find underground substations working in parallel with stations on the surface. The a-c. supply for these underground stations may be taken down through a borehole or when the proper precautions are taken may be carried through the air-way or even through the haulage way to the substation. The voltage of the d-c. power supply for mines is either approximately 250 volts or 500 volts, the higher voltage installations becoming scarcer as time goes on.

AUTOMATIC SUBSTATIONS

Many of the modern substations are equipped with full automatic features exactly the same as many of the railway automatic substations with a possible exception that I know of no mine substation which shuts down on failure of load. This added feature would not be practical in a great majority of mines as the load is varying continually in the substation from a maximum to minimum at very short intervals. The automatic features, however, which are included are as listed below. These protective features apply to both synchronous converter and motor-generator substations containing one or more units and are arranged to protect against

A-c. over load
D-c. over load
D-c. reverse power
D-c. reverse polarity
A-c. under voltage
Loss of motor excitation
Loss of generator excitation
Single-phase starting
Imperfect starting
Over-heated bearings
Over-heated windings
Over-speed

Perhaps the most interesting feature of this automatic control is the d-c. circuit breaker which will open on an over-load or short circuit and will remain open until the short circuit has been removed, after which it will close automatically. In view of the numerous short circuits to which substation apparatus is subjected, some few operators have installed what is known as a high-speed circuit breaker. With the ordinary circuit breaker a considerable time elapses from the time the short circuit occurs until it is opened at the circuit breaker and frequently machines will arc-over under this condition; and even if they fail to arc-over considerable burning of the brushes and arcing of the commutator ensues. The high-speed circuit breaker will completely disconnect the machine from the line in less than 0.01 sec. This rapid action prevents the current from rising to any very high value beyond the setting of the circuit breaker and consequently it takes the shock of a dead short circuit from the machine.

Pumps

All mines require a drainage system of some sort. In many operations the problem of keeping the mine

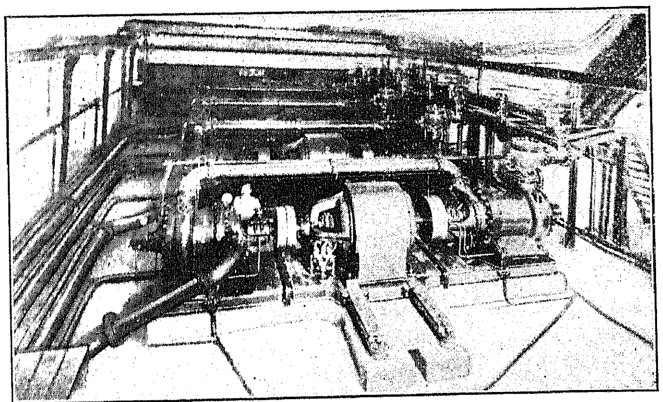

Fig. 11—Four 1750-H. P. 2000-Volt, 1500-Rev. per Min. Motors Driving Centrifugal Pumps, Randfontein Central Gold Mining Co., Ltd., So. Africa

free from water is one of the most difficult and most expensive. For instance, the average pumping condition throughout the anthracite field is 20 tons of water pumped to one ton of coal mined. Many of the mines, particularly in wet seasons, exceed this figure three or four times. Consequently, we find inside some of our large mines enormous pumping plants and sometimes the capacity is large enough to supply a fairly large city. The water pumped is usually acidulous to such an extent that in many instances pumps have to be made of very special and expensive acid-resisting metals.

Pumps are divided into two general classifications namely; the multi-cylinder plunger pump and the centrifugal pump. The former requires a moderate-speed motor usually geared, while the latter calls for a high-speed motor arranged for direct connection. In either case the problem of the electrical engineer is the same. The motor must have moisture-resisting insulation and must be very carefully constructed, particularly in the insulation of its coils. The atmosphere of an underground pump house is usually very humid and unless special precaution is taken the coils will breathe, taking in very moist air which deposits its moisture inside the coils tending to weaken the installation. The larger electrical manufacturing companies have designed a standard line of high-speed induction motors for the driving of centrifugal pumps.

There are no special features connected with the control of pumps as they are usually run at constant speed until the sump-level is lowered to a desired amount, after which they are shut down either automatically by means of a float switch or by hand.

Some of these pumping stations have been made fully automatic and arranged so that when the level of the sump rises to a predetermined value, a priming device comes into play which primes the pump, and after the priming is accomplished the main driving motor is thrown across the line and the pump started. The main motor cannot start until the pump is primed. Should the pump lose its suction for any reason, the equipment automatically shuts down. The most up-to-date installation of this sort, which it has been the writer's privilege to see, is in one of the mines of the Philadelphia-Reading Coal and Iron Company.

The selection of the proper centrifugal pump for a given job should receive very careful consideration. Pump manufacturers list the same pumps for various speeds and heads. The efficiency curve of a pump when plotted to speed in the majority of cases shows a very decided maximum and a rapid falling off either side of this high efficiency point. If a pump is selected to operate at a speed very different from the high efficiency point, the result, irrespective of the drive, will be a very inefficient installation.

In many wet mines we find what is known as gathering pumps which consist of small portable equipments which can be moved about the mine and take care of local flood conditions. These gathering pumps are usually of the centrifugal type and manually controlled, being driven by an induction motor or a d-c. motor taking power from the trolley supply.

The foregoing gives a very brief description of apparatus in general use about the mine. There are, of course, many small other applications for motor drive such as small booster fans, small portable air compressors, electric driven rock drills, etc., but neither time nor space will permit any description of these less important applications.

Hoisting

Of all the problems connected with the mine that of the proper selection of the hoist is perhaps the most interesting. Electric hoists have long since passed beyond the experimental stage and have innumerable times demonstrated their greater economy as compared

with any other form of hoisting. The electrical engineer is no longer asked to compare the economy of the electric hoist with that of the steam engine. One manufacturing company has, within the past 15 years sold 230,000 h. p. in electric hoist divided among 450 units. The only problems now to be solved are how large shall the drive for the hoist be, what is the

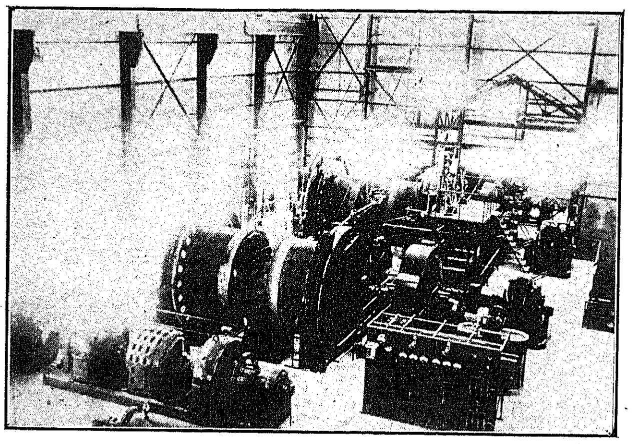

FIG. 12—AUTOMATIC MAIN HOISTS, INSPIRATION CONSOLIDATED COPPER CO., MIAMI, ARIZONA

best shape to make the hoist drum and finally what is the best system for the hoist in question.

The question of size of hoist can be readily determined from the duty cycle. This duty cycle can be calculated with great accuracy as shown by a paper presented before the spring meeting of the Institute at Birming-

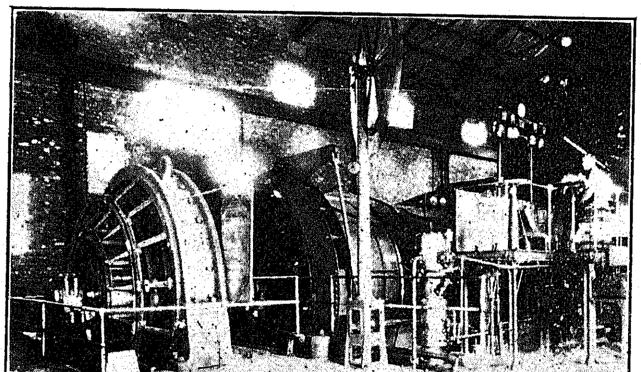

FIG. 13—ONE OF THE TWO DUPLICATE 5000-H. P. MINE HOIST EQUIPMENTS

Installed by the Randfontein Central Gold Mining Company in South Africa at their north and south shafts, each equipment consisting of two 2500-h. p. 160 rev. per min. d-c. motors, one of which is shown above. These two hoists are the largest electrically driven hoists in the world.

ham this year by the writer and F. R. Grant. This paper shows the original calculated duty cycle and the duty cycle that was actually obtained, not on a graphic meter, but on an oscillograph which read volts, amperes and speed. The areas and peaks checked within a negligible percentage.

The best shape of drum can only be determined after several duty cycles have been made using various shapes. In many instances, a plain cylindrical drum is necessary. This is particularly true if hoisting is to be accomplished from more than one level. The conical drum and the cylindro-conical drum have only a special field of application, but in this field the proper

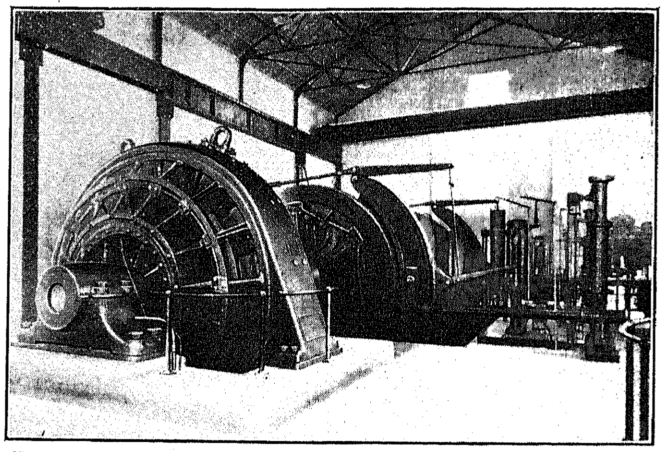

FIG. 14—TYPE MPC-16-1800-H. P. 80-525-VOLT HOIST MOTOR DRIVING FIRST MOTION DOUBLE CYLINDRICAL HOIST, ELU ORLU MINING COMPANY, BUTTE, MONTANA

selection of the shape is of quite vital importance. For instance, on short, fast cycles the rating of the main-drive motor can be reduced as much as 35 per cent by the use of a cylindro-conical drum as compared with a straight cylindrical drum.

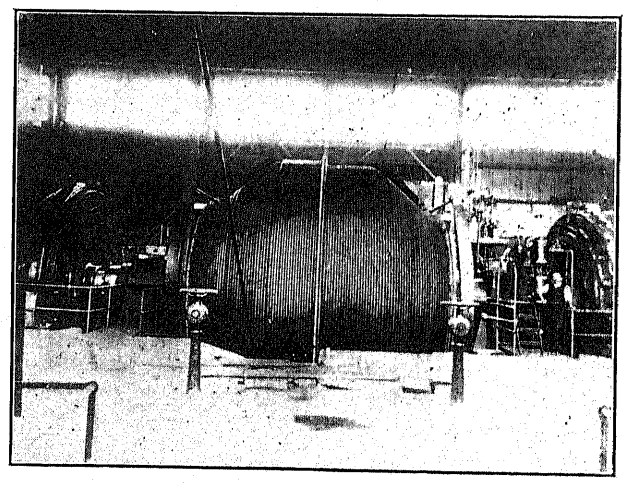

FIG. 15—4000-H. P. D-C. HOIST, SOUTH RAND SHAFT, CROWN MINES, LTD., SOUTH AFRICA, CYLINDRO-CONICAL DRUMS

In drums other than cylindrical, the up load is started on the small diameter while the down load starts with a large diameter. This difference in diameters reduces the starting torque very materially and in fast cycles the acceleration is frequently the controlling factor in the motor rating. This reduction of starting torque is therefore very important.

There are limits, of course, beyond which it is not well to go in proportioning the large and small diameters.

The small diameter is usually fixed by the diameter of the rope. Conservative hoist engineers feel that the ratio of rope to drum diameter should not be less than 1 to 60, otherwise the rope will deteriorate quite rapidly due to the bending stresses. Thus with the minimum diameter determined, the maximum diameter is limited by the weight and consequent $W R^2$ of the drum. It is very easy to defeat the entire object of the drum by running its $W R^2$ too high.

There seems to be no limit in the steepness of the spiral on which the rope climbs from the smaller to the larger diameter, drums having been constructed where the diameter increases as rapidly as two feet per turn.

The conical and cylindro-conical drums assist also in keeping down the peaks in very deep shafts where the weight of the rope is equal to, or as is frequently the case, far exceeds the weight of the material hoisted. An excellent illustration of this is found in one of the 4000-h. p. hoists installed at the Crown Mines, South Africa. This particular shaft has a vertical depth of over 3500 ft. and carried a weight of ore of 16,000 lb. The rope was two inches in diameter and had a total weight of more than 23,000 lb. For this reason a drum was selected 12 ft. small diameter, 20½ ft. large diameter, the drum being of the cylindro-conical type, the cone portion occupying about half of the face and the rope being wound in two layers on the large cylindrical portion. By the adoption of this drum the over balancing effect of the rope was nicely compensated for and the starting load is reduced very materially.

As to the proper system of use, we have the choice of a single induction motor usually geared to the hoist drum through one set of gearing, or we have the d-c. motor driven from a motor-generator set with Ward Leonard control, the motor-generator set consisting of a synchronous or induction motor set without flywheel. Finally, we have a d-c. motor driving the hoist from a motor-generator set with Ilgner control. By Ilgner control, I mean an induction motor-generator set with a flywheel large enough to remove objectionable peaks from the line. Very briefly, this control consists of a motor-generator set as above described and a slip regulator, which, as the load tends to rise above a predetermined value, inserts resistance in the rotor of the induction motor of the motor-generator set thereby holding the torque of the induction motor practically constant. The load on the d-c machine may call for a much greater torque than the induction motor will exert. The result is the set will slow down in speed, the flywheel giving up energy. As soon as the load is removed from the d-c. end, the induction motor being considerably below synchronous speed will draw sufficient load from the line to bring the set back to nearly synchronous speed and restoring to the flywheel the energy it gave up during the heavy demand. A properly designed Ilgner system will keep the input to the hoisting equipment practically at a constant value, if hoisting is carried on at a constant rate, or it will limit the demand to any predetermined value desired.

Thus you see, we have two distinct systems of hoist drive, one using a single induction motor of the slip-ring type with the speed controlled by a variable resistance in the rotor circuit. The second system involves a d-c. generator either direct connected or geared to the hoist drums, and a motor-generator set with or without a flywheel for driving the hoist motor. The second system naturally will cost three or four times that of the first. The question naturally arises why should the second system ever be used. The answer is as in all such installations total cost, namely, interest in fixed charges plus operating costs.

The control of the induction motor hoists is so simple that it needs little or no description. A large resistance is connected across the collector rings and is cut in and out at the will of the operator by means of contactors operated from the master controller. The control is, of course, equipped with current limits so that the acceleration peaks will not go beyond certain predetermined values, but these peaks come directly from the line and no type of resistance will reduce them. In other words, acceleration of a given mass is to be accomplished in a given time and it will require the expenditure of a certain number of horse power seconds. The acceleration of the hoist load by this method of control is exactly the same as the acceleration of any other load where a constant line potential is held. Approximately one-half of the energy taken from the line during acceleration will be dissipated in resistance.

With the d-c. system using Ward Leonard control there is practically no rheostatic loss, since the speed of the hoist is controlled by the generator voltage.

On short fast cycles this saving in acceleration losses amounts to so much that the difference in the kilowatt hours per trip when using induction motor as compared with the Ward Leonard is sufficient to warrant a large expenditure for the d-c. system.

Further, the d-c. system of control is very much more flexible and lends itself a little better to the application of safety and speed controlling devices. The d-c. hoist can be run at reduced speeds with no rheostatic losses. This is impossible with the a-c. hoist.

It is impossible to state with any degree of certainty which system is the more economical until a thorough analysis of the problem is made.

Automatic Hoisting

Due to the ease of control where the d-c. Ward Leonard system is used it has been found feasible to install completely automatic hoists. By this I mean, a hoist which can be started from a push button in the morning and run continuously for 24 hr. or longer, if necessary, without any manual attention whatever. A beautiful example of this is found in Inspiration, Arizona. These hoists have been in operation 9 years

without a single objectionable instant. A much larger hoist has been put in operation at the Inspiration property which embodies many of the automatic features found in the original installation. The hoist motor frame on this later installation is the largest single-hoist motor equipment in the world. It is rated 2150 h. p. at 53 rev. per min., the rating being given on 40-deg. cent. rise continuous operation.

Whether or not a fly-wheel is used for the equalization of the incoming power depends on two factors. First, if purchased power is used and instantaneous demands are penalized then a fly-wheel should be installed. Second, if the hoist is to be operated from a small plant, either privately owned or a public utility, the addition of a flywheel will frequently be of such value in reducing the peaks on the line that even though the plant be small no additional capacity will be necessary. This would not be the case if an induction-motor hoist or a motor-generator set without a fly-wheel were installed.

Undercutting Machines

These machines are used only in coal mines but there very extensively. The purpose of the machine is to cut a very thin channel across the bottom of the coal face. This channel is about six inches high and from six to ten feet deep. The mechanical parts of this machine are very ingenious. The cutting part usually consists of an endless chain carrying cutter teeth. The machine is started in one corner of the room and the cutter feeds itself under the coal until it has entered its entire length. Clutches are then engaged and the machine feeds itself across the face. It makes all motions under its own power. After the coal has been under-cut it requires very little shock to break it down.

The motor drive for these machines may be either direct current or alternating current. The motor is usually totally enclosed and rated on a one-hour continuous run basis. Service is extremely severe and only the very best of workmanship and material will survive this kind of operation.

Strip Mining

Numerous ore and coal deposits have been located so close to the surface that they can be attacked by removing the overburden. This system of mining is commonly known as strip mining. Very large electrically-operated shovels very similar to the steam shovel have been developed for this stripping work. The largest in use at the present time is what is known as the model 350, meaning that the entire weight of the equipment is approximately 350 tons. This shovel is capable of handling a ten-yard dipper and has a boom 90 ft. in length. The duty on the motors of an electric shovel is probably the most severe encountered anywhere. They are continually starting and stopping and being subjected to heavy over-loads. Notwithstanding this fact, however, the electric shovel is rapidly coming into its own.

The majority of electric shovels has a motor for each operation, namely, the hoist, the swing and the crowd. These motors are run from individual generators which form part of a four-unit motor-generator set. The control is a slight modification of the Ward Leonard, the difference being that each generator has a differential series field which limits the current output

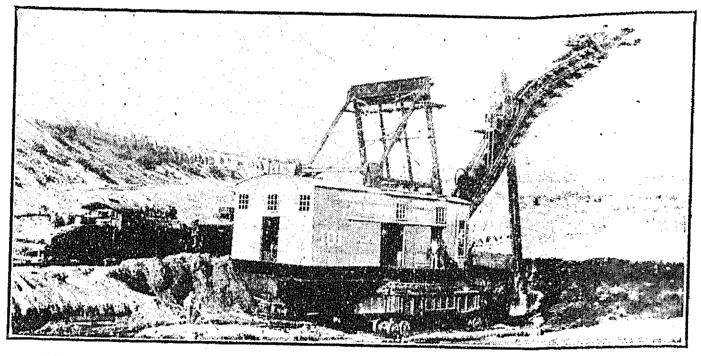

Fig. 16—Model 350 Marion Electric Shovel, the Largest of its Type Built

of the generator to a predetermined value. Thus it is impossible for the operator to abuse the electrical apparatus or the mechanical apparatus beyond a certain point.

Induction motors have been installed on electric shovels but from all information the writer has been able to secure the d-c. Ward Leonard control is much more dependable and the operating costs considerably lower.

Discussion

G. B. Rosenblatt: The paper apparently deals mostly with the application of certain electrical equipment to coal mining and makes little reference to metal-mining practise with which I am much more familiar. If it will be remembered that the remarks I have to offer are based on my experience in the metal-mining field and may fit in with coal-mining practise only in so far as they may apply to it, I would like to offer the following comments:

Emphasis is laid by Mr. Stone on the importance of maintaining ventilation underground. He then suggests for the drive of the fans to maintain this ventilation, a synchronous motor of the type designated as "supersynchronous," that is, the type whose stator revolves during starting. Admission is made that this type has never been applied to such work but the author advocates it. It is my opinion that the design of the so-called super-synchronous motor has not progressed to the point where it may be considered sufficiently reliable for such an important application. This type of motor has today been used almost entirely for the drive of ball or tube mills in cement plants. While continuity of operation is important in such service, it is not paramount. If a tube mill shuts down due to motor trouble, a certain production is lost—but if a mine fan is shut down due to motor trouble at critical moments, men die. In connection with investigations conducted by a prominent western mining organization which decided on synchronous motor drive for its tube mills, existing installations of the so-called supersynchronous motor were investigated. The results of

this investigation were that the synchronous motor with stator revolving for starting was not deemed altogether reliable. It may therefore be considered that this type of motor in its present stage of development is not suitable for mine-fan drive where human lives are at stake.

In discussing the applications of synchronous motors to mining work, it is to be regretted that no mention has been made of the really large field for such installations afforded by air compressor and pump drive. The introduction of synchronous motors into the mining industry is really a very important matter to all of the large power systems which supply such load as well as to the mining companies which generate their own power. All metal mines use a large amount of compressed air. Simple direct-connected synchronous motors are most readily applied to the drive of the requisite compressors. Of late, synchronous motors have also been very successfully applied to driving mine pumps and there are now some very large underground pump stations in western mines equipped entirely with synchronous-motor-driven pumps.

The author seems to feel that the field of usefulness for storage-battery locomotives underground is decidedly limited and possibly decreasing. My own experience does not bear this out. In metal mining particularly, we find the properly designed storage battery locomotive increasing in popularity and use. It is the poorly designed and improperly applied storage-battery locomotive that has caused the failure of certain installations of storage-battery haulage. Coming right down to fundamentals, the comparison is not fairly to be made between the trolley type or gathering-reel locomotive and a storage-battery locomotive, but should rather be made between the two types of haulage systems as a whole, including in such comparisons all items that go into the actual cost of hauling a unit of ore or coal over a unit of distance. The machinery designer—the factory engineer—may be much interested in different advantageous details of one type of locomotive as against another, but the purchaser and the user—the man that pays the bills—is primarily concerned with what it costs to haul his ore or coal per ton and per mile.

Mr. Stone states "induction motors have been installed on electric shovels but from all information the writer has been able to secure, the d-c. Ward-Leoanrd control is much more dependable and the operating costs considerably lower."

The relative advantages of a-c. versus d-c. for large shovel drive has been a moot question among interested engineers for the past several years and each system has had its staunch supporters. Some while ago, a prominent copper company which had for years been doing their mining with over 20 large steam shovels decided to electrify the shovel operations. The arguments submitted by the various supporters of the two systems of electric drive—a-c. versus d-c.—were carefully and painstakingly reviewed by the management of the mining company who finally came to the conclusion that all the arguments presented were based largely on opinions and deductions and not on known facts, so they set out to find the facts for themselves. They bought and installed two shovels—both identical mechanically—one equipped with Ward-Leonard d-c. equipment, the other with a-c. induction motors. The electrical installation of each type was supervised by the manufacturers advocating that particular type, so that both shovels had the advantage of the best electrical engineering talent. These shovels were then put into regular mining operation and their performance carefully watched and recorded by both the engineering and operating staffs of the mining company. After several months operations, the mining company decided that sufficient data had been collected to permit it to determine upon the type of shovel for its subsequent electrification. In order to assure itself that its judgment in making this important decision would be as correct as possible, the mining company secured the services of one of the best known American electrical engineers and a prominent member of this Institute to assist its own engineering department in selecting the most advantageous equipment. As a result they bought shovels equipped with a-c. induction motors—not the Ward-Leonard d-c. equipment.

The test records of this mining company covering the actual operation of both types of shovels under real mining conditions are most interesting. They indicate that the a-c. equipment: (1) Costs less to buy than the d-c.; (2) Is much simpler than the d-c.; (3) Should have materially less maintenance than the d-c.; (4) Consumes slightly—very slightly—more power than the d-c. per average ton of ore dug; (5) Can dig a bit faster than the d-c. equipment; (6) Imposes somewhat greater peaks and considerably poorer power factor on the power supply line.

These tests were made with big railway-type shovels mounted on caterpillars and the results, while conclusive, may not apply to all installations. However, the outcome of these large scale service tests certainly confutes Mr. Stone's statements regarding the general superiority of d-c. equipment for electric shovels.

C. H. Matthews (by letter): This paper seems to cover the application of electrical equipment to coal mines from the manufacturer's standpoint and I wish to make several comments that affect the practical use of the equipment described.

Mine ventilation, as Mr. Stone states, is of paramount importance and the most reliable and proven apparatus must be selected. The common design of synchronous motor with magnetic clutch is a very reliable piece of equipment and is suitable for driving fans of almost any capacity and speed.

Induction motors have proven efficient and reliable for driving mine fans but must be used with some form of speed reducer whereas the synchronous motor can be efficiently built for almost any speed for direct connection.

Where power-factor correction is necessary synchronous motor-generators and synchronous motors driving air compressors usually give the desired results, and the use of synchronous motors on mine fans and centrifugal pumps is desirable for lowering the power costs.

The use of storage-battery locomotives is a necessity in many metal mines if economical transportation is to be obtained and since the requirement of "permissible" equipment in gaseous mines the storage-battery locomotive seems to be getting a more permanent berth. There are many engineers who differ on the advisability of storage-battery applications, but there still remains a demand which must be satisfied.

The suggested speed of 3 to 3½ mi. per hour for gathering locomotives was probably based upon storage-battery locomotive speeds which speeds are maintained at a fairly constant rate over the working day. With trolley locomotives the speed depends upon the trolley voltage so that in the majority of mines a trolley locomotive designed for a speed of 3 to 3½ mi. per hour at rated voltage and draw-bar pull may not handle the same output as a storage-battery locomotive of the same weight and geared for the same speed. Since the voltage has a direct bearing upon the speed of trolley locomotives and as the trolley voltage is seldom maintained at normal value it would seem desirable to design for speeds of 4 to 5 mi. per hour at rated voltage and draw-bar pull. Some of the locomotive manufacturers used 500-volt motors on 250-volt power to obtain slow speeds for gathering. This was an easy way to secure data on slow-speed service but it reduced the rating of the motor equipment which from an operating point of view is not desirable. A study of motor curves on slow speeds of 3 to 3½ mi. per hour when using 500-volt motors on 250-volt power shows that the light-load speeds do not increase in the same manner as with motors designed for 250-volt slow-speed operation, so that a drop in trolley voltage causes a decrease in speed over the whole speed curve which is not compensated for to any great extent by light loads.

Graham Bright (by letter): I believe that a little more attention should be given to the question of the isolated power plant for coal mines. It is true that with central-station power available, in the large majority of cases there is little excuse for

the existence of the isolated power plant. There are, however, some localities where central-station power is still not available, and there are other cases where the central-station rates and form of contract are such that where the mining company has a fair supply of good water, and in some cases can utilize waste fuel of no commercial value, it would not only be feasible but would be economical to install an isolated plant.

The most important question, by far, in regard to the installation of an isolated power plant, is that of water supply. In most cases, the water available in the vicinity of a coal mine is very poor, and cannot be used in boilers without a treating plant. It is true that it is possible to treat water so that it will be very satisfactory for boiler service, but these treating plants require a certain amount of skill for their operation, and this skill is seldom available in the coal fields. In a great many cases, as soon as a man is educated to take care of the treating plant, he is likely to leave the locality, and the only one available for this particular situation is, figuratively, a man who knows nothing whatever of this kind of work, and no one has the time to teach him the details. The result is that the boiler plant gets in very bad shape and may be ruined in a short time.

Mr. Stone mentions the desirability of having a stand-by source of power where the mines are gaseous or collect water rapidly. A form of gasoline-engine-driven generator has been frequently applied, and Mr. Stone mentions that the hoist and fan. under such conditions, can be operated at reduced speeds. With the ordinary type of unit, operating at full frequency, this this can, of course, be accomplished with a fan only in case it is of the two-speed type, or of the variable-speed type. The hoist can be operated at reduced speed only by means of inserting resistance in the hoist motor, and this does not greatly reduce the amount of power required, since the extra power is absorbed by resistance. Where it is necessary to keep the fan and hoist in operation, the writer has proposed a scheme of supplying a gasoline-engine-driven generator, operating at reduced frequency. This permits the fan to operate at a lower speed, with very much less power, and permits the hoist to operate at reduced speed with an economical use of power. A plant of this type has been installed at one of the mines of the Y. & O. Coal Company, near Pittsburgh, and low-frequency emergency power can be made available within thirty seconds after loss of the central-station power.

Mr. Stone indicates that the load factor of the anthracite mine will be something like 42 per cent. I believe that in some of the mines where very heavy pumping takes place the load factor is even higher than 42 per cent. In the average bituminous mine, however, where the ventilation and pumping are both light, the load factor will average about 25 per cent, and in some cases may be as low as 15 per cent. This, of course, is one of the reasons why the cost of power at some of the smaller bituminous mines is rather high on a kilowatt-hour basis.

Mr. Stone illustrates a very ingenious scheme for allowing the use of a synchronous motor for operating a mine fan. The objection to the synchronous motor has always been that it has a very comparatively low pull-in, while for fan operation the motor should have a pull-in of 100 per cent. Unless a great deal of power-factor correction is required, the installation of a motor of sufficient capacity to produce the proper pull-in would not be economical. The use of a clutch has not been advocated much in the past, due to the added complication. I believe the time is coming when the synchronous motor will be used very commonly for the installation of mine fans, but I feel that the motor described by Mr. Stone is only a step in the ultimate direction. The objection to this type of motor is that extra collector rings are required, and in many cases these collector rings will carry a voltage of 2200. Another inherent objection to this type of motor is that for economical design, the peripheral speed of the rotating element of the motor should be fairly high. The stationary part of a motor is generally made of steel punchings, which furnish the required active iron surrounded by a shell of cast iron or cast steel. In case the stationary part is to rotate, as described by Mr. Stone, then the limit in speed would be determined by the outside diameter of the stationary part. Even when made of cast steel, this part would have to be carefully balanced and additional bearings supplied. This would mean that the peripheral speed of the rotor would be very much less than the economical speed, and for this reason, the motor would be more expensive than the standard type. As stated before, I believe that the motor described by Mr. Stone is but a step in the evolution of the synchronous motor, and the time is coming when we will have what is practically a standard motor with a magnetic or similar clutch, preferably inside of the motor, which can be operated automatically, and this motor will not cost a great deal more than the standard motor.

Mr. Stone's curves, showing the power taken by different types of motors, are very interesting, and indicate that the brush-shifting motor is well worth considering, where variable speeds can be utilized.

I am glad to know the stand that Mr. Stone has taken regarding the application of storage-battery locomotives to mines, as I know of a great many cases where misapplications have been made and the storage-battery locomotive has been given a "black eye" simply because of misapplication.

The application of contactor control for mine locomotives has a great many advantages. In the first place, it makes a much safer controller for the operator. A number of accidents have occurred where the operator has been seriously burned, due to the ordinary drum type of controller blowing out. With the contactor control, the operator has only the master controller close to him, and the danger of his being burned is very remote. Another advantage of the contactor control is that it forces the mine management to install sufficient copper to give a fair voltage regulation. This not only saves a considerable loss in power, but increases the output of the mine, and cuts down the maintenance of apparatus caused by burn-outs.

The application of contactor control also lends itself to dynamic braking, without seriously complicating the control itself. It also simplifies tandem operation in that only one power cable is required between locomotives.

The application of equalizer systems is becoming quite prevalent for both two- and three-motor locomotives, as a proper equalizing system will not only increase the power of the locomotive by keeping the load equally distributed on the wheels, but will make a much better tracking locomotive, thus preventing costly and annoying derailments. The usual method of applying an equalizer system to a two-axle locomotive is a rather difficult matter if a stable locomotive is desired. Unless the equalizer bars are restrained in some manner, the locomotive may become tilted to one end or the other and remain in that position. This is also true of the three-axle locomotive, where the axles are equalized all the way along each side. Where this type of equalizer is used, you will frequently notice that the locomotive is considerably closer to the track at one end than it is at the other. One way to eliminate this unstable condition is to equalize two axles on the sides and cross-equalize the third axle.

A feature illustrated in Fig. 9 of Mr. Stone's paper, but not mentioned by him, is the method of taking the end thrust on the end of the axle, rather than on the wheel hub. This is a distinct improvement on the older method, and is being almost universally adopted. It provides an easy method for taking up the end play and for lubricating the surfaces which take the end thrust. It also keeps the supply of lubricant for the main journals in a much cleaner condition, and for this reason the maintenance on the main journals and brasses should be much reduced.

I agree with Mr. Stone that the question of whether to use the synchronous converter or the motor-generator set for substations is largely determined by the nature of the power supplied.

With good voltage and frequency regulation there is no reason why the rotary converter should not give as good service as the motor-generator set, and it will have much better efficiency. In many of the bituminous mines, the substation will operate a considerable portion of the time at very light load. The losses with a synchronous converter are only about one-half of what they would be with a motor-generator set under these conditions. Where sufficient copper is installed, the constant voltage supplied by the synchronous converter will give very satisfactory operation. The over-compounding obtained by a motor-generator set in many cases indicates a considerable loss, and the high voltage near the substation during heavy loads is often injurious to compound and shunt-wound motors working in the vicinity. The automatic substation has come to stay, and with this equipment available there is no real excuse why good regulation should not be obtained in most of the working places in the average coal mine.

Mr. Stone's remarks in connection with the application of specially shaped drums to hoists are very much to the point, and where short, fast cycles are required, a very careful analysis must be made or the effect of the specially shaped drum will be entirely defeated.

In connection with electric shovels, the question of which is the best type of equipment to use has not as yet been finally settled. There seems to be a great deal of merit in the application of direct-current motors, using motor-generator sets and Ward-Leonard control. This type of equipment is rather complicated when it comes to the number of machines involved, but, of course, has an extremely simple and efficient control. The straight alternating-current motor, however, requires very much less equipment, and where the power system has sufficient capacity, this type of equipment has some advantages over the direct-current equipment. Just recently a large mining company in the West, which uses a great many shovels for a stripping operation, has conducted tests on both types of equipment, and have come to the conclusion that alternating-current is more efficient and less costly to install. From the results of the tests and investigations, they have decided to start equipping all of their steam shovels with the alternating-current system, using induction motors.

The direct-current shovel equipment in operation at this time using motor-generator sets and field control seems to be rather sluggish when compared to the alternating-current, and it is generally found upon comparison that the alternating-current equipment will dig and load more material in a given time than the direct-current of the same capacity.

F. L. Stone: Referring to Mr. Matthews' very interesting discussion, I agree with him entirely in his comments on storage-battery locomotives. There are places where their installation indicates good judgment on the part of the management. Like many other pieces of apparatus, it could almost be considered as a necessary evil under certain conditions. I tried to make this clear in the paper. It is the promiscuous and careless application of storage-battery locomotives to work that they are not suited to perform to which the writer objects.

Reference has been made to a prominent mining company in the West, where two practically duplicate shovels were installed, one being driven by a-c. motors and the other by d-c. motors, with variable voltage control. Before the tests on these equipments had reached a stage from which anything very definite could be deduced, the mining company purchased seven additional a-c. equipments. After the shovels had been in operation a year or more and some of the new a-c. shovels had been delivered and were put in operation, the mining company then felt that it had sufficient data to make an intelligent selection. It then purchased eight d-c. equipments. This, I think, together with the fact that many other companies have, on investigation, purchased d-c. drive, fully substantiates my statement.

In regard to Mr. Bright's discussion, will say that I am sorry I did not have time or space to go into great detail in connection with the problem of isolated plants versus purchased power.

Mr. Bright's comments on the super-synchronous motor show a very clear understanding of the subject. I might state that over fifty of these machines have been shipped and put in service. The collector-ring trouble which Mr. Bright refers to was taken care of by thoughtful and careful design. No trouble from this source has been brought to the writer's attention. The stator, as Mr. Bright points out, must be and is, very carefully balanced. The peripheral speeds of the stator are not at all excessive, and the factors of safety are very large. The ease of control while starting the load by means of the band brake is a very noticeable feature in this motor. The load can be brought up at a high rate of speed or at a low rate of speed, or the rates can be varied during the starting cycle at the will of the operator.

Practises in Telephone Transmission
Maintenance Work

BY W. H. HARDEN
Member, A. I. E. E.
American Telephone and Telegraph Company, New York, N. Y.

Review of the Subject.—*This paper describes the practical applications of transmission maintenance methods in a telephone system. The methods applicable to toll circuits of various types are first discussed, information being included in this connection on the maintenance of the amplifier circuits involved in telephone repeaters and carrier. Testing methods applicable to the local or exchange area plant are next described, the description including both manual and machine switching systems. The results accomplished in toll and local transmission maintenance work are considered from the standpoint of the kinds of troubles which can be eliminated and the effect which these troubles have on service.*

The methods described in the main body of the paper relate particularly to tests of volume efficiency. Certain other transmission maintenance testing methods directly associated with volume efficiency tests are briefly described in Appendix A of the paper.

* * * * *

IT is the purpose of this paper to present a general picture of the practical applications of methods of measuring transmission efficiency in the Bell System which have been developed by study and experience under plant operating conditions. The rapid growth of the telephone industry has made it necessary that these methods be such as to allow them to be applied on a large scale in a systematic and economical manner thereby providing for a quick periodic check of the efficiency of the various types of circuits as they are used in service.

Transmission maintenance can be broadly defined as that maintenance work which is directed primarily towards insuring that the talking efficiencies of the telephone circuits are those for which the circuits are designed. There are, of course, many elements which affect the talking efficiency and various d-c. and a-c. tests are available for checking the electrical characteristics of circuits and equipment to insure that these characteristics are being maintained in accordance with the proper standards. In the final analysis however, an overall test of the transmission efficiency of the circuit in the condition it is used in service will show at once whether it is giving the loss, or in the case of amplifier circuits, the gain which it should give. Transmission tests, therefore, offer a means whereby many of the electrical characteristics of circuits can be quickly and accurately checked.

In referring to transmission testing apparatus in this paper, four standard types described in papers previously presented before the Institute are involved. The first three types listed below were described by Best[1] and the fourth by Clark.[2] Reference in these papers was also made to the standard oscillators used in supplying the measuring currents for the sets.

1—*A Transmission Measuring Set.* This is an "ear balance" portable set suitable for loop transmission testing only and designed primarily for testing equipment and circuits in the smaller central offices.

3—*A Transmission Measuring Set.* This is a "meter balance" portable set suitable for both loop and straightaway transmission testing and designed primarily for testing circuits and equipment in the larger central offices.

4—*A Transmission Measuring Set.* This is a "meter balance" set suitable for both loop and straightaway transmission testing and designed for permanent installation at the larger toll offices primarily for testing toll circuits.

2—*A Gain Set.* This is a "meter balance" set designed for measuring amplifier gains.

Volume transmission efficiency is expressed in terms of Transmission Units[3] and measuring apparatus is calibrated to read these units directly. The principles involved in the use of these units in transmission testing work as well as the principles of the measuring apparatus employed were discussed in the papers referred to above. Certain other testing methods in addition to volume efficiency tests are also extensively used in transmission maintenance work and some of the more important of these are briefly discussed in Appendix A of this paper.

Since the routine procedures in testing toll circuits using the above apparatus differ considerably from those followed in the local or exchange area plant, the toll and local practises have been considered separately in the following discussions:

Transmission Tests on Toll Circuits

The importance of having available means for quickly checking the transmission efficiency of toll circuits and of economically maintaining the proper standard of transmission is evident when it is considered that in a plant such as that operated by the Bell System there are at the present time more than 20,000 toll circuits in service. The circuits making up this system are of various types and construction, depending on the service requirements and length, and also upon certain other factors determined by engineering and economical design considerations.

From the standpoint of maintaining transmission

1. See Bibliography.

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

efficiency between toll offices, the various types of toll circuits can be divided into three general classes: one, non-repeatered circuits, two, circuits equipped with telephone repeaters and three, circuits equipped for carrier operation. The latter two classes are alike in many respects as far as the maintenance methods are concerned and both require somewhat more attention than the circuits not equipped with amplifying apparatus. The length and number of repeaters involved are also important factors which must be taken account of in tandem repeater and carrier circuit maintenance. Very long tandem repeater circuits such, for example, as the long toll cable circuits described by Clark[2] require special maintenance procedures similar in many respects to those required in carrier maintenance.

The 4-A type of transmission measuring set generally used for testing toll circuits may be considered as a toll transmission test desk. Fig. 1 shows a picture of one of the latest models together with an oscillator for supplying the measuring current, installed at a toll office for use in routine testing. The set is provided with trunks to both the toll testboard and toll switchboard, and also with call circuits to toll operators' positions for use in ordering up circuits for test. The electrical measuring circuit is designed so that tests may be made on two toll circuits looped at the distant end, or straightaway on one toll circuit the distant terminal of which terminates in an office also equipped with a transmission measuring set of the same type.

To illustrate the application of this toll transmission

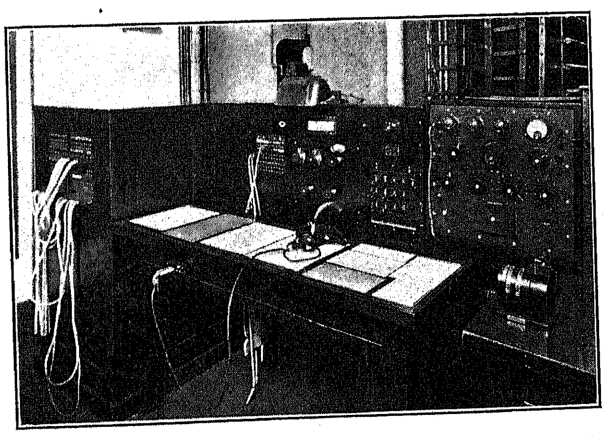

Fig. 1—Illustration of 4-A Transmission Measuring Set and 4-B Oscillator Installed in a Toll Test Room

test desk, Fig. 2 shows schematically an arrangement of four toll offices having circuits between them of the three general classes—non-repeatered, repeatered and carrier. Offices A and D are equipped with transmission measuring sets of the type shown in Fig. 1. A logical testing procedure for the arrangement in Fig. 2 is for offices A and D to test the non-repeatered circuits 1 to 4 and 10 to 13 by having them looped two at a time at the distant terminal offices B and C. By "triangulation measurements" on any three circuits in each group, the equivalent of each individual circuit can be readily computed.

For the circuits 5 to 9 extending between offices A and D equipped with telephone repeaters or carrier, straightaway measurements can be made in each direction with the two transmission measuring sets provided. Loop tests could, of course, also be made on the circuits from either office A or D, but this would require cutting the telephone repeaters out of one circuit or having available a non-repeatered or non-carrier circuit, since

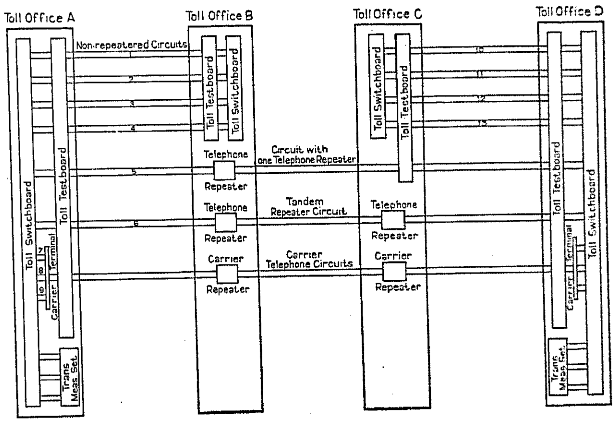

Fig. 2—Schematic Diagram of Typical Toll Circuit Layout to Illustrate General Method of Testing Non-Repeatered, Repeatered and Carrier Circuits

the gains of the repeaters in the two directions introduce variable factors in the overall equivalents which do not permit triangulation computations to be made. The overall tests on the carrier circuits do not differ in any way from the tests on repeatered or non-repeatered circuits, each carrier channel being tested as a separate circuit through the switchboards. The measuring current is modulated and demodulated in the same manner as voice currents under regular operating conditions and the measured equivalent, therefore, indicates the overall transmission efficiency.

The map of Fig. 3 shows the locations in the Bell System of transmission measuring sets of the general type described above. At a number of the larger toll centers, such as New York and Chicago, where the number of toll circuits to be tested require it, several transmission measuring sets are installed. There are now in operation between 40 and 50 of these sets, making it possible to test all of the longer and more important toll routes in the system. The shorter toll circuits radiating out from the large toll centers are also tested with these same sets. At the smaller offices where fixed transmission measuring sets are not warranted, the toll circuits which cannot be picked up by the larger offices are tested by portable transmission measuring sets of the 1-A or 3-A types in connection with other maintenance work.

One very essential requirement in carrying on a systematic testing program is to have records of the detailed makeup of the toll circuits which give both the

circuit layouts and the equipment associated with the circuits. Such a record is valuable, not only in giving the maintenance forces a picture of the circuits and equipment which they are testing, but it also furnishes a means for establishing the transmission standards to which they should work. When transmission tests indicate trouble, this record becomes of particular service in locating and clearing the cause.

Fig. 4 shows a sample of the type of toll circuit layout record card which has proven very satisfactory and is now generally used in the Bell System.

range of frequencies involved, and that conditions do not exist which will disturb the overall balance between the circuits and networks sufficiently to cause poor quality of transmission.

Considering telephone repeater maintenance, Fig. 5 shows a schematic diagram of a 22 type repeater and indicates the important tests which are made locally to insure that the apparatus is functioning in a satisfactory manner as a part of a toll circuit. The numbers applied to the different tests listed in the figure show approximately the points in the repeater circuit at

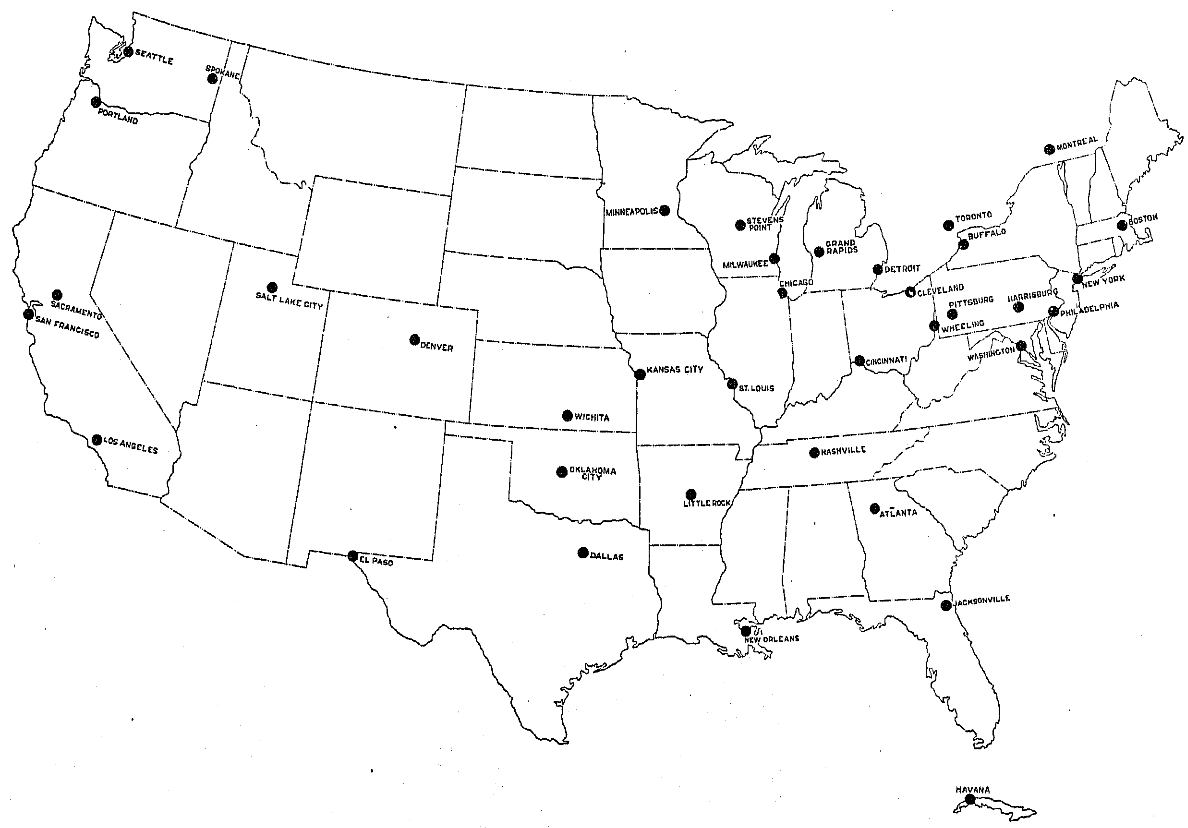

FIG. 3—MAP SHOWING LOCATIONS IN BELL SYSTEM OF PERMANENT TRANSMISSION MEASURING SETS

Telephone Repeater and Carrier Maintenance. Voice frequency telephone repeaters were discussed in a paper by Messrs. Gherardi and Jewett[4] and carrier systems in a paper by Messrs. Colpitts and Blackwell.[5] The various arrangements of amplifiers to provide for telephone repeater and for carrier operation as described in these papers make up integral parts of toll circuits and introduce elements in the circuits which have to be given particular local attention in maintaining the overall transmission efficiency. Since both telephone repeaters and carrier employ the same types of vacuum tubes with very similar arrangements for power supply, the maintenance requirements for the two are much the same. The chief items to be observed in both carrier and repeater maintenance are that the gains specified to give a desired overall transmission equivalent be kept as constant as possible, that these gains remain fairly uniform within the

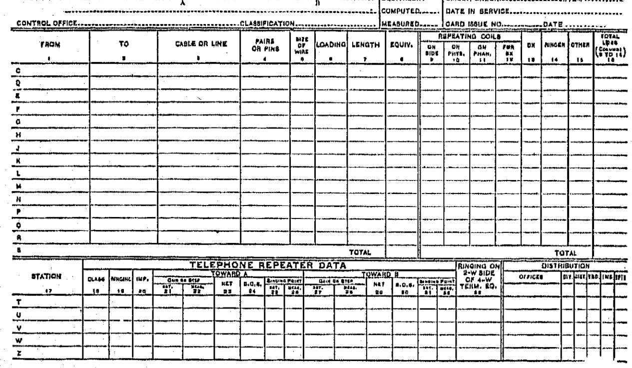

FIG. 4—SAMPLE OF A TOLL CIRCUIT LAYOUT RECORD CARD

which the tests are made, the purposes of the tests being evident from their names.

When carrier operation is applied to toll circuits, an

additional transmission system is introduced involving the use of currents of higher frequencies than those in the voice range. From a maintenance standpoint this means that certain additional testing methods must be employed which will insure the proper generation and transmission of the carrier currents and that the modulation and demodulation of the voice frequency currents is accomplished without distortion or excess loss in overall transmission.

To give a general picture of the more important features involved in the transmission maintenance of carrier systems, Fig. 6 shows a schematic diagram of a carrier layout having one carrier repeater. The particular arrangement shown is for the type *B* system described by Messrs. Colpitts and Blackwell,[5] although the same general maintenance considerations apply to any of the present systems. It will be noted that three series of tests are required, one for the carrier repeaters, one for the carrier terminals and one for the system as a whole. The nature of these various tests and the approximate points in the carrier system where they are applied will be evident from the names and numbers used in the figure.

For both telephone repeaters and carrier systems, provision is made in the regular testing equipment so that the tests can be very quickly applied both as a routine proposition and also when required for trouble location.

Transmission Tests on Exchange Area Circuits

The transmission conditions in the exchange area plant are important not only from the standpoint of insuring good local service but also to insure good toll service, since the local plant forms the terminals of toll connections. The exchange or local plant offers a somewhat different transmission maintenance problem than the toll plant, particularly with respect to the routine testing procedures which must be followed to insure satisfactory transmission. This will be evident when it is considered that in each city and town a complete telephone system is in operation which involves the use of a large number of circuits of various types. There are also in use three general types of telephone switching equipments; manual, panel machine switching, and step-by-step machine switching, and in certain cities combinations of these equipments. It is estimated that at the present time in the Bell System there are in the neighborhood of two and one-half million exchange area circuits, exclusive of subscribers' lines, involving equipment other than contacts and wiring which may directly affect the transmission of speech.

The general classes of exchange area circuits in both manual and machine switching offices, important from a transmission maintenance standpoint, are listed in Table I. The operating features of manual telephone systems are generally well known as are also the features of step-by-step machine switching systems, both having been in use for many years. The panel machine switching system which is a relatively recent development was described in a paper by Messrs. Craft, Morehouse and Charlesworth.[6]

Subscribers' loops and sets	
Operators' telephone sets for Special service positions	

General classes of exchange area circuits involving equipment other than contacts and wiring which affect telephone transmission.

While it may appear at first hand from the above discussion that transmission testing in the exchange plant is a complicated and expensive matter, this has not proven to be the case. It has been found by experience that the systematic use of transmission measuring sets, following the testing methods which have been developed provides a means for periodically checking transmission conditions with a relatively small amount of testing apparatus and with a small maintenance force. All of the transmission circuits exclusive of subscribers' lines in a 10,000-line central office, either manual or machine switching, can, for example, be completely tested by two men in a period of from two to four weeks, (five and one-half 8-hour days per week assumed) any trouble found being cleared as the testing work is done. The maintenance of the subscribers' lines is not included in this work since it is taken care of by other methods as outlined later.

In order to give a general picture of the application of transmission testing in the exchange telephone plant, a brief discussion of the methods employed in both manual and machine switching systems is given below. In either system the loop method of testing proves most satisfactory, that is, one measuring set is used and where both terminals of a circuit are available as in cord circuits, a loop test through the circuit is made. In testing trunk circuits two trunks are looped together at their distant terminals and a measurement made on the two combined.

Transmission Tests on Manual Exchange Area Circuits. In central office, P. B. X. and toll switchboards, the cord circuits and associated operators' circuits are tested by using a portable transmission measuring set, moving this along the boards as required to pick up the cords. Fig. 7 shows a 3-*A* transmission measuring set being operated at an *A* switchboard position. The cords are picked up and plugged directly into the set as shown and measurements made of the loss of both the cord and operator's circuits. Trunk circuit tests are made at the switchboards in the same manner as previously described for loop transmission tests on toll circuits, portable measuring sets such as shown in Fig. 7 generally being employed for this work.

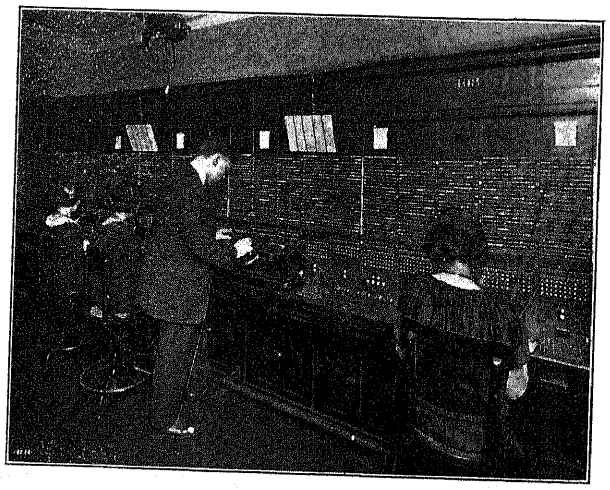

FIG. 7—ILLUSTRATION OF A 3-A TRANSMISSION MEASURING SET BEING OPERATED IN A MANUAL OFFICE

Operators' sets are inspected periodically and transmitter and receiver efficiency testing methods are under field trial which provide a means for testing these instruments in central offices. The miscellaneous transmission circuits in an office are tested at the points where they can be most conveniently picked up. The tests on toll test board circuits are made at this board and involve chiefly loop tests on the equipment associated with the toll circuits in the office and tests on the toll line circuits between the toll testboard and toll switchboard.

Transmission Tests on Machine Switching Circuits. The transmission circuits in panel machine switching systems are identical to those in manual systems, while these circuits in step-by-step systems are of a different design but essentially the same as far as transmission losses are concerned. Transmission tests on machine switching circuits are similar to those on manual cir-

cuits but involve special methods for picking up the circuits and holding them while the measurements are made. The standard types of transmission measuring sets are used in this work in conjunction with the regular testing equipment provided in the machine switching offices and the methods which have been developed offer a quick and convenient means for making the tests. In manual offices the circuits terminate in jacks or plugs at switchboards where they are readily accessible. In machine switching systems, provision is made for terminating the circuits in jacks at test desks or frames where they can be picked up by patching cords and tested as conveniently as the corresponding types of circuits in manual offices. Machine switching systems offer an important advantage in transmission testing work, particularly in trunk testing, in that the circuits to be tested can be looped automatically by the use of dials or selector test sets, thereby doing away with the necessity for having someone at the distant office complete the loops manually.

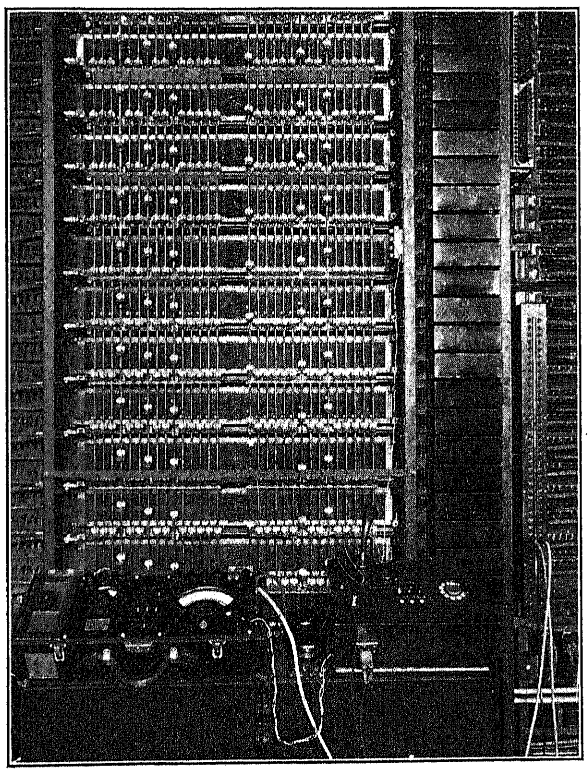

Fig. 8—Illustration of a 3-A Transmission Measuring Set, Set up in a Panel Machine Switching Office for Testing District Selectors

In panel machine switching offices the circuits involving transmission equipment corresponding to cord circuits are the "district" and "incoming" selectors. These are tested by setting up the transmission measuring set at the district or incoming frames and connecting the set to the test jacks associated with the circuits. Tests on trunks between manual and panel machine switching offices where both systems are in operation in the same exchange area are generally made from the manual office, the loops being dialed from the *A* switchboard, while trunks between two machine switching offices are tested from the outgoing end of the trunks.

Fig. 8 shows a 3-*A* transmission measuring set, set up in a machine switching office ready for making tests on district selectors. To illustrate the general method

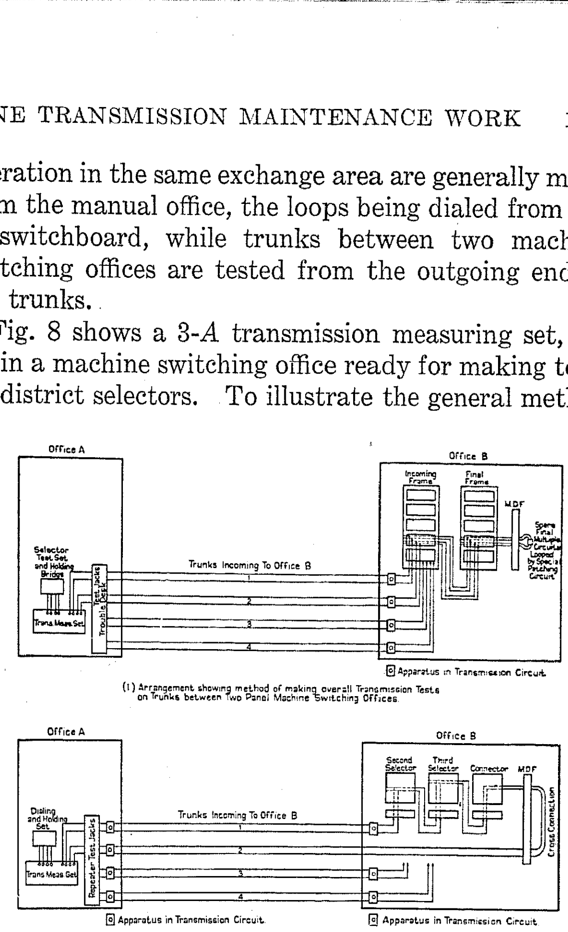

Fig. 9—Schematic Diagrams Showing Methods of Making Transmission Tests on (a) Trunks Between Panel Machine Switching Offices and (b) between Step by Step Machine Switching Offices

of testing panel machine switching circuits, the upper diagram of Fig. 9 shows the schematic arrangement for measuring trunks between two panel machine switching offices. The transmission measuring set is located at office A, and connection made to the outgoing end of the trunks to office B through the test jacks at the trouble desk. A standard selector test set used in local maintenance work and a high impedance holding coil are also connected to the trunks through the measuring set, these being used to establish the loop and hold this loop while the tests are made. At office B two spare multiple circuits are cross-connected at the main distributing frame. Any two trunks in the group can then be automatically looped together at office B by the use of the selector test set which functions to connect the trunks to the two spare multiple circuits previously cross-connected at office B.

In step-by-step machine switching offices the circuits involving transmission equipment corresponding to cord circuits are the connectors. Each connector is provided with a test jack through which connection can be made to a transmission measuring set and the loop completed over a test trunk by dialing. Local selectors do not contain any equipment other than contacts and wiring in the transmission circuits but these can be tested in the same manner as connectors if it is desired to check the wiping contacts and wiring. Toll selectors which involve equipment in the trans-

mission circuit can also be tested in the same manner as connectors. Trunks between manual and machine switching offices can be most conveniently tested from the manual office, the trunk loops being established directly by dialing.

To illustrate the general method of testing step-by-step machine switching circuits, the lower diagram of Fig. 9 shows the schematic circuit arrangement for testing trunks between two machine switching offices. The transmission measuring set is located at office A in a position so that it can be patched to the outgoing trunk repeater test jacks and an arrangement for dialing and holding is connected to the trunks through the measuring set. At office B the apparatus in one trunk is disconnected and this trunk used as a test trunk by cross-connecting it at the main distributing frame to a spare subscriber's multiple terminal. All trunks in the group can then be tested by dialing over them, from office A, the number of this spare terminal at office B which automatically loops them back over the test trunk.

Maintenance of Subscribers' Lines and Stations.

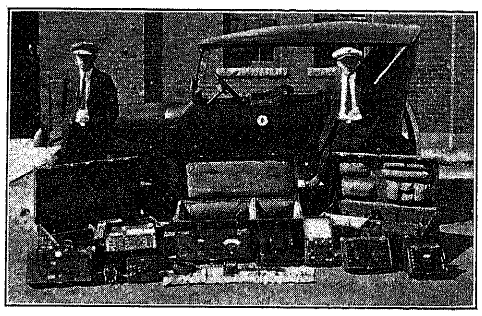

FIG. 10—ILLUSTRATION OF A TYPICAL TRANSMISSION TESTING TEAM LAYOUT

The circuits making up subscribers' lines from switchboard to instruments consist simply of pairs of conductors, almost always in cable, with the necessary protective devices. These can be checked by certain d-c. tests described in a recent paper.[7] Equipment is also provided in local test boards for use in making talking transmission tests between the station and the test board. Accurate machine methods for determining the efficiency of transmitters and receivers have been developed for testing new instruments and instruments returned from service.

General Scheme of Testing Exchange Area Circuits. The plan being followed in the Bell System for systematically checking the transmission conditions of exchange area circuits is to have all offices tested periodically by men equipped with portable transmission measuring sets who travel from office to office. It has been found by experience that after an office has once been tested and any transmission troubles eliminated, it is only necessary thereafter to make transmission tests at infrequent intervals, these subsequent tests serving primarily as a check on the local maintenance conditions. With a testing plan of this kind large areas can be covered by a small traveling force with a small amount of testing equipment. This results in a very economical transmission testing program while at the same time insuring that transmission conditions are maintained satisfactorily.

Fig. 10 shows a typical transmission testing team layout. The team is equipped with an automobile which proves an economical means of transportation between offices and exchange areas and provides a convenient method for carrying the testing equipment. During transportation this equipment is packed in padded trunks which insures against injury. In this particular case the equipment includes, in addition to transmission testing sets and oscillators, other apparatus such as a wheatstone bridge, crosstalk set and noise measuring set so that other maintenance work may be done in connection with transmission testing whenever this is desired.

RESULTS ACCOMPLISHED

The results accomplished in transmission maintenance work can best be appreciated by considering the kinds of troubles which adversely affect transmission and which can be detected and eliminated by routine testing methods. Consideration is first given to the general causes of troubles which are detrimental to both toll and local transmission, and later the features in this connection more particularly identified with telephone repeaters and carrier systems are discussed.

The different classes of circuits given in Table I are made up of various combinations of the following individual parts:

Repeating Coils	Plugs	
Retardation Coils	Jacks	
Relays	Keys	
Condensers	Heat Coils	
Resistances	Carbons	
Auto-Transformers	Wiring	Switchboard to M. D. F.
Induction Coils		Cross-connection
Loading Coils		Outside
Cords	Transmitters	
	Receivers	

The above parts are combined in various ways to make up the complete operating circuits such as cord circuits, operators' circuits, trunk circuits, etc. Each complete circuit causes a definite normal loss to telephone transmission which must be taken account of in designing the plant to meet various service requirements. If, however, any of the parts used are defective, if the wrong combinations of parts are used, or if the installation work is not correctly done, excess transmission losses will result which may very seriously affect the transmission when the particular circuits involved are employed in an overall connection.

Classification of Common Types of Troubles. An analysis of a large amount of transmission testing data has made it possible to develop a definite trouble classification which is particularly helpful in trans-

mission maintenance work and which permits the most efficient use of the results in eliminating transmission troubles. Experience has shown that the troubles found can be divided into two general classes, A—Troubles which can be detected either by simple d-c. or a-c. tests in connection with the regular day-by-day maintenance work or by transmission measuring sets, and B—Troubles which can be detected most readily by transmission measuring sets. The most important troubles in the above classes are as follows:

Class A	Class B
Opens	Electrical Defects
Grounds	Incorrect Wiring
Crosses	Wrong Type of Equipment
Cutouts	Missing Equipment
	High Resistance
	Low Insulation

If, in making transmission tests in a central office, a high percentage of Class A troubles is found the remedy is generally to instigate more rigid local maintenance routines paying particular attention to the type of circuits in which the troubles are located. The percentage of Class B troubles is not as a rule as high as the Class A troubles and experience has shown that when Class B troubles are once eliminated by transmission testing methods only infrequent subsequent tests are required to take care of any additional troubles of this class which may get into the plant.

In determining what constitutes an excess loss, the value of the transmission as well as the practical design and manufacturing considerations to meet operating limits are taken into account. An excess gain is also considered as a trouble on circuits equipped with amplifiers, since this may produce poor quality of transmission which is likely to be more detrimental to service than an excess loss. The value of transmission based on economical design considerations varies, depending on the first cost and annual charge of the particular types of circuits involved. A gain of one TU in the toll plant is generally worth more, for example, than one in the local plant, since it costs more to provide. In transmission maintenance work the cost of making transmission tests and clearing trouble is balanced against the value of the transmission gained for the purpose of establishing economical transmission limits to work to.

Specific Examples of Common Troubles Found and their Effect on Transmission. Certain kinds of troubles which are detected by transmission measuring sets do not cause excess losses which can be quantitatively measured. Such troubles are, however, readily detected by "ear balance" transmission measuring sets in that they cause noise or scratches and by the "meter balance" sets from fluctuations of the needle of the indicating meter. The most common trouble of this kind is due to cutouts or opens which may be caused by dirty connections, loose connections, improper key and relay adjustments, etc. While not causing a quantitative value of excess loss, this class of trouble is very detrimental to transmission and more serious in many instances than fixed excess losses. Indeterminate troubles of this nature are given an arbitrary excess loss value based on experience.

Considering troubles which give definite losses, the most common kinds are caused by electrical defects in equipment, incorrect wiring of equipment in circuits and wrong types of equipment. The other classes of troubles, such as crosses, high resistances, and low insulation, also generally give measurable excess losses but these are not as common in the plant, since troubles of this nature are more likely to affect the signaling and operation of the circuits and are, therefore, eliminated by the regular maintenance work. Missing equipment will in certain cases cause a gain in transmission but affects the circuits adversely in other ways.

Typical examples of common troubles, with the excess losses which they cause, are given in the following table:

Type of Circuit and Equipment	Cause of Trouble	Approximate Excess Transmission Loss
Repeating coils in cords, incoming trunk circuits, selectors, toll connectors	Electrical defects (Generally short circuited turns)	1.5 to 5.0 TU
	Incorrect wiring (Generally reversed windings)	2.0 to 13.0 TU
Supervisory relays in "A" cord circuits	Electrical defects (Open non-inductive winding)	About 2.5 TU
Bridged retardation coils or relays in toll cord circuits, composite sets, connectors and step-by-step repeaters	Electrical defects (Generally short circuited turns)	1.0 to 5.0 TU
Repeating coils on loaded toll switching trunks	Wrong type of equipment, incorrect wiring	1.0 to 4.0 TU
Induction coils in operators' telephone sets	Electrical defects. Incorrect wiring	1.0 to 13.0 TU

There are, of course, many other specific types of troubles detected by transmission tests which give definite quantitative losses but the above will serve to illustrate the value of this testing work in eliminating excess losses in a telephone plant.

Maintenance Features Peculiar to Telephone Repeaters and Carrier Systems. The same classification of troubles discussed above applies to repeaters and carrier systems. Amplifier equipment, however, employs certain features which are not common to the more simple telephone circuits and some of the troubles which may occur if the proper maintenance procedures are not followed will seriously affect service. It is for this reason that repeater and carrier installations are provided with special testing equipment which is always available for use either in routine maintenance or in locating and clearing any troubles which may occur in service. Automatic regulating devices are also provided wherever this is practicable in order to

reduce to a minimum the amount of manual regulation and maintenance.

The important elements in both repeaters and carriers which may directly affect transmission or cause service troubles in other ways are as follows:

Filament Batteries	Potentiometers
Plate Batteries	Filters
Grid Batteries	Transmission Equalizers
Vacuum Tubes	Signaling Equipment
Balancing Equipment	Patching Arrangements

The tests outlined in the main body of the paper aim to insure that the above essential parts of repeater and carrier circuits are functioning properly and that the equipment as a whole is giving the desired results in overall transmission efficiency.

Conclusion

The above discussions of testing methods and the results accomplished indicate how a comprehensive and economical transmission maintenance program can be applied to a telephone plant to check the volume efficiency of the circuits. Consideration is continually being given to new testing methods and their applications in order that further improvements in service may be effected and advantage taken of increased economies in testing.

Appendix A

Principles of Testing Methods Closely Associated with Transmission Efficiency Tests

Tests of volume efficiency often need to be supplemented by other methods of testing in transmission maintenance work. Transmission efficiency both as regards volume and quality may be seriously affected by noise or crosstalk, and tests for any conditions of this kind are therefore important in maintenance work. Furthermore when efficiency tests show excess losses or unsatisfactory circuit conditions other testing methods prove very valuable in locating the cause.

To illustrate this phase of transmission maintenance work the principles of some of the more important testing methods are briefly described below. Two of the tests described employ a method very similar to loop transmission testing while others employ the well known "null" method. A special method employing three winding transformers and amplifiers widely used to determine impedance balance conditions between lines and networks is also described. Several methods which involve simply current and voltage measurements have been mentioned in this paper but these are generally well known and therefore require no detailed description.

1. Measurements of Crosstalk

In the circuit shown in Fig. 11, if a-c. power is supplied to a circuit known as the "disturbing" circuit and unbalances exist between this circuit and a second known as the "disturbed" circuit, power will be transferred from one circuit to the other causing crosstalk in the second. A definite power transmission loss therefore takes place between the two circuits which can be measured by a loop transmission test similar to the efficiency tests described in the main body of the paper. An adjustable shunt called a "crosstalk meter" calibrated in either *TU* or in crosstalk units is substituted for the two circuits. With the same power supplied alternately to both the "disturbing" circuit and the meter and with the sending and receiving end impedance conditions as shown, the meter shunt is

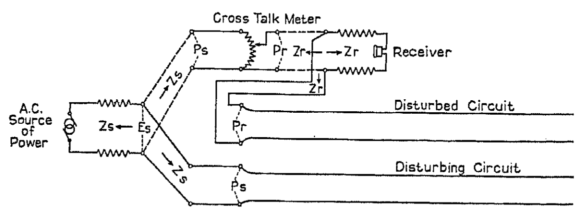

Fig. 11—Diagram Showing Principles of Crosstalk Measurements

adjusted until, in the opinion of the observer, the annoyance produced by the tone in the receiver is judged to be equal for the two conditions. The reading of the shunt if there was no distortion of the line crosstalk currents would then give the volume of crosstalk which could be expressed in *TU* as $10 \log_{10} P_r/P_s$ similar to loop transmission testing. However, this relation only holds approximately in practise since the line crosstalk measured is produced by various currents having different phase relations and a certain amount of distortion therefore occurs. The commercial form of crosstalk set now used is equipped to give the approximate impedance relations required and also

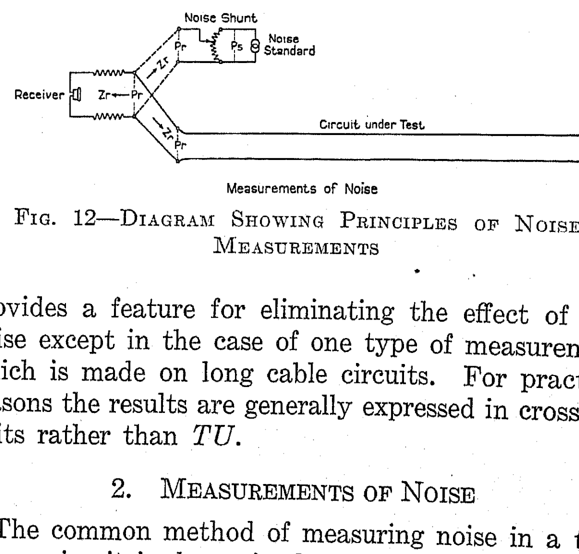

Fig. 12—Diagram Showing Principles of Noise Measurements

provides a feature for eliminating the effect of line noise except in the case of one type of measurement which is made on long cable circuits. For practical reasons the results are generally expressed in crosstalk units rather than *TU*.

2. Measurements of Noise

The common method of measuring noise in a telephone circuit is shown in the diagram of Fig. 12. In this test an artificial noise current produced by a generator of constant power P_s called a "noise standard" is substituted for the line noise current. If the

two noise currents were exactly alike as regards wave shape and the relative magnitude of the frequencies involved they would produce the same tone in the receiver and their volumes could be made equal by adjustment of the noise shunt. The power ratio, P_r/P_s, as indicated by the shunt, would then give a measure of the line noise in terms of the noise standard. This condition however, is not met with in practise due to differences in wave shape of the two noise currents. For this reason noise measurements are made by adjusting the noise shunt until the interfering effects of the noise on the line and from the shunt are judged to be the same for which condition the power supplied to the receiving network by the noise standard is not necessarily the same as that supplied by the line. The receiving end impedances however, are kept as nearly alike as practicable to prevent reflection losses.

3. Measurements of Line-Network Balance (21-Circuit Balance Test)

The testing arrangement of Fig. 13 shows the principle of the 21-circuit balance test referred to in the main body of the paper in connection with telephone repeater and carrier maintenance. In this test the gain of an amplifier calibrated in *TU* is used to compensate for the loss through a three winding transformer or output coil of a telephone repeater. If the impedances of the balancing network and line were exactly alike at all frequencies, *i. e.*, $Z_n = Z_L$, and no other unbalances existed in the circuit none of the power supplied by the amplifier to the input of the three-winding transformer would be transferred to the output, *i. e.*, the power ratio P_s/P_r would be infinity. However, this ideal condition cannot be produced in practise so that there is always a finite power loss between the input and output of the transformer which can be measured approximately by the gain of an amplifier calibrated in *TU*. An internal path for

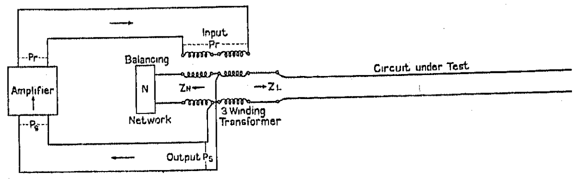

Fig. 13—Diagram Showing Principles of 21 Circuit Balance Tests

currents which may produce "singing" or a sustained tone is established if the gain of the amplifier P_r/P_s is greater than the loss P_s/P_r through the three-winding transformer. As unbalances between network and line become greater the loss through the three-winding transformer becomes less thereby requiring less gain in the amplifier to produce a "singing" condition. It should be noted in this connection that to produce the condition described above exactly, the current received around the "singing" path must be in phase with the starting current. In practise this condition obtains sufficiently accurately so that the gain of the amplifier required to produce "singing" gives an approximate measure of the impedance balance between line and network.

4. Measurements of Resistance, Reactance and Impedance

Diagram (a) of Fig. 14 shows the wheatstone bridge circuit for d-c. resistance measurements. It is unnecessary to describe the well known principles of this

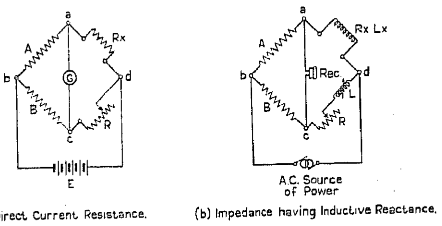

Fig. 14—Diagrams Showing Principles of Null Methods for Measuring Resistance, Reactance and Impedance

bridge but mention is made of it here in view of its importance and use in telephone maintenance work. It supplies an indispensible method of measurement for certain trouble locations, such as crosses and grounds and embodies the fundamental principles of all null tests.

Diagram (b) of Fig. 14 gives a bridge circuit for measuring impedance, the particular arrangement shown being for measurements of impedances having inductive reactance. The bridge measurements express impedance in terms of its resistance component and equivalent inductance or capacity. In measuring an impedance having inductive reactance at any frequency, *f*, for example, a balance gives $R = R_x$ and $L = L_x$. At the frequency *f*, the effective resistance is given directly by the value of *R* and the reactance by the relation, $2\,\pi\,f\,L$. The impedance is the vectorial sum of these two or $\sqrt{R^2 + (2\,\pi\,f\,L)^2}$. In maintenance work involving impedance measurements as will be noted in the next testing method described, the effective resistance component and the equivalent inductance are generally used directly without combining.

5. Measurements of Line Impedance and Location of Impedance Irregularities

Fig. 15 shows a telephone circuit connected to a bridge and terminated at its distant end in characteristic impedance. If the circuit has approximately uniform impedance throughout its length the resistance and equivalent inductance curves of this impedance within a range of frequencies will be fairly smooth as indicated by *A* and *C* of the figure. The curves are not perfectly smooth since it is not practicable to construct the line for perfect impedance uniformity. If at

some point in the circuit an irregularity is present such as an omitted loading coil, an inserted length of line of different construction, etc., which changes the impedance, this will produce a periodic change in the resistance and inductance curves A and C such as shown by Curve B. Curve C will be changed in the same way as Curve A but for simplification this is not shown on the diagram.

The change in impedance in the circuit reflects some of the current sent out back to the sending end where it adds to or subtracts from the sending current depending on the phase relations of the two currents at any particular frequency. Since impedance equals E/I its value changes as the value of I changes. This is made use of in line impedance measuring work to give

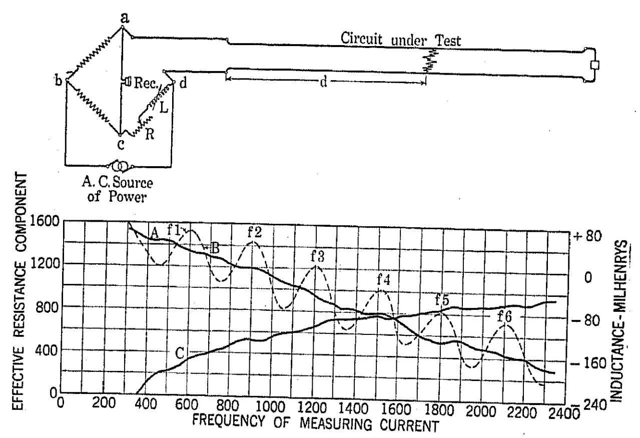

Fig. 15—Diagram and Impedance Curves Showing Principles of Line Impedance Measurements by Null Method and Location of Impedance Irregularities

a location of impedance irregularities which may exist somewhere in the line.

Referring to Fig. 15, let d equal the distance in miles to an impedance irregularity and f, one frequency at which the resistance component of the impedance is a maximum. The next maximum point will occur at a frequency f_2 such that as the frequency has been increased, one complete wave length is added in the distance traveled by the reflected current. Maximum points at f_3, f_4, etc., occur in the same way as the frequency is increased. Considering the two values f_1 and f_2 let

V = velocity of current in miles per second

W_1 = wave length at frequency f_1

W_2 = " " " " f_2

N = number of wave lengths in distance traveled by reflected current or 2 d.

At frequency f_1 then,

$$N = \frac{2\,d}{W_1}$$

and at f_2,
$$N + 1 = \frac{2\,d}{W_2}$$

also at f_1, $W_1 = V/f_1$

and at f_2, $W_2 = V/f_2$

Substituting above

$$N = \frac{2\,d\,f_1}{V} \text{ and}$$

$$N + 1 = \frac{2\,d\,f_2}{V}$$

Subtracting, $$1 = \frac{2\,d\,f_2}{V} - \frac{2\,d\,f_1}{V} \text{ or}$$

$$d = \frac{V}{2\,(f_2 - f_1)} \text{ which is the distance}$$

in miles from the sending end of the circuit to the point of impedance irregularity. The velocity of propagation V is not exactly constant within the entire frequency range but does not vary sufficiently to materially effect the accuracy of impedance trouble locations by this method.

Telephone Circuit Unbalances
Determination of Magnitude and Location

BY L. P. FERRIS and R. G. McCURDY

Review of the Subject.—*The maintenance of telephone circuits in a high state of efficiency with respect to balance is important since unbalances contribute to crosstalk between telephone circuits and to noise when such circuits are involved in inductive exposures. Methods and apparatus are described which afford operating telephone companies means for maintaining their circuits in the condition of minimum practicable unbalance.*

Different types of unbalance are discussed, also their effects under different conditions of energization of the unbalanced circuit and neighboring conductors.

Methods are described for determining:

(1) *The general condition of circuits with respect to balance by crosstalk measurements from their terminals,*

(2) *The approximate location of unbalances along a line by measurements over a range of frequencies with a bridge at one end of the line, and*

(3) *The final location of unbalances by field measurements with an unbalance detector which may be operated by a lineman and does not usually require interruption of telephone service, except momentarily.*

Toll circuit office unbalances are briefly discussed and a special bridge for detecting, locating and measuring the unbalances of composite sets is described.

In an appendix is given a mathematical treatment of the bridge method for locating unbalances and a discussion of the necessity of terminating the circuits involved in the tests in their characteristic line impedances.

Introduction

Noise induced in a telephone circuit may arise in two different ways: First, by reason of dissymmetry in its relation to the inducing circuit, unequal voltages are induced in its two sides; Second, by reason of dissymmetry of its two sides in their relation to ground or to other telephone conductors, the voltage induced between the conductors and ground or along the conductors causes a voltage between the two sides of the unbalanced circuit. In the usual case, the voltages induced to ground or along the conductors are large compared to their differences, so that unbalances of the telephone circuits themselves have an important bearing on the problem of preventing noise in such circuits.

Dissymmetry with respect to the inducing circuit involves, of course, only that part of the disturbed circuit within the inductive exposure. This type of unbalance involves properties of the inducing circuit as well as of the telephone circuit and is therefore dealt with no further in this paper. Unbalances of the telephone circuits themselves may involve those parts of the circuit within the inductive exposure as well as the unexposed parts of the circuit and the terminal apparatus.

A telephone circuit would be balanced if its two sides had equal self and mutual impedances and equal admittances to ground and to other conductors in each elementary section of its length. In other words, the sides of a balanced circuit would be symmetrical in their relations to ground and to other nearby circuits. Such a circuit would have no difference in voltage between its two sides when equal voltages are induced between them and ground at any point of the circuit or when equal voltages are induced along them.

It should be noted that this definition does not require longitudinal uniformity as a condition of balance. It merely requires that corresponding constants of the two sides of the circuit shall be equal at the same point and that this condition shall be satisfied for every point along the circuit. In practise it is neither necessary nor possible that this definition be rigorously satisfied, but a close approach to this ideal state of balance is obtained by transposing or twisting the conductors as a pair so that unbalances in neighboring sections of any circuit tend to neutralize, and by careful attention to the design and maintenance of the line and all connected apparatus.

Types of Unbalances

Unbalances of telephone circuits are of two general types. The first may be called self unbalances involving only the conductors of the circuit and ground, and the second, mutual unbalances involving also the other conductors. Thus, a self unbalance would exist even though all conductors except those of the circuit in question were removed to a great distance. Since in the usual case, both sides of circuits are constructed of wires of the same size and conductivity and at the same distance above the earth, there are no inherent self unbalances. Such unbalances are largely accidental and arise from such causes as defective joints, defective loading coils, broken insulators, tree leaks, or from dissymmetry in apparatus inserting series impedances in the circuit, or connecting admittances between the sides of the circuit and ground. Unbalances of this type do not depend upon the condition of surrounding circuits, although the noise effects caused by these unbalances may so depend.

The resultant unbalanced current or voltage in a circuit depends on both the self and mutual unbalances and upon the mode of energization and terminal impedances of both the circuit in question and neighbor-

---

Presented at the Pacific Coast Convention of the A. I. E. E., Pasadena, Cal., October 13-17, 1924.

ing conductors. In practise, it is not possible to measure the effects of the two types of unbalance separately.

It will be of interest to discuss briefly the relative importance of the two types of unbalance in their effects on noise and crosstalk with a view to examining the adequacy of various methods which may be used for measuring and locating unbalances.

Fig. 1 indicates a circuit which is perfectly balanced. This circuit consists of two similar conductors parallel to each other and to the plane surface of the earth, and removed to a great distance from all other conductors. Such a circuit can have only self unbalances, which in the practical case might consist of slight differences in conductor diameter, in conductivity and in sag, variations in the contour of the earth, resistance in joints and differences in series impedances or shunt admittances introduced by connected apparatus.

Fig. 2 shows the four parallel untransposed conductors of a phantom group. In this case the phantom would be unbalanced to each of its side circuits. If equal voltages were induced to ground or along each of the four conductors (similar apparatus being assumed connected to the two side circuits), a voltage would be caused in each side circuit, while no voltage would be caused in the phantom.

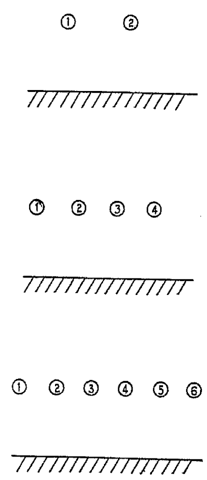
Fig. 3 indicates three circuits, each consisting of two similar untransposed parallel conductors. In this case, assuming perfect construction, each circuit would have no self unbalances. However, no one of the circuits would be symmetrical in its relation to each of the other conductors. If equal voltages were induced to ground or along the two sides of circuit 3-4, and both 1-2 and 5-6 were left either free or connected to earth, no voltage would be caused between the sides of 3-4. The same would be true if equal voltages were induced along all six of the conductors or from them to ground. Voltages would be caused, however, in both circuits 1-2 and 5-6 under this condition. A voltage would be set up in circuit 3-4 if equal voltages were induced from its sides to ground or along its sides, while different conditions were imposed on circuits 1-2 and 5-6 as, for example, if 1-2 were isolated and 5-6 connected to ground.

In the practical case, involving multi-wire lines, none of the circuits on the line are inherently balanced in respect to their mutual relations to all other conductors. A close approximation to such balance is obtained, however, by means of transpositions whereby the unbalances existing in one section are neutralized by those in a nearby section of line. Thus, transposition errors are a source of mutual unbalances.

In any practicable method of determining unbalances, the current or voltage measured in the circuit, or the impedance of a compensating unbalance which would reduce the voltage and current to zero, are complicated functions of the location, character and magnitude of the self and mutual unbalances, and the mode of energization and terminal impedances of the test circuit and neighboring conductors. The effects of mutual unbalances are particularly dependent upon the energization and impedance conditions of the neighboring conductors.

Methods of Energizing Circuits

If unbalances are measured by energizing a superposed circuit consisting of the two sides of the circuit in parallel to ground, leaving other conductors free, and observing the unbalanced current, the effect of transposition errors will usually be small as compared to even small self unbalances which might be present. The current due to the mutual unbalances is, in this case, a secondary effect, because of the relatively small amount of power in each of the neighboring conductors. The current and voltage in the energized superposed circuit induce current and voltage in circuits composed of the neighboring conductors and ground, since transpositions are not effective in reducing induction between grounded



Figs. 1, 2 and 3

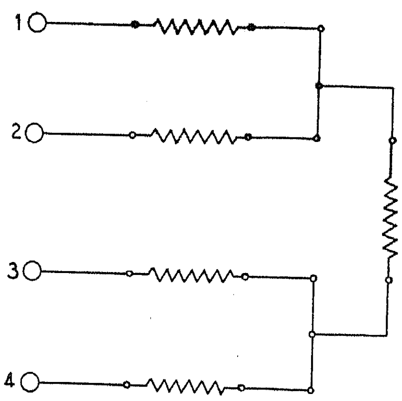


Fig. 4—Simple Network for Terminating a Phantom Group

circuits. These induced currents and voltages in the individual neighboring conductors are much smaller than the original current and voltage in the conductors of the superposed circuit. The induced currents and voltages in turn react by induction upon the current and voltage in the superposed circuit, and because of the transposition error this reaction is unsymmetrical, resulting in a current and voltage in the metallic circuit which forms one side of the superposed circuit.

If unbalances are measured by applying with respect to ground, the same voltage to all of the conductors on the line, the current set up in the test circuit due to a transposition error will no longer be a secondary effect, since the voltages and currents in each of the neighboring conductors will then be of approximately the same magnitudes as those in the conductors of the circuit whose unbalances are being determined. In this case the effect of a transposition error is increased relatively to that in the first case and becomes comparable in importance to the effect of a self unbalance.

If, however, the unbalances are measured by determining the crosstalk between the circuit in question and its phantom, with certain exceptions noted below the transposition error is also a primary effect. The current and voltage in closely adjacent conductors (those of the other side of the phantom) are of the same magnitude, but opposite in phase, as those in the conductors of the circuit whose unbalances are being measured. In this case the effects of a transposition error are probably more important as compared to those of self unbalances, than if all conductors of the line were energized simultaneously at the same voltage.

In an inductive exposure the voltages to ground and longitudinal currents of all conductors of the various circuits on the line are of the same order of magnitude. Consequently, the effects of transposition errors in the unexposed sections of line on the resultant unbalanced current in a circuit are more important than if this circuit alone were energized.

In maintaining telephone circuits in a condition of satisfactory balance from the standpoint of noise it is necessary that the methods employed to detect and locate unbalances be such as to cover all types of dissymmetry which contribute to noise. In order that all unbalances might be given proper weight in the measurement, it would be desirable, of course, to energize the test and the neighboring conductors in the same manner, relatively, as when the energization is due to inductive exposures. This is, however, impracticable.

If the methods used are sensitive enough to detect all sources of unbalance on any part of the circuit, large enough to contribute to noise or crosstalk, it is not essential that they cause the same relative effects on the measurements as on the noise or crosstalk. As brought out in the previous discussion, the important sources of unbalance contributing to noise are defects in line and connected apparatus (self unbalances) and transposition errors (mutual unbalances). With the exception of vertical pole-pair phantom groups all such unbalances in side circuits contribute to crosstalk in the phantom and this crosstalk may be used therefore as a measure of unbalance of side circuits. Transposition errors in vertical pole-pair phantom groups have very little effect on phantom-to-side crosstalk. Unbalances may exist in any phantom group which will not contribute to crosstalk but which will contribute to noise in the phantom circuit. Similarly, a non-phantom pair may be unbalanced for noise, but these unbalances may not cause appreciable crosstalk to any existing circuit. However, in all these cases where crosstalk is not caused in any existing circuits, special superposed circuits may be set up for test purposes in which these unbalances will cause crosstalk.

A simple arrangement for such a purpose is a superposed circuit having for one side the conductors in parallel of the circuit under test, and ground for the other. As already stated, however, transposition errors cause relatively small effect on crosstalk in this case. If, instead of the ground, the conductors in parallel of another phantom or non-phantomed pair, preferably on the same crossarm, be used to form the superposed circuit, transposition errors will be indicated as well as the self unbalances, in the same manner as in the case of crosstalk between a horizontal phantom and its side.

The methods which are in use in maintaining balanced telephone circuits in the plant of the Bell System utilize the crosstalk to metallic superposed circuits made up as above described as a criterion of unbalance. These methods provide means for indicating the unbalanced condition of a circuit by measurements of crosstalk made at its terminals; for obtaining an approximate location of sources of unbalance by measurements from one end of the circuit; and for securing a definite location of the unbalance by local measurements along the circuit, these latter measurements not involving opening the circuit.

In general, the magnitude of the crosstalk measured between two circuits will depend upon the frequency of the testing current used. When the source of the crosstalk is a capacitance or inductance unbalance, this is due to the increase in crosstalk with frequency. Also, when more than one unbalance is present, the crosstalk currents caused by the different unbalances add at some frequencies and subtract at others. Thus, a single-frequency crosstalk measurement is not a reliable indication of the general condition of the circuit as regards unbalances. Crosstalk measurements must, therefore, be made at a number of single frequencies or with a source of energy of complex wave form.

In practise both schemes are used, a complex wave being employed to obtain an indication of the general condition of the circuit and a number of single frequencies being employed successively to determine the location of unbalances.

Termination of Circuits

It is desirable in making unbalance or crosstalk tests that the measurements be made in such a way that the effect of any given unbalance on the crosstalk or equivalent unbalance of the circuit be independent of the length of circuit tested. In order to obtain this result, reflected waves from the distant ends of the circuits must be minimized. This is accomplished by terminating the circuits in networks whose impedances approximately equal the impedances of infinite lengths of the circuit. The precision with which it is necessary for these network impedances to simulate the characteristic line impedances depends upon the attenuation losses in the section of line under test. If the section be long enough terminations are unnecessary. Three types of network have been developed for use in these measurements which simulate the line impedances to different degrees of precision.

The first type of network, which is shown by Fig. 4, consists of a group of carefully balanced resistances. It is for use principally on cable circuits but may also be

used on open-wire circuits for the crosstalk tests to indicate the general condition of a circuit as to unbalances. More accurate terminations are required for the measurements to obtain unbalance locations unless the section tested is long.

A second type of network is shown by Fig. 5 which is more particularly adapted to tests on open-wire circuits. In this case the circuit under test and the superposed circuit used as the reference are terminated by a

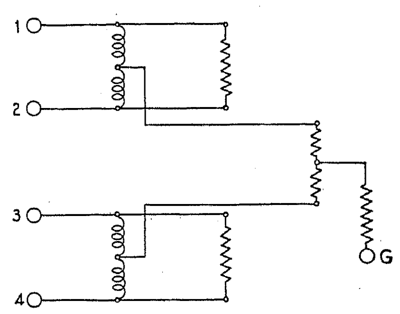

Fig. 5—Network for Terminating Simultaneously All Circuits of a Phantom Group. Binding Post G may be Connected to Four Wires in Parallel of a Nearby Phantom Group

carefully balanced retardation coil and resistances, rather than by resistances alone. Through the use of keys it is possible to arrange for terminating circuits of various types including both non-loaded and loaded circuits.

The third type of network shown by Fig. 6 is used when a more accurate termination than is possible with the other types is required. This network is usually

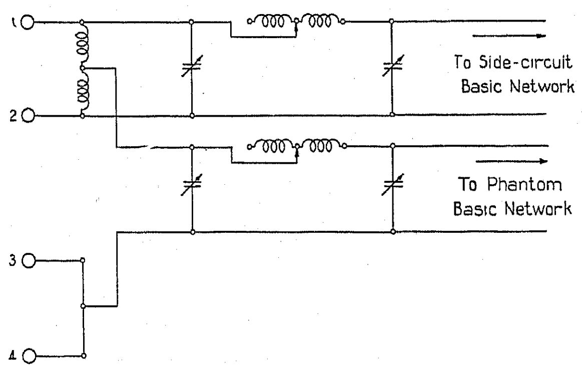

Fig. 6—Adjustable Building-Out Section. Schematic Circuit when used for Building-Out Simultaneously Phantom and Side Circuit

required only in connection with measurements made at one of the circuit terminals to locate unbalances. By the use of this adjustable "building-out section" in conjunction with an adjustable "basic network," it is possible to terminate open-wire circuits of any type and in the case of loaded circuits, at any point in the loading section, with a minimum of departure from the correct impedance. The networks of this third type are similar to those used in securing two-way repeater operation.

Crosstalk Set

The crosstalk set shown by Fig. 7 is used for measuring crosstalk between telephone circuits at frequencies within the voice range. This figure shows the schematic circuit arrangement when measuring "near-end" phantom-to-side crosstalk. "Near-end" crosstalk occurs when the talking and listening are done at the same end of the line. In the left-hand position of the switch, a source of testing current is connected to a crosstalk meter, which is a simple form of potentiometer. In the right-hand position the switch is connected to transformer A, the impedance ratio of which is adjustable, so that the impedance of any standard type of telephone circuit as measured through the transformer can be made approximately equal to that of the crosstalk meter. With this arrangement the power into the transformer is approximately equal to that into the crosstalk meter, particularly when the impedance of the source of current is about equal to that of the crosstalk meter.

Transformer B, also an adjustable impedance ratio

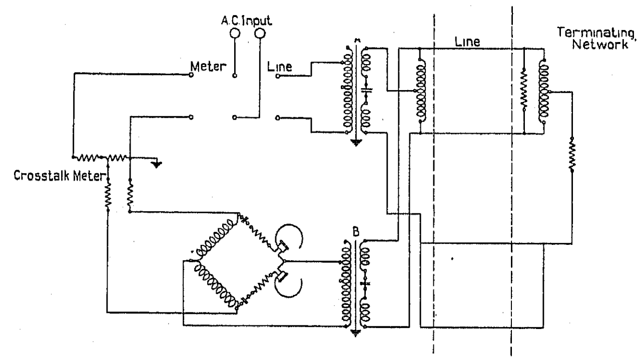

Fig. 7—Crosstalk Set. Schematic Circuit when Measuring Near-End Phantom-to-Side Crosstalk

transformer, is designed to permit a disturbed circuit of any standard type to deliver about the same power to the crosstalk set as it would deliver to a long circuit of its own type. Both transformer B and the crosstalk meter are connected to a network of resistances, condensers, receivers and a retardation coil, arranged in the same general manner as the four arms of a Wheatstone bridge. The branches to which the crosstalk meter and the disturbed circuit are connected have practically no effect upon each other and the disturbed circuit may therefore remain connected to the receivers while the source of disturbing current is switched to the crosstalk meter, thereby allowing the noise from the disturbed circuit to remain constant. This arrangement greatly facilitates accurate crosstalk comparisons on noisy circuits.

Measurements are made by listening to the crosstalk on the disturbed circuit and then to the tone produced by the current from the crosstalk meter, adjusting the latter until the two are equal. The reading of the scale on the crosstalk meter then represents the crosstalk

between the circuits under test expressed in crosstalk units. The crosstalk unit is chosen to indicate a convenient relation between power sent into the disturbing circuit and that received from the disturbed circuit.

Bridge for Locating Unbalances

When the measurement of crosstalk indicates that the unbalances of the circuit are greater than the allowable limit, measurements may be made with an impedance unbalance bridge to obtain an approximate location of the unbalances. The method is adapted from a similar one for locating irregularities in the impedances of metallic telephone circuits which interfere with repeater operation. It may be usefully applied only to circuits of considerable length, approximating 50 miles or more of open wire. Shorter lengths may be tested in cables. The bridge is shown in schematic form in Fig. 8 connected, with a phantom circuit as a superposed reference, to locate the unbalances of a side circuit.

The bridge is made up of a pair of equal ratio arms with a fixed inductance and resistance which are con-

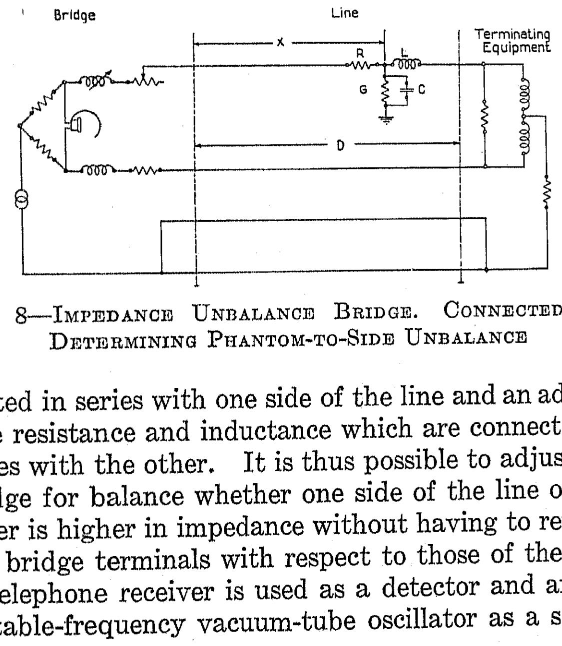

Fig. 8—Impedance Unbalance Bridge. Connected for Determining Phantom-to-Side Unbalance

nected in series with one side of the line and an adjustable resistance and inductance which are connected in series with the other. It is thus possible to adjust the bridge for balance whether one side of the line or the other is higher in impedance without having to reverse the bridge terminals with respect to those of the line. A telephone receiver is used as a detector and an adjustable-frequency vacuum-tube oscillator as a source of energy.

The method consists in balancing the bridge at a number of frequencies at definite intervals in the range from 200 to 2000 cycles and determining the magnitude and sign of the resistance and inductance unbalances which must be inserted in the bridge in order to compensate for those in the line. The values of equivalent resistance and inductance unbalance thus obtained are plotted as functions of the frequency. From these curves a location may be determined for the unbalance or unbalances if their number is not too great.

In principle this method is based upon the finite velocity of phase propagation of electric waves along the reference circuit to the unbalance and back along the circuit under test to the bridge. Thereby, the wave of unbalanced current received at the bridge from the distant unbalance is retarded in phase with respect to the current sent into the reference circuit, in addition to any localized phase shift produced by this unbalance. Only a localized phase shift occurs in the crosstalk or unbalance current set up by the compensating unbalance which is inserted in the bridge. Therefore. the compensating unbalance must be of such a character that its phase shift differs from that produced by the distant unbalance by an amount equal to the phase retardation caused by the finite velocity of phase propagation along the circuits. This phase retardation for a given location of unbalance depends on the frequency of the test current, since the distance to the unbalance measured in wave lengths varies inversely with the frequency. By measuring over a range of frequencies, the localized phase shift may be eliminated and that frequency ascertained for which the total distance of propagation to and from the unbalance is equal to one wave length. Thus its approximate location may be determined if the velocities of phase propagation on the two circuits be known. The method is based upon the assumption that the velocities of phase propagation and localized phase shifts are substantially independent of the frequency. These assumptions hold sufficiently well over the necessary working range of frequencies, and for the types of unbalance usually encountered. A mathematical discussion of the method is given in an appendix.

As an example of the method, consider a non-loaded open-wire phantom group in which the velocities of phase propagation are 180,000 mi. per sec. Let it be assumed that a series resistance unbalance is present 100 miles from the bridge. This is a wave length at 1800 cycles. It is various fractions of a wave length at other frequencies as indicated by the table below. This table indicates also the phase of the current in the reference (phantom) circuit at the position of the unbalance and that of the crosstalk current when propagated back over the circuit under test to the bridge, with respect to the current sent into the reference circuit at the bridge.

f	Fraction of Wave Length	Phase of Current in Reference Circuit at Unbalance	Phase of Crosstalk Current at Bridge Due to Unbalance at $L = 100$
225	1/8	−45 deg.	−90 deg.
450	1/4	−90 deg.	−180 deg.
675	3/8	−135 deg.	−270 deg.
900	1/2	−180 deg.	0 deg.
1125	5/8	−225 deg.	−90 deg.
1350	3/4	−270 deg.	−180 deg.
1575	7/8	−315 deg.	−270 deg.
1800	1	0 deg.	0 deg.

If unbalance be inserted at the bridge to compensate for that in the line, it is evident that at 900 cycles and at 1800 cycles this compensating unbalance must be of the same character (resistance in this case) as that out on the line and on the opposite side of the circuit.

At 450 and 1350 cycles the compensating unbalance will also be resistance but in the same side of the line. At 225 and 1125 cycles the compensating unbalance must be an inductive reactance in the same side of the line and at 675 and 1575 cycles an inductive reactance in the opposite side of the line. The values of equivalent unbalance are plotted on Fig. 9, changes in attenuation with frequency being neglected. It will be seen that periodic curves are obtained having a frequency interval of 900 cycles. This is the frequency for which the distance out to the unbalance and back corresponds to a full wave length. The rule for cases in which the velocity of phase propagation is the same in the test and reference circuits, is expressed by the formula:

$$X = \frac{V}{2 f_i}$$

where X is the distance to the V is the unbalance, velocity of phase propagation and f_i is the frequency interval of the curves.

When more than one unbalance is present, the curves obtained are the resultants of the simple periodic curves

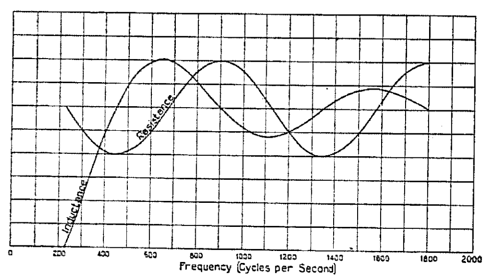

FIG. 9—EQUIVALENT IMPEDANCE UNBALANCE. NON-LOADED OPEN-WIRE SIDE CIRCUIT

which each of the individual unbalances would give if present alone. It is evident that when there are a large number of unbalances present the curves become very difficult of analysis. As a rule, the periods corresponding to the several unbalances present have no common integral multiple within the range of frequencies tested. Analysis by the methods used for analyzing periodic waves is therefore not possible. While the curves are thus made up of periodic waves they are not in themselves periodic.

When the several unbalances differ considerably in size it is often possible to make an analysis by inspection locating initially the largest unbalance. After this one unbalance has been located and cleared a second set of curves may be made which will now contain one less unbalance than before and will be correspondingly simpler to analyze. Where the unbalances are of approximately the same size but at a considerable distance apart they may often be separated by arranging to terminate the circuit at some intermediate point which will include one or two of the unbalances and eliminate the others. When the nearer unbalance has been located and cleared the longer section may be tested and the more distant ones located.

Fig. 10 shows curves taken on a cable circuit before and after removing a series resistance unbalance. Figs. 11 and 12 show curves taken on open-wire circuits, the former on a phantom circuit, before and after removing an inductance unbalance caused by the use of the wrong type of loading coil on one of the sides, and

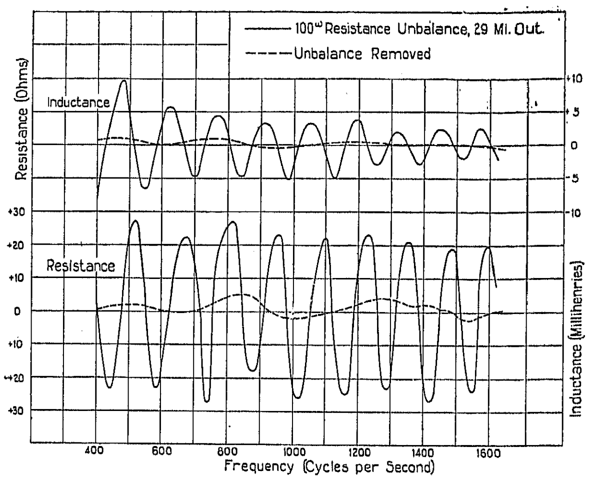

FIG. 10—EQUIVALENT IMPEDANCE UNBALANCE. HEAVY-LOADED NO. 19-GAGE CABLE SIDE CIRCUIT

the latter on a side circuit, before and after correcting a transposition error. It will be noted that equivalent resistance and inductance unbalances are plotted rather than equivalent resistance and reactance unbalances. This is done both because of greater convenience and because the former curves are more easily analyzed. The reactance in the bridge is introduced by an inductometer from which inductance unbalance may be read directly. If reactance were desired it would have to be calculated from the inductance setting. When the unbalance is a resistance, its effect is approximately independent of frequency and an equivalent resistance curve is obtained which is periodic while the inductance curve is the product of a periodic curve and of a curve

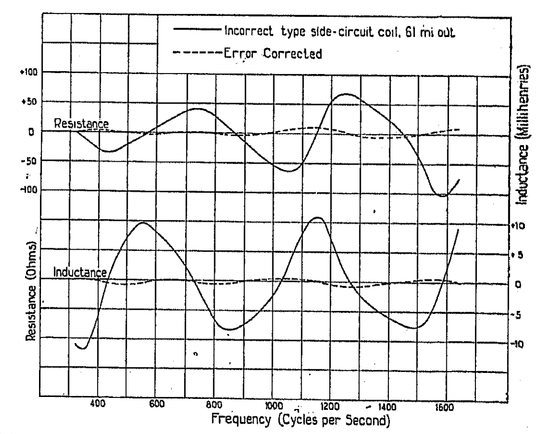

FIG. 11—EQUIVALENT IMPEDANCE UNBALANCE. LOADED NO. 8 B. W. G. OPEN-WIRE PHANTOM CIRCUIT

whose ordinates are inversely proportional to frequency. When the unbalance is series inductance or shunt capacitance, the effect increases with frequency and an equivalent inductance curve is obtained which is periodic while the resistance curve is the product of a periodic curve and of a curve whose ordinates are directly proportional to frequency. Thus, for both types of unbalance one periodic curve is obtained, while if reactance were plotted, only resistance unbalances would yield such curves. These curves are, of course,

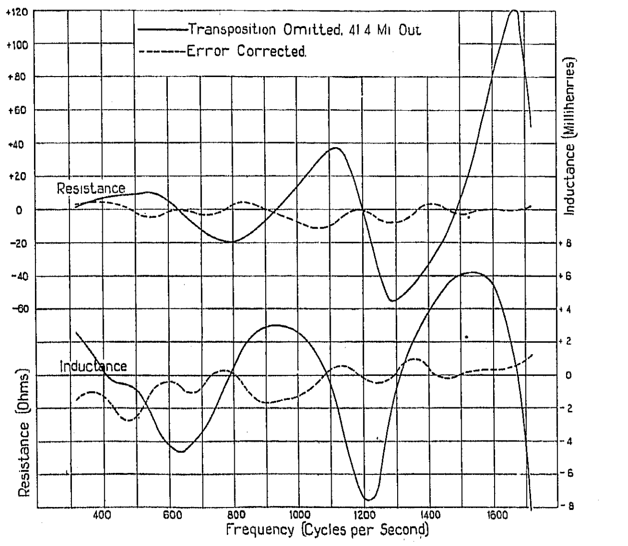

Fig. 12—Equivalent Impedance Unbalance. Loaded No. 12 N. B. S. G. Open-Wire Side Circuit

modified somewhat by the variation of attenuation with frequency but usually this effect is too small to introduce much difficulty into the analysis.

From the information given by these curves it is usually practicable to locate a single unbalance or one considerably larger than any other existing on the circuit, within one or two 8-mile transposition sections. Series unbalances in loading coils or immediately adjacent thereto may usually be located at the correct load point. To locate definitely transposition errors and resistance in joints, in either loaded or non-loaded lines, it will often be necessary to cover two 8-mi. transposition sections with the unbalance detector as described below.

Unbalance Detector

This unbalance detector consists of two parts, known as the sending and receiving sets. These parts are bridged to a circuit at points on either side of the suspected point of unbalance as indicated by the bridge, it being unnecessary to open the line wires. A test with the apparatus shows definitely if the circuit is unbalanced between the points at which the two parts are connected. It does not show the location of the unbalance. If an unbalance is found to exist in the section of line between the sets, they are moved closer together and the test repeated, this process being continued until the unbalance is reached. Fig. 13 shows a schematic circuit of the two parts of the set as arranged for testing side circuits of a phantom group. The entire equipment can be operated by one person.

The sending set is shown as a single-frequency generator connected across the phantom or other reference circuit, the sides being short-circuited. The receiving set consists essentially of two phantom coils, two potentiometers and a receiver. The single-frequency generator causes a current in the phantom circuit in both directions from the point of connection. If the four wires are perfectly balanced, the currents in them will be equal in magnitude and phase if the potentiometers are set so that the resistances on the two sides of the contacts are equal. In this case no sound will be heard in a receiver when connected to either of the phantom coils.

If a resistance unbalance X is present in wire 1, the impedances of wires 1 and 2 will be unequal and the currents in them, therefore, unequal. In this case a tone will be heard in the receiver. By adjusting the potentiometer contact until the unbalance of the potentiometer offsets the effect of X, the currents in the line windings of the coil will be approximately equal and the currents in the receiver consequently small. The reading of the potentiometer can, therefore, be used to indicate the condition of the circuit between the sending and receiving sets. When a transposition error is present the unbalance caused is indicated by current in the receiver which it is not possible to balance out by adjusting the potentiometer.

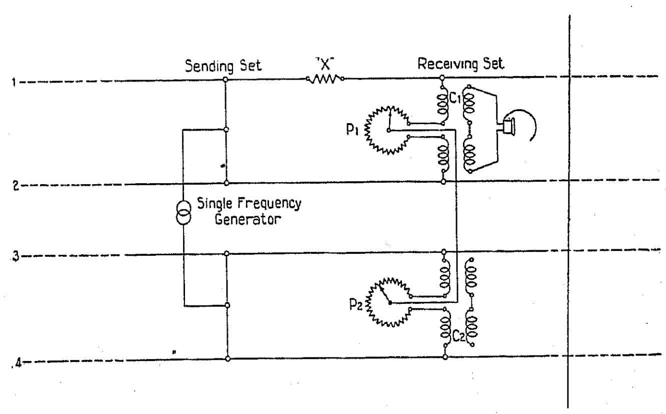

Fig. 13—Unbalance Detector. Schematic Circuit when Testing Side Circuits of Phantom Group

The actual circuit of the apparatus differs somewhat from that shown in the schematic circuit. The oscillator is not permanently connected across the circuit to be tested, but is arranged so that it can be connected to it by relays controlled by a key in the receiving set. When the key is not operated, the oscillator is not in operation and the sending set is connected to the circuit in such a manner as not to interfere with the use of the circuit for telephone purposes.

In addition to its use for finally locating an unbalance

whose approximate location has been determined by the impedance unbalance bridge, this unbalance detector may be used also when the length of line is too short to justify the use of the bridge method and when the number of the unbalances makes the complexity of the curves too great for even an approximate location with the bridge. In these latter cases the entire length of circuit may be covered with the detector.

Office Unbalances

The normal equipment of a toll telephone circuit includes a transformer or repeating coil which isolates the telephone apparatus from the line and from the telegraph apparatus. This transformer interrupts the transmission of longitudinal currents through the telephone office apparatus and prevents impressing noise voltage to ground on the unbalances of such apparatus. Apparatus used for superposing direct-current telegraph and carrier-frequency channels on the telephone

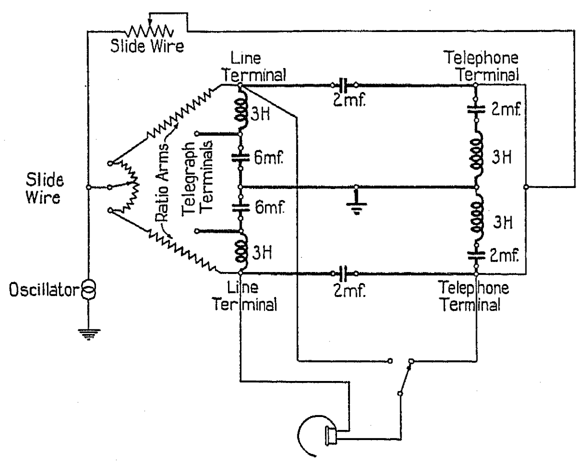

FIG. 14—COMPOSITE SET BRIDGE. SCHEMATIC CIRCUIT WHEN MEASURING UNBALANCE OF TELEGRAPH BRANCHES OF COMPOSITE SET. HEAVY LINES SHOW COMPOSITE SET

circuit is on the line side of this transformer and is therefore subjected to the action of longitudinal currents and voltages to ground. The line-filter set used for separating the carrier channels from the voice-frequency and d-c. telegraph channels has series and shunt branches in the two side circuits of a phantom group but no branches to ground. Unbalances in this set have a more important effect on crosstalk than on noise. Unbalances in the line-filter set may be detected by the use of the crosstalk set, connecting it to the office side of the filter with a terminating network on the line side.

The composite set used for superposing the d-c. telegraph channels on the telephone circuit has both series branches and branches connected from each wire to ground. For this reason, and because it is more generally used in the toll telephone plant than the line-filter set, special methods and apparatus have been developed for conveniently determining its condition from the standpoint of balance and for locating and determining the magnitude of such unbalances as may exist.

Some of the parts of the composite set can be tested with a simple slide wire bridge. Other parts, particularly the telegraph branches, cannot be so tested. By means of a special arrangement in the composite set bridge, the device which has been designed for rapid testing of the parts of a composite set as well as the whole set, the telegraph branches can be accurately measured without disconnecting any of the parts. A schematic circuit of the bridge, as arranged for testing these branches, is shown in Fig. 14. A simple slide wire bridge is connected across the line terminals of the composite set. A source of testing current is connected between the moving contact on the slide wire and ground. In order to prevent unbalances in the other branches of the composite set from affecting the measurements, the source of testing current is connected through an adjustable resistance to the telephone terminals. By simultaneous adjustment of this resistance and the slide wire of the bridge, it is possible to bring the line and telephone terminals to approximately the same potential. If this be done, the effect of the remainder of the composite set is eliminated and a measurement with the receiver connected across the ratio arms in the usual manner gives the unbalance of the telegraph branches alone. A receiver connected across either of the series condensers, as indicated, is used to determine when the line and telephone terminals are at the same potential, no sound being heard when this condition obtains.

Conclusion

While the effect of unbalances of a telephone circuit in contributing to noise depends much upon how and where the circuit is energized and on the energization and condition of other nearby telephone circuits, the test methods which have been devised permit the detection of all important unbalances which may contribute to noise. All of the apparatus for applying these methods has been standardized and made up in portable form for convenience in field testing. Much of it has been in use for several years.

The development of this apparatus, and of the methods outlined, provides the operating telephone companies with effective means for detecting faults of balance, and for maintaining circuits in a high state of efficiency from this standpoint. These methods are particularly applicable to toll circuits but some of them can also be applied to local circuits where necessary. This is important in minimizing crosstalk among telephone circuits and noise interference when such circuits are raised above the potential of the earth by induction from neighboring power circuits.

Further investigations of unbalances are in progress to determine more definitely the relationship between the magnitude and location of unbalances and their resultant effect at the circuit terminals when the circuits are energized inductively.

ACKNOWLEDGMENT

Credit is due chiefly to F. H. Best and P. W. Blye for carrying out the work leading to the development in practical form of the apparatus described. The authors wish to express their appreciation to them and also to H. M. Trueblood, A. G. Chapman and other colleagues for many helpful suggestions and criticisms received during the preparation of this paper.

Appendix

Theory of Bridge Method for Locating Unbalances

Fig. 8 shows, schematically, an unbalanced two-wire side-circuit connected to an unbalance bridge with the phantom used as a reference. In what follows, the circuit is assumed to be uniform (non-loaded) and the unbalances are assumed to be lumped and so small that they do not alter appreciably the total impedance of the circuit. Both the test and reference circuits are assumed to be terminated in characteristic impedance at the distant end.

Let:

γ_s = propagation constant of the side-circuit

γ_r = " " " " reference circuit

$\gamma = \gamma_s + \gamma_r = \alpha + j\,\beta$

Z_r = characteristic impedance of the reference circuit

Z_s = " " " " side-circuit

Z'_s = impedance of side-circuit looking toward bridge at distance x from bridge

Z_b = impedance of bridge looked at from line

I_r = current in the reference circuit at point of connection to bridge

I_r' = current in the reference circuit at distance x from bridge

i_s = side-circuit current at the bridge due to unbalances inserted in the bridge

i_s' = side-circuit current at the bridge due to unbalances in the line

i_s'' = side-circuit current due to unbalances in the line at distance x from bridge, looking toward the bridge.

Series unbalances R and L and shunt unbalances to ground G and C are assumed at a distance x from bridge. As regards the side-circuit current at the bridge, the same effect might be produced by values of equivalent series resistance and inductance unbalances R_e and L_e at the bridge. The bridge may, therefore, be balanced by inserting series unbalances $-R_e$ and $-L_e$.

The reference circuit current in one wire at a distance x from the bridge is

$$\frac{1}{2}\,I_r' = \frac{1}{2}\,I_r\,e^{-\gamma_r x} \qquad (1)$$

The reference circuit current in traversing the series unbalance sets up a voltage in the side-circuit which is

$$v_s' = \frac{1}{2}\,I_r'\,(R + j\,\omega\,L) \qquad (2)$$

This voltage acts through an impedance equal to the sum of the impedances of the side-circuit in two directions from the unbalance and sets up a current in the side-circuit which is

$$i_s''' = \frac{1}{2} I_r'\,\frac{R + j\,\omega\,L}{Z_s + Z_s'} \qquad (3)$$

The voltage to ground (one-half of the reference circuit voltage) at the distance x from the bridge is

$$V_g' = \frac{1}{2}\,I_r'\,Z_r \qquad (4)$$

This voltage sets up a current through the admittance unbalance in series with the admittance to ground of the whole circuit which, on the assumption that $G + j\,\omega\,C$ is small, is determined by the equation

$$i_g' = \frac{1}{2}\,I_r'\,Z_r\,(G + j\,\omega\,C) \qquad (5)$$

In obtaining the current in the side-circuit due to this current i_g' to ground, it is convenient to think of another path to ground on the other side of the circuit of zero admittance and, therefore, of zero total current to ground. The zero current in the path of zero admittance on the one wire and the current i_g' in the "unbalance" of finite admittance to ground on the other, may be said to be resolved into two equal components each equal to $i_g'/2$. Those in the zero current path are opposite in phase and those in the unbalance in the same phase, thus

$$\frac{1}{2}\,i_g' - \frac{1}{2}\,i_g' = 0 \qquad (6)$$

$$\frac{1}{2}\,i_g' + \frac{1}{2}\,i_g' = i_g' \qquad (7)$$

It will thus be seen that this is equivalent to supplying two equal sets of currents, one of which is a current in the reference circuit and the other in the side-circuit. As $G + j\,\omega\,C$ is assumed small, i_g' will be small compared to I_r' and the change in reference circuit current may, therefore, be neglected.

The current in the side-circuit will divide between the sections of circuit in the two directions from the unbalance in inverse proportion to the side-circuit impedances and the current propagated toward the bridge will be

$$i_s^{iv} = -\,\frac{1}{4}\,\frac{G + j\,\omega\,C}{Z_s + Z_s'}\,Z_s\,Z_r\,I_r' \qquad (8)$$

The total unbalanced current propagated toward the bridge is

$$i_s'' = i_s''' + i_s^{iv} \qquad (9)$$

or, adding equations (3) and (8), and substituting from (1)

$$i_s'' = \left[\frac{1}{2}\frac{R + j\,\omega\,L}{Z_s + Z_s'} - \frac{1}{4}\,Z_r\,Z_s\,\frac{G + j\,\omega\,C}{Z_s + Z_s'}\right] I_r e^{-\gamma_r x} \tag{10}$$

and, combining terms,

$$i_s'' = \frac{1}{2}\,\frac{R + j\,\omega\,L - \frac{1}{2}\,Z_r Z_s\,(G + j\,\omega\,C)}{Z_s + Z_s'}\,I_r e^{-\gamma_r x} \tag{11}$$

In terms of the side-circuit current at the unbalance, the side-circuit current at the bridge, caused by the unbalance, is

$$i_s' = i_s''\,\frac{Z_s}{Z_s \cosh\,\gamma_s x + Z_b \sinh\,\gamma_s x} \tag{12}$$

and the impedance looking from the unbalance toward the bridge is

$$Z_s' = Z_s\,\frac{Z_b \cosh\,\gamma_s x + Z_s \sinh\,\gamma_s x}{Z_s \cosh\,\gamma_s x + Z_b \sinh\,\gamma_s x} \tag{13}$$

Substituting equation (13) in (11) and the result in (12),

$$i_s' = \frac{1}{2}\,\frac{R + j\,\omega\,L - \frac{1}{2}\,Z_r Z_s\,(G + j\,\omega\,C)}{(Z_b + Z_s)\,(\cosh\,\gamma_s x + \sinh\,\gamma_s x)}\,I_r\,e^{-\gamma_r x} \tag{14}$$

$$i_s' = \frac{1}{2}\,\frac{R + j\,\omega\,L - \frac{1}{2}\,Z_r Z_s\,(G + j\,\omega\,C)}{Z_b + Z_s}\,I_r\,e^{(-\gamma_r - \gamma_s)x} \tag{15}$$

The side-circuit current set up by the action of I_r on the compensating unbalances $-\,R_e$ and $-\,L_e$ is

$$i_s = -\,\frac{1}{2}\,\frac{R_e + j\,\omega\,L_e}{Z_b + Z_s}\,I_r \tag{16}$$

If the bridge is balanced, there is no voltage across the receiver, therefore

$$i_s + i_s' = 0 \tag{17}$$

Substituting the values of i_s and i_s' from (16) and (15) in (17)

$$R_e + j\,\omega\,L_e = \left[R + j\,\omega\,L - \frac{1}{2}\,Z_r Z_s\,(G + j\,\omega\,C)\right] e^{-\gamma x} \tag{18}$$

or

$$R_e + j\,\omega\,L_e = \left[R + j\,\omega\,L - \frac{1}{2}\,Z_r Z_s\,(G + j\,\omega\,C)\right] \cdot (\cos\beta\,x - j\sin\beta\,x)\,e^{-\alpha x} \tag{19}$$

Resolving equation (19) into its real and imaginary parts, on the assumption that Z_r and Z_s are pure resistances[1],

$$R_e = e^{-\alpha x}\left[\left(R - \frac{1}{2}\,Z_s Z_r\,G\right)\cos\beta\,x + \left(\omega\,L - \frac{1}{2}\,Z_r Z_s\,\omega\,C\right)\sin\beta\,x\right] \tag{20}$$

$$\omega\,L_e = e^{-\alpha x}\left[\left(\omega\,L - \frac{1}{2}\,Z_r Z_s\,\omega\,C\right)\cos\beta\,x - \left(R - \frac{1}{2}\,Z_r Z_s\,G\right)\sin\beta\,x\right] \tag{21}$$

or

$$R_e = e^{-\alpha x}\sqrt{\left(R - \frac{1}{2}\,Z_r Z_s G\right)^2 + \omega^2\left(L - \frac{1}{2}\,Z_r Z_s C\right)^2}\;\cos\left[\beta\,x - \tan^{-1}\frac{\omega\left(L - \frac{1}{2}\,Z_r Z_s C\right)}{R - \frac{1}{2}\,Z_r Z_s G}\right] \tag{22}$$

$$\omega\,L_e = -\,e^{-\alpha x}\sqrt{\left(R - \frac{1}{2}\,Z_r Z_s G\right)^2 + \omega^2\left(L - \frac{1}{2}\,Z_r Z_s C\right)^2}\;\sin\left[\beta\,x - \tan^{-1}\frac{\omega\left(L - \frac{1}{2}\,Z_r Z_s C\right)}{R - \frac{1}{2}\,Z_r Z_s G}\right] \tag{23}$$

The value of β in these formulas may be expressed in terms of frequency as

$\beta = \dfrac{2\,\pi\,f}{V}$, V = a function of V_s and V_r, the velocities of phase propagation on the side and reference circuits, respectively. Since

$$\beta = \beta_s + \beta_r \text{ and } \beta_s = \frac{2\,\pi\,f}{V_s},\ \beta_r = \frac{2\,\pi\,f}{V_r},$$

$$\beta = 2\,\pi\,f\,\frac{(V_s + V_r)}{V_s V_r}$$

Substituting $\dfrac{2\,\pi\,f}{V}$ for β, formulas (22) and (23) may be rewritten as follows:

$$R_e = K\cos\left(\frac{2\,\pi\,x}{V}\,f - \phi\right) \tag{24}$$

$$\omega\,L_e = -\,K\sin\left(\frac{2\,\pi\,x}{V}\,f - \phi\right) \tag{25}$$

If R_e and $\omega\,L_e$ were plotted against frequency the curves would be perfect sine and cosine curves provided the values K, V and ϕ were constant with frequency. If this were so, the resistance curve would pass through a maximum when $\dfrac{2\,\pi\,x}{V}\,f - \phi = 0,\ 2\,\pi,\ 4\,\pi,$

1. This assumption holds fairly well for non-loaded circuits at frequencies above 400 cycles. The magnitude of the reactance term is smaller on circuits of the larger gage conductors.

etc. Let f_0, f_2, f_4, etc., indicate the frequencies at which the successive maxima occur, then

$$\frac{2\,\pi\,x}{V}\,f_0 - \phi = 0,\ f_0 = \frac{\phi\,V}{2\,\pi\,x}$$

$$\frac{2\,\pi\,x}{V}\,f_2 - \phi = 2\,\pi,\ f_2 = \frac{V}{x} + \frac{\phi\,V}{2\,\pi\,x}$$

$$\frac{2\,\pi\,x}{V}\,f_4 - \phi = 4\,\pi,\ f_4 = \frac{2\,V}{x} + \frac{\phi\,V}{2\,\pi\,x}$$

The frequency interval between positive peaks would then be

$$f_i = f_4 - f_2 = f_2 - f_0 = \frac{V}{x} \tag{26}$$

and conversely the distance from the bridge out to the unbalance would be equal to

$$x = \left(\frac{V_s\,V_r}{V_s + V_r}\right)\frac{1}{f_i} \tag{27}$$

If inductance and capacitance unbalances are absent the lag angle ϕ becomes 0 and is constant with frequency. If resistance and leakage unbalances are absent the angle ϕ becomes constant and has a value of 90 deg. For other cases the tangent of the angle ϕ is proportional to frequency, assuming R, L, G, C, Z_r and Z_s to be constants. The types of unbalance ordinarily encountered are such as to give values of ϕ nearly equal to 0 or to 90 deg. for all frequencies within the working range. Examples of such are: resistances in joints, for which ϕ is 0; and transposition errors and inductance unbalances as in loading coils, for which ϕ is practically 90 deg.

Inspection of equations (**24**) and (**25**) shows that variations in V and ϕ with frequency will result in variations in the *period* of the curves. In order to eliminate as far as practicable the effect of changes in period due to either of these factors, it is advisable to use the average period over as large a range of frequencies as possible.

Obviously, the factor

$$K = e^{-\alpha x}\sqrt{\left(R - \frac{1}{2}\,Z_r Z_s G\right)^2 + \omega^2\left(L - \frac{1}{2}\,Z_r Z_s C\right)^2}$$

cannot be independent of frequency. Variations in this factor cause variations in the amplitude of the curves but do not cause much change in the intervals between successive maxima. The actual changes in this factor with frequency depend upon the type of circuit involved and the particular type of unbalance existing on that circuit. In general terms, the variation of amplitude as frequency increases is as follows:

Series Resistance Unbalance. (R)

R_e. Amplitude decreases slowly due to increase in the attenuation constant, α, with frequency.

L_e. Since L_e is inversely proportional to ω its amplitude decreases directly as frequency increases. A further decrease in amplitude is caused by the increase in α with frequency.

In this case usually the resistance curve is of greater usefulness in determining the frequency interval.

Series Inductance Unbalance. (L)

R_e. In this case R_e is directly proportional to ω which tends to make the amplitude of R_e increase directly with frequency. This increase in amplitude is opposed by the increase in the attenuation constant α with frequency. This latter effect is, however, small compared to the former.

L_e. Amplitude decreases slowly due to increase in α with frequency.

In this case the inductance curve is of greater usefulness in determining the frequency interval.

Shunt Leakage Unbalance. (G)

Assuming Z_s and Z_r to be resistances and constant with frequency the amplitudes of the R_e and L_e curves behave as in the case of a series resistance unbalance. This assumption holds fairly well for non-loaded circuits at frequencies above 400 cycles.

Shunt Capacitance Unbalance. (C)

Assuming Z_s and Z_r to be resistances and constant with frequency the amplitudes of the R_e and L_e curves behave as in the case of a series inductance unbalance. Shunt capacitance unbalances are usually due to transposition errors which introduce simultaneously inductance unbalance. Such unbalances are not lumped but distributed along the circuit and, therefore, the curves obtained become somewhat distorted in the upper part of the frequency range.

In many cases two or more unbalances are found on a circuit. In such a case the curve might be represented by an equation made up by adding the equivalent resistance and inductance corresponding to each unbalance. The equation would consist of two or more terms similar to equation (**19**).

It should be noted that only very rarely would the individual curves resulting from the two or more unbalances have periods with a common multiple corresponding to a frequency interval included in the range tested. The composite curves are not, therefore, susceptible of analysis by the methods used in analyzing periodic waves.

While the theory given above is based upon circuits with uniformly distributed constants, it may also be applied to loaded circuits, with the assumption that the capacitance in the successive sections of line is lumped. The end section of the line adjacent to the bridge is assumed to be a full section, although 0, one-half coil or full coil loading may be present in the office adjacent to the bridge. All series unbalances are assumed to occur in or immediately adjacent to the loading coils. If such unbalances occur within the section or if less than full section termination is used at the end adjacent to the bridge, distortion in the curves will result.

Shunt capacitance unbalance is generally introduced by transposition errors and is accompanied by series

inductance unbalance. These unbalances are distributed along the sections. The characteristic impedance of loaded circuits varies at different points along the section, and except for mid-section the reactance term is important. The magnitude of the impedance varies considerably with frequency, although the phase-angle changes much less rapidly.

The velocity of phase propagation changes with frequency on loaded circuits much more rapidly than on non-loaded circuits, especially as the cut-off frequency is approached.

On account of these various factors tending to distort the curves obtained, it is not generally practicable to locate unbalances in loaded circuits closer than within a loading section on either side of the correct point unless the unbalance is a series unbalance in a loading coil or immediately adjacent thereto. If the proper end section be used at the bridge or if the circuit be built out to give this condition, it will usually be possible to locate such a series unbalance at the correct load point. To locate definitely a shunt unbalance, it will often be necessary to cover two successive sections (16 miles of open-wire line) with the unbalance detector in order to obtain the final location.

Termination of Circuits under Test

In making measurements of the unbalance of a circuit, it is necessary to terminate both the circuit under test and also the reference circuit. If the circuit were balanced with respect to the reference, the measurements would reveal no unbalance irrespective of the termination at the distant end but in the case of an unbalanced circuit, lack of terminations would result in unbalances at a number of apparent locations at and beyond the distant end of the circuit.

In examining this problem it is convenient to assume that the bridge impedances as looked at from the terminals of either the reference or the test circuits are equal to the characteristic impedances of these circuits. This assumption is valid, as far as obtaining the relative values of the line and compensating unbalances is concerned, because any reflection from the bridge end of the circuits affects the line and compensating unbalances relatively in the same manner as the original voltages and currents.

Referring again to Fig. 8, let both circuits be open at the distance D from the bridge and suppose that the unbalance at x is a pure resistance R. Then the current in the reference circuit at any point will consist of two terms, one being the original wave and the second the wave reflected from the open end of the circuit. Thus, if $2\,E_r$ be the open-circuit voltage of the oscillator, the current in the reference circuit at any point x will be

$$I_r' = \frac{E_r}{Z_r}\left[e^{-\gamma_r x} - e^{-\gamma_r (2D - x)}\right] \qquad (28)$$

Each of these two components of current in the reference circuit acting on the unbalance R, will cause two components of current in the side-circuit, one the current propagated directly from the unbalance to the bridge, and the other propagated to the open end and reflected back to the bridge. At the bridge this current will be, using the methods of the first part of this appendix,

$$I_s' = \frac{E_r}{Z_r}\cdot\frac{R}{4\,Z_s}\left[e^{-(\gamma_r+\gamma_s)x} - e^{-\gamma_r(2D-x)-\gamma_s x}\right]$$

$$-\frac{E_r}{Z_r}\cdot\frac{R}{4\,Z_s}\left[e^{-\gamma_r x-\gamma_s(2D-x)} - e^{-(\gamma_r+\gamma_s)(2D-x)}\right] \qquad (29)$$

Let the compensating unbalance $-R_e - j\,\omega\,L_e$ equal $-Z_e$. This unbalance will cause, similarly, four more components of unbalance current in the side-circuit. This current at the bridge is

$$I_s = -\frac{E_r}{Z_r}\,\frac{Z_e}{4\,Z_s}\left[1 - e^{-\gamma_r 2D} - e^{-\gamma_s 2D} + e^{-(\gamma_r+\gamma_s)2D}\right] \qquad (30)$$

These four components in each case are respectively propagation (1) to the unbalance along the reference circuit and back over the side-circuit, (2) along the reference circuit to the open end, reflection in opposite phase back to the unbalance on the reference circuit and to the bridge over the side circuit, (3) along the reference circuit to the unbalance, along the side circuit to the open end, reflection in opposite phase and back to the bridge along the side current, and (4) along the reference circuit to the open end and back to the unbalance in opposite phase, along the side-circuit to the open end, reflection again in opposite phase and back along the side-circuit to the bridge.

Z_e may be evaluated in terms of R, the propagation constants of the circuits and the distances involved, by equating the sum of the right-hand sides of equations (29) and (30) to zero. Thus,

$$Z_e = R\left[\frac{e^{-(\gamma_r+\gamma_s)x} - e^{-\gamma_r(2D-x)-\gamma_s x}}{1 - e^{-\gamma_r 2D} - e^{-\gamma_s 2D} + e^{-(\gamma_r+\gamma_s)2D}}\right]$$

$$+ R\left[\frac{-e^{-\gamma_r x-\gamma_s(2D-x)} + e^{-(\gamma_r+\gamma_s)(2D-x)}}{1 - e^{-\gamma_r 2D} - e^{-\gamma_s 2D} + e^{-(\gamma_r+\gamma_s)2D}}\right] \qquad (31)$$

As an example of the interpretation of this expression in terms of the equivalent resistance and inductance unbalance, consider the case of phantom-side unbalance measurements on a fully loaded or non-loaded group, for which the velocities of phase propagation on the two circuits are substantially equal. It will also be assumed that the difference in the attenuation constants of the two circuits is small as compared to their sum and that a wave propagated over lengths equal to or greater than twice the total length of both circuits becomes negligibly small. Then equation (31) becomes, calling $\gamma = \gamma_r + \gamma_s$

$$Z_e = R\,\frac{e^{-\gamma x} - 2\,e^{-\gamma D} + e^{-\gamma(2D-x)}}{1 - 2\,e^{-\gamma D}} \qquad (32)$$

Dividing and rejecting terms as small or smaller than $e^{-2\gamma D}$ as before.

$$Z_e = R\left[e^{-\gamma x} - 2\, e^{-\gamma D} + e^{-\gamma(2D-x)} + 2\, e^{-\gamma(D+x)} \right] \quad (33)$$

Substituting $\alpha + j\,\dfrac{2\,\pi\,f}{V}$ for γ and equating real and imaginary terms as in the first part of this appendix,

$$R_e = R\left[e^{-\alpha x} \cos \frac{2\,\pi\,x}{V} f - 2\, e^{-\alpha D} \cos \frac{2\,\pi\,D}{V} f \right]$$

$$+ R\left[e^{-\alpha(2D-x)} \cos \frac{2\,\pi\,(2\,D - x)}{V} \right.$$

$$\left. + 2\, e^{-\alpha(D+x)} \cos \frac{2\,\pi\,(D + x)\,f}{V} \right] \quad (34)$$

Examination of this equation shows that the curve will be composed of four periodic components, the first corresponding to the actual unbalance at x, the second corresponding to a smaller unbalance apparently located at the distant end, and the third and fourth apparently located beyond the distant end. Other smaller and apparently more distant unbalances have been neglected, in rejecting terms of the order $e^{-2\gamma D}$ and smaller.

The inductance curve, the expression for which has not been written out, would be similarly complex.

If the distant ends of the circuits were short-circuited instead of open these apparent locations would still be indicated, the signs of some of the terms merely being reversed. If one of the circuits were open or shorted and the other were properly terminated, the magnitudes of the unbalances apparently located at D and $D + x$ would be reduced and that located at $D - x$ would vanish.

Tests to locate unbalances on non-phantomed pairs, phantom circuits or sides of vertical phantoms, employ as a reference a superposed circuit having for its other side the conductors in parallel of some nearby non-phantomed pair or phantom group. Such a reference circuit is not transposed and when energized from the bridge, voltages and currents will be induced in other conductors of the line. These voltages and currents will react by induction on the voltages and currents of both the reference and test circuits and on account of reflections from the distant ends, unbalances will be indicated apparently located at and beyond the distant end. Experience shows that these reflection effects are not large and that the complication in the curves is not important, provided the test and reference circuits themselves are properly terminated.

Discussion

PRACTICES IN TELEPHONE TRANSMISSION MAINTENANCE WORK

(Harden)

TELEPHONE CIRCUIT UNBALANCES

(Ferris and McCurdy)

Pasadena, Cal., October 17, 1924

D. I. Cone: To the engineers and maintenance people of the operating telephone systems these advances in the means for maintaining the circuits are very gratifying. There are two major reasons for their need: First, in order to employ economically the communication plant, as many types of service as possible are put on the wires. Balancing the circuits is one means employed to separate one channel of communication from another. Second: The growth of power circuits and their inductive fields has been so great that communication circuits, which originally had the field very much to themselves, are now forced to exist in the presence of large inductive and conductive fields. Since the same people want both power and communication service it is impossible altogether to prevent that. The original telephone circuits would be wholly inoperative under present-day conditions but for the advances made, on the one hand, by the method of balancing the communication circuits, and on the other hand, by measures taken in the supply circuits to limit their fields of influence.

The Pacific Telephone & Telegraph System has about 3000 toll circuits, which it is our duty to maintain in efficient operating condition. Mr. Harden has described to you the testing technique employed for transmission maintenance. As a part of this we have, for several years, been making annual noise tests on these toll circuits, in addition to special tests made at times when changes either in the telephone circuit or in the neighboring power circuit are made, and acceptance tests of new circuits. When the crosstalk meter, which Mr. Ferris described, became available, measurements with it to determine the condition of the circuits were incorporated and are now regularly made as a part of our routine.

Since the impedance-unbalance bridge became available some years ago, we have made much use of it in locating unbalances of the types mentioned, particularly resistance unbalances and transposition irregularities. In this Pacific Coast toll network we have several hundred thousand circuit transpositions whose maintenance is a large problem. It would be possible to present to you many curves obtained on our circuits, similar to those shown in Figs. 9, 10, 11 and 12 of the paper, but these illustrate so well the characteristics obtained and the ability of this apparatus to show the nature of unbalances that it seems unnecessary to add more examples.

Referring to Fig. 10, where an artificial unbalance was inserted at a known distance, it is easily possible, by the formula given, to calculate the velocity of travel of the waves in that circuit. This was a loaded cable circuit and I find the velocity to be 7900 mi. per second. That is very different from the velocity in the open wire lines and we find it desirable to take account of this difference of velocity in cables and open wires when we are testing circuits which enter the office through long toll entering cables. The setup given in Fig. 10 affords a means of obtaining a "calibration" of the velocity factor.

To illustrate the necessity for obtaining balance, not only where there are inductive exposures, but throughout the line, suppose a line into which a branch line connects, the branch line being exposed to a source of noise. The induced energy will flow into the main section of the line and if there are unbalances on this main line, we will have trouble from the exposure, even though perfect balance were obtained on the branch circuit.

It might be asked, what is the relation of these more recent methods to the previously available working methods used? The advance seems to me to come in the form of a very definite

improvement of technique. The impedance-unbalance bridge represents the application of alternating current at varying frequencies to the old familiar Varley loop test much used for location of faults with the Wheatstone Bridge. Using the same idea, but a variety of alternating-current frequencies, it detects effects which the direct-current bridge cannot discover.

We often make use of the induced noise voltage to ground, comparing it with the induced voltage between wires. That has served as a rough method of indicating balance, which had some usefulness, employing the source of energy which happened to be there in the form of the disturbing circuits. On the other hand, in the methods here described, we have a definitely controlled and applied source of energy, with its manifest advantages.

By the pursuit of the methods indicated in the paper in providing and maintaining a high grade of balance in the telephone circuits important reductions in noise and in crosstalk have been realized in our plant. To offset this we have been confronted with the rapid expansion of the power circuits. That it has been possible to improve the conditions has been due to the faithful efforts of a large group of men. Having devoted their energies to the solution of this problem, they have enabled us to make remarkable advances in this direction. I feel moved to pay tribute to the work of these men because of the exceptional hours at which they often have to work in order that the normal service of the communication and power circuits may not be interrupted.

H. W. Hitchcock: In regard to the value of adequate transmission maintenance, such as is described in Mr. Harden's paper, I think it quite obvious that in the case of a toll circuit which involves an investment of possibly several thousand dollars, it is extremely important that the circuit be kept in a high degree of efficiency, as we can hardly afford to lose a considerable portion of its volume efficiency by allowing small troubles to creep in. As this is quite evident, it needs no further elaboration and I shall confine my further remarks to a discussion of the advantages to be derived from proper transmission maintenance in the local exchange plant where its value perhaps is not so apparent.

Unless one has given the matter close consideration, he may have the idea that a telephone plant grows in a more or less haphazard way. In fact, we set up quite a definite transmission standard of efficiency, which applies to the entire plant. That is, we attempt to make it possible for every subscriber to talk to every other subscriber with approximately the same degree of efficiency. This standard of efficiency has been arrived at from a study of extensive laboratory tests and from trying out certain standards in actual practice. In the latter case, particularly, the result is a combined reaction from a large number of people having all kinds of ears and voices and personal temperaments.

As a result of years of experience and trial, we have established a standard which we call a twenty-mile standard. This means that the telephone circuit to give good transmission can have the same loss as that produced by 20 miles of standard 19 gage cable. This standard is possible because the modern telephone transmitter produces in the circuit, telephone currents representing an amplification of several hundred times over the acoustic power directly by the voice against the transmitter diaphragm and therefore for satisfactory telephone conversations the telephone power delivered to the receiver at the far end of the circuit need be only a fraction of 1 per cent of the input power at the transmitting end. The fact that the overall electrical efficiency of the circuit itself is low is not of importance as we are dealing in the ultimate with the overall efficiency from the voice of the speaker to the ear of the listener. Furthermore, a very small amount of acoustic power at the receiving end is sufficient to give a very clear conversation and when you are talking with a person over the telephone you are anxious to make him understand what you have to say; you are not trying to warm up his ear.

Disregarding, for the present, the matter of cost, the proper volume of efficiency might be arrived at somewhat as follows:

Two telephone instruments might be connected together with a very short circuit and speech exchanged over them. In such a case, it would be found that the volume of tone would be unnecessarily loud, in fact it would be something like trying to talk to another person if he insisted upon shouting in your ear. The circuit between the telephones might then be extended until the speech became very weak and made it necessary to listen very closely and possibly ask that the speaker shout or repeat frequently in order that the speech might be understood. Obviously, a circuit having some intermediate efficiency would be preferable to either of these, and the one which, on the whole, would give the best results could be determined by repeated trial.

In establishing a standard, however, the economic factor cannot be ignored. The more power which you transmit over a circuit of a given length, the more copper you must place in it, with a corresponding increase in cost. From an economic consideration, then we would use the smallest wire which it is possible to employ and still transmit understandable speech.

As a result of these somewhat conflicting requirements, we select a standard which we believe will give good speech transmission, enabling one person to talk to another without unnecessary repetition and without having to shout, and at the same time provide the service at a price which will make it attractive for him to use freely.

Having established such a standard, it is obviously poor economy to depart from it in either direction. To do so tends to limit the service, to discourage its use, or make it unsatisfactory to the public. This will result on the one hand, from too great a cost if too high a degree of efficiency is attempted, and on the other, from poor and unsatisfactory transmission if a circuit of insufficient efficiency is provided.

In the design of a telephone plant, we usually assume approximately one hundred per cent efficiency for all the parts which go to make it up. Of course, it is impossible to expect that such parts will always be. and remain indefinitely, at this high degree of efficiency. Troubles are bound to creep in, just as they creep into any plant, so that we must face the fact that our plant tends to deteriorate, or that we will occasionally find defective instruments, such as transmitters, receivers or other parts. There are in general two ways by which this deterioration can be cared for. One is by providing a margin of safety in our plant design sufficient to make up for these occasional defects. The other is to detect these troubles as they arise and remove them. I believe it is obvious to all of you that the first method is not a very satisfactory one. It means that the entire plant must be much more expensively constructed than would otherwise be necessary. Moreover it is not satisfactory from the subscriber's point of view. For example, a subscriber's instrument may, for some reason, have deteriorated until it only is ten per cent as as good as it should be. He reports it and the company sends an adjuster to discuss the matter with him. The company's representative may say to the subscriber: "We appreciate that your set may be in very poor shape; in fact, it may only be ten per cent as good as it should be. To offset this, however we have designed your circuit, and those of your ten neighbors, lines, ten per cent better than we think is necessary, so that the average efficiency of our plant is satisfactory: nine instruments are ten per cent better than is necessary as against one instrument which is only ten per cent as good as it should be." The reaction of such an individual is obvious. He would reply that this is very nice for his neighbors perhaps but is of very little benefit to him.

In order to make such a method effective, it would be necessary to have all of the instruments several times as good as would normally be required and this would be prohibitive in expense. When we provide only a small margin of safety to take care of

isolated cases of trouble, we fail to accomplish the thing which we set out to do. The only way, then, is to detect these troubles as they appear and clear them promptly. Unfortunately, for the telephone company, they do not always announce themselves. Some of them, of course, do, such as "opens," "grounds," "crosses," or troubles of that kind. In these cases the supervisory signals fail to function or it is impossible to talk at all or the circuit is very noisy. Such troubles quickly call attention to themselves and are promptly remedied.

Another class of trouble is one which may produce only a moderate reduction in efficiency such as a few short-circuited turns on a coil or a partially defective condenser or a high-resistance joint. Such a circuit will usually give the proper supervisory response and can be talked over with a certain degree of facility. However, should such troubles be allowed to remain they will cause a gradual deterioration in the plant with a corresponding increase in the number of unsatisfactory connections. The only way to detect such trouble is by a series of systematic tests conducted periodically which cover the entire plant. In this way we find the troubles which are hidden away and which will not appear on ordinary inspection or as a result of the usual maintenance tests. To make such tests it is necessary that special instruments and routines be developed and followed and it is these tools, these instruments, these methods, which Mr. Harden has described and which we now have available for this kind of work. These new facilities are of tremendous value to us as you can well appreciate since they make it possible to give a good and uniform standard of service with a plant designed with the maximum degree of economy.

Farley Osgood: I might just say a word on the matter of inductive interference. I think it is the duty of the power engineer to make known any contemplated plan he may have for construction to his telephone friends as soon as it is practicable for him to do so. A number of years ago the lines were built without due consideration to any neighbors and the problem of interference got to be more and more a disturbing one, until its seriousness was recognized and committees formed to deal with it. These committees, the National Electric Light Committee and the Joint Overall Committee, with men from both groups, worked out a most friendly relationship all over the country and the basis of it all is to confide in each other any plans of construction, of course, with the understanding that there will be no propaganda about the plans. The engineers of the two properties should know each other's plans at the start in order that disturbances may be avoided by injecting into the construction program the present known methods of elimination.

V. D. Elliot: I think, that the men who are employed by the larger power companies, particularly those which have extensive private telephone systems, could, with advantage to themselves and to their companies, become more familiar with the subjects treated in these papers. I know that a number of these instruments, if not all of them, could, with certain modifications, be used for testing work on the private telephone systems of the large power companies.

I wish to say, by way of appreciation, that the telephone men of Southern California have shown a cooperative spirit to the Edison Company, by giving helpful suggestions, loaning apparatus and offering their help in any way possible to aid us in following out these ideas on our system.

It may be of interest to some of the telephone men and, perhaps, to the power men to know of a case of telephone line balance, which occurred on the telephone system of the Edison Company.

The telephone lead, which was built for the operation of the Big Creek System of the Southern California Edison Company, as originally constructed, had four wires, carried on a pole line separated by varying distances from the 150,000-volt power circuits. It was never intended to be other than a two-circuit line as the crossarms were of such size as to accommodate only the four wires, and the transposition system was only designed to take care of crosstalk balance between the pairs.

When we started construction work on raising the Big Creek Dams there was need for an additional circuit from our Los Angeles office to Big Creek. I was asked to see if a phantom circuit could be installed without great expense. We put on phantom coils at the two ends and made a trial and found that we could operate without undue crosstalk, without any phantom transpositions. The line has been rebuilt in certain sections and phantom transpositions have there been installed and provisions have been made to accommodate any number of future wires and also to take care of any outside induction that may be present. Exclusive of these places there are 100 to 150 miles of the lead which have no phantom transpositions, but the crosstalk and noise on that phantom circuit is tolerable from our standpoint and we can carry on a conversation and without interfering with the talking on the side circuits.

This I think is a different experience from that which the telephone men have had and I thought it might be of interest to them and also to the power men who have telephone circuits and are contemplating the use of phantom circuits.

Four years ago we superimposed a simplex telegraph circuit on top of the others and it is operating successfully without interference with the other channels.

Mr. Ashbrook, of our company, has tried out recently, in an experimental way, apparatus for stopping, or minimizing acoustic shocks which occur on these telephone circuits due to flashovers on the power lines. The power line is in general proximity to this line for its entire length of 241 mi. At some places the lines are 8 mi. apart and in other cases they run parallel at 1000 ft. separation, but in general the average horizontal separation is about one-half mile. At times of flashover currents as high as 900 amperes going from the power circuit with a ground return, create a large magnetic loop which induces considerable voltage between ground and the telephone line. This voltage has a very steep wave front and part of it appears as a voltage between wires due to unavoidable telephone line unbalances resulting in an acoustic shock or "bat in the ear."

Mr. Ashbrook has a method to overcome this effect, but we do not know as yet whether or not it will be applicable as a regular adjunct to the telephone system.

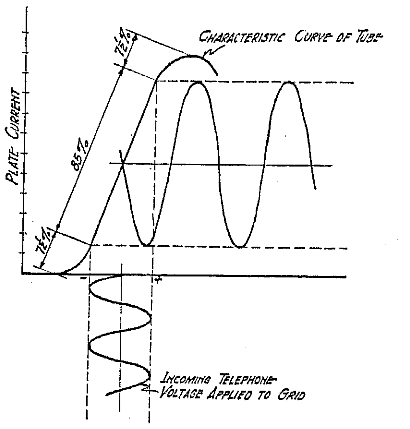
R. B. Ashbrook: The vacuum tube is utilized as a voltage-limiting device by operating the vacuum tube at such a point on its static characteristic curve that the voltage produced by normal telephone communication and applied to the grid causes a change of plate current over approximately 85 per cent of its characteristic curve. It is obvious that 7½ per cent increase in negative voltage will result in the plate current being reduced to zero and further increase will have no effect. If the increase is in the positive direction the plate current will increase until the saturation current corresponding to the existing filament temperature is reached. Further positive increase in the grid potential cannot result in further increase in the plate current, in fact as it becomes more positive it attracts a greater number of electrons to itself and causes a corresponding decrease in plate current.

A recent demonstration has proven beyond a doubt its usefulness to power companies operating telephone lines subjected to between-wire voltages occasioned by energizing or de-energizing parallel transmission lines.

Two operators, one a student wearing an operator's head set equipped with the acoustic-shock-suppression apparatus, the other with the usual operator's telephone set were connected with a telephone line at the time that a transmission line failed. The operator received a severe acoustic shock which was very painful and necessitated doctor's care for several days before resuming her duties while the student operator was not positive whether she heard it at all.

J. E. Woodbridge: The work of the Department of Develop-

ment and Research of the American Telephone and Telegraph Company on the lines described in this paper is of vital importance to the settlement of the problems of inductive interference which confront two divisions of the electrical industry. Such work is essential to the establishment of precise rules for legislative enactment in this controversy where such legislation is found necessary.



This is for the following reason:

A telephone circuit balanced in all respects, including balance to other circuits, is immune to inductive interference.

The real difficulty is, of course, to get such a balanced telephone circuit. An equally real difficulty in the past negotiations between the two interests has been to get either a criterion of unbalance, or a means of measuring the unbalance of communication circuits.

At the time when the Joint Committee on Inductive Interference, appointed by the California State Railroad Commission, was struggling with its problems, namely, from 1913 to 1917, the Committee members recognized the importance of the balance of telephone circuits, and that the legislation based on the Committee's findings ought to include rules on such balance so that undue diligence for the mitigation of interference should not be put upon the power systems. The difficulty, however, of measuring unbalances or of defining practicable balance made it impossible to include in the code any quantitative rules for limiting unbalances of telephone circuits.

This difficulty has now been partially removed by the work outlined in this paper. It is to be hoped that the work will be carried further to determine and make it possible to define reasonable or practical units of unbalance that can be specified as limits or tolerances in commerical construction and operation.

R. G. McCurdy: Mr. Cone refers to a method of measuring unbalances by determining the ratio of the noise measured in the metallic telephone circuit to the noise voltage measured to ground. While this test is valuable as preliminary indication it is generally not conclusive, because as mentioned in the paper, the noise measured in the metallic circuit includes two effects; one dependent upon unbalances of the circuit in its relations to ground and other telephone circuits, and the other dependent upon the dissymmetry in its relations to parallel power circuits. If this ratio indicates a high voltage to ground and a low noise in the metallic circuit, we are justified in concluding that the circuit is well balanced. If, however, the ratio is in the opposite direction, it may be concluded either that the circuit is unbalanced or that relatively large voltages are induced in the metallic circuit because of dissymmetry to parallel power circuits. Thus, in order to obtain any definite indication of the existence of unbalances of the circuit to ground or to other telephone circuits, tests must be made under controlled conditions, as described in the paper.

Mr. Elliott brings up the case of a line with a single phantom group, which was in a satisfactory condition from the standpoints of crosstalk and noise on both the side and phantom circuits with no transpositions in the phantom circuit. It should be observed that when no other circuits are nearby, complete balance may be secured between the two side circuits and between each side circuit and the phantom, provided each side circuit is made up of wires of the same size and with transpositions placed only in the side circuits. If any more telephone circuits are added to the same line, or if power circuits are constructed in proximity, it then becomes necessary to consider the balance of the phantom circuit. Under these conditions, all four wires of the phantom group must be of the same size and transpositions must be placed in the phantom circuit. I take it, in the case discussed by Mr. Elliott, no close exposures existed to other circuits.

L. P. Ferris: The use of the vacuum tube as an energy-limiting device referred to by Mr. Ashbrook has long been recognized by telephone engineers and has been proposed specifically for this purpose (H. D. Arnold, U. S. Patent No. 1168270, January 18, 1916). The telephone repeater in common use in many of our long telephone circuits employs vacuum tubes, and of course possesses this energy-limiting characteristic. Application of this method was considered a number of years ago in a case of parallelism between a telephone cable and a power circuit, which at times of short circuit caused acoustic shock to telephone operators. The large number of telephone circuits to be protected made the cost of vacuum-tube terminal equipment practically prohibitive. Other methods were found effective and more economical. It is, however, a different matter where only one or two circuits are involved as on a power company's private dispatch line.

Mr Woodbridge has stated that "a telephone circuit balanced in all respects, including balance to other circuits, is immune to inductive interference." This is theoretically true if the induced voltages to ground are not large enough to endanger personnel, break down insulation, or operate protective devices. Voltages high enough to interrupt service may be induced, even though the circuit be balanced in the manner Mr. Woodbridge suggests. Without exception, however, it might be said that a power circuit balanced in all respects, including balance to other circuits and its mode of energization, would cause no inductive interference. Both conditions are ideal but unrealizable in practise and, therefore, largely of academic interest. Balance of both systems, power and telephone within themselves, and with respect to each other, is important in preventing interference. Practically useful definitions of unbalance must, however, recognize these three distinct problems—balance of each system within itself, and mutual balance in exposures. Aside from the undesirable technical complications involved in making the unbalance of one system dependent upon the condition of the other, the importance is apparent from an administrative standpoint, of placing upon each party the responsibility for maintenance of its system in balance, only so far as conditions are under its control. This reduces the zone of joint responsibility to its minimum dimensions; *i. e.*, to the section where the two systems are in relatively close proximity, the exposure, which in general, involves but a small part of each system. Here responsibility for balance is inherently joint or divided, a situation not to be unnecessarily extended. It was with a background of such practical considerations in mind that our definition of a balanced telephone circuit was formulated, and in the opening paragraphs of the paper it is pointed out that it deals only with unbalances of the telephone circuits themselves, independent of their relation to power circuits. Thus, the problem of mutual unbalance within exposures, largely a problem of coordinated transposition design, and the problem of power-circuit balance, were purposely excluded from

the scope of the present paper. This, of course, does not mean we feel them any less important than the problem considered.

Mr. Woodbridge referring to the work of the California Joint Committee on Inductive Interference, mentions the difficulty then recognized of getting a criterion and measure of unbalance, and of setting any quantitative limits. The authors were associated with Mr. Woodbridge in this early joint work and as an outgrowth of the need then developed, the investigation reported in this paper was undertaken. That the results have been put into effective use on the Pacific Coast, it is gratifying to note from Mr. Cone's discussion. We recognize and have so stated in the conclusion of the paper that not all has been done along this line and with the joint development and research work now under way with power engineers, we hope as does Mr. Woodbridge that it may be possible to specify practical tolerances in construction and operation.

Report of the Board of Directors

FOR THE FISCAL YEAR ENDING APRIL 30, 1924

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Fortieth Annual Report, for the fiscal year ending April 30, 1924. A general balance sheet showing the condition of the Institute's finances on April 30, 1924, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year; more detailed information has been published from month to month in the Institute JOURNAL.

Directors' Meetings.—The Board of Directors held seven meetings during the year; five were held in New York and one each in Swampscott, Mass., and Philadelphia, Pa. The Executive Committee functioned when necessary in the intervals between regular board meetings.

Information regarding the more important activities of the Institute which have been under consideration of the Board of Directors, the committees and the various officers, is published each month in the section of the JOURNAL devoted to "Institute Activities."

Meetings.—The policy of holding in addition to the Annual business meeting four general meetings of the Institute each year was continued. The meetings held were as follows: Annual, Pacific Coast, Midwinter and Spring Conventions.

Annual Meeting.—The Annual Business Meeting was held at Institute headquarters, New York, on May 18, 1923. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1923 was presented. The Tellers Committee made its report upon the election of officers for the administrative year beginning August 1, 1923.

In the evening the members of the Board of Directors, past-presidents of the Institute and the president-elect met at dinner and informally discussed the affairs of the Institute.

Annual Convention.—The Thirty-ninth Annual Convention was held at Swampscott, Mass. on June 25 to June 29, 1923. Six technical sessions were held including parallel sessions, two mornings. A total of twenty-eight papers were presented. A large number of entertainment features were provided including lectures, musicals, moving pictures, dancing, tennis, golf, etc. The total registration of 1616 surpassed by several hundred, all previous records. An event of interest was the past-president's luncheon attended by sixteen of the twenty-four living past-presidents. The annual conferences of the Sections Committee were held on the Monday preceding the official opening of the convention, forty Sections were represented. Results of the conferences were published in pamphlet form.

Pacific Coast Convention.—The Twelfth Pacific Coast Convention was held at Del Monte, Cal., on October 2nd to 5th, 1923. Four technical sessions were held at which twenty-eight papers were presented. On the evening of October 4th the Edison Medal was presented to Dr. Robt. A. Millikan. The total attendance at the convention was 252.

Midwinter Convention. The Twelfth Midwinter Convention and 40th Anniversary Celebration was held in Philadelphia, Pa. February 4th to 8th, 1924. This was the largest convention in Institute history with a total attendance of 1738 registered members and guests, and the first midwinter meeting held outside of New York. Forty technical papers were presented at nine technical sessions. Among events of particular interest were the 40th Anniversary ceremonies, the Transportation Sessions addressed by men prominent in the railway field, the dedication of the Moore School of Electrical Engineering, conference on Engineering Education and the presentation of the Edison Medal to John W. Lieb. A variety of inspection trips and entertainment features was provided.

Spring Convention.—The Third Spring Convention was held in Birmingham, Alabama, April 7th to 11th, 1924. Seven technical sessions were held and twenty-nine papers presented in addition to three addresses on water-power development.

Abstracts of the reports of the chairman of many of the Institute committees and delegations are included herein under various headings.

Meetings and Papers Committee.—During the past year this Committee has prepared the programs for the four national conventions in conjunction with local convention committees. In addition to the technical sessions an attempt was made to stage certain feature sessions at each convention which would aid the industry or the membership in that locality and would prove interesting and attractive to all attending the meetings. At the Midwinter Convention the feature sessions were devoted to the reminiscences of electrical pioneers and to the broad aspects of railroad transportation. At the Birmingham Convention operating problems were discussed and feature meetings were held on hydroelectric developments. At the Edgewater Beach Convention the problems connected with metro-

politan transmission and distribution will be treated in technical sessions and in addition the work of the Standards Committee will be outlined. Another departure at this meeting is a complete session devoted to the reports of the technical committees. At the Pasadena Convention the technical aspects of energy utilization will be featured and in addition the value of interconnection will be outlined, while Dr. Millikan and his associates will divulge some notable researches.

At each of the conventions every effort was made to secure the hearty cooperation of public officials, utility executives and other business men in the convention activities so that the Institute would become better known and receive greater consideration. The results of this policy have been good and an appreciable stride has been made in securing a better understanding of the work of the Institute among those more directly connected with the business, legal and financial aspects of the electrical industry.

The committee has codified and coordinated its work so that definite methods of procedure and permanent policies are now on record. A complete guide for handling Institute conventions has been produced to be given to local convention committees.

Another positive contribution has been the revision of the pamphlet for authors of Institute papers.

The Committee has been particularly active in coordinating the work of the technical committees and has formulated very definitely the scope and type of technical paper suitable for Institute presentation and has established a uniform method of procedure for securing, examining and scheduling papers for convention and Section presentation.

It has given considerable thought to Section and Geographical District activities and advocates the development of the Geographical meetings as a permanent plan for stimulating Institute activity in each section of the country. These regional meetings also will give an outlet for the presentation of many papers submitted to the committee and are capable of being developed so that only two national conventions each year will ultimately be advisable, the Midwinter and June meetings.

A definite plan for cooperating with Sections and Geographical Districts in arranging programs has been made.

The committee has met at least once each month during the year and there has been a great stimulation of interest in the Institute and its work which is reflected in the very large number of papers presented during the year.

Publication Committee.—Regular meetings of the committee are now held monthly, and the chairman maintains continuous contact with the secretary and with the editor of the JOURNAL so that there will be no delay in disposing of routine matters which require cooperative consideration.

As distinguished from the period covered by the War years when there was a dearth of material submitted for publication and when it was difficult to procure a sufficient amount of matter for the JOURNAL, the present experience is that the number of technical papers submitted for presentation at meetings and for publication has increased so that the task of properly disposing of these many contributions is greatly enlarged.

The present plan of holding four national meetings each year, for each of which from thirty to forty technical papers are submitted, brings for publication a mass of material which far exceeds that brought in under the old order. The problem as it has enlarged, has required certain alterations in publication policies such as those presented fully in the October, 1923, JOURNAL. Editorial analysis of the papers received during the past year discloses that engineer authors, in many instances, follow the plan of building their stories around blueprints and photographs available in the files instead of writing clear stories and drawing upon illustration for the purpose only of illustrating features which cannot clearly be described in words. The former is perhaps the easy way for the author, but the publication costs thus imposed on the Institute are mounting seriously.

The committee hopes that improvement in this respect can be effected by revision of the pamphlet of suggestions to authors. This undertaking is now in hand.

Sections and Branches.—The various Sections of the Institute throughout the country continued their activities during the past year upon about the same scope as heretofore as indicated by the brief reports published each month in the JOURNAL. The Mexico Section authorized by the Directors during the previous year was established.

The activity among the Student Branches has been particularly marked during the past year. Many of the colleges have held a larger number of meetings than heretofore as shown in the following table. New Branches were authorized at the Catholic University of America, University of Florida, Rhode Island State College, University of South Dakota, University of Tennessee and University of Utah.

	For Fiscal Year Ending						
	May 1 1918	May 1 1919	May 1 1920	May 1 1921	May 1 1922	May 1 1923	May 1 1924
SECTION							
Number of Sections	34	34	36	42	45	46	47
Number of Section meetings held	245	217	262	303	373	344	381
Total Attendance	34,614	25,837	30,741	37,823	54,378	46,672	58,945
BRANCHES							
Number of Branches	59	61	62	65	67	68	77
Number of Branch meetings held	268	156	360	443	439	503	530
Attendance	10,683	6,441	16,827	21,629	25,358	26,893	25,674

Standards Committee.—The main activities of the Standards Committee throughout the year have been concentrated on the general revision of the Institute Standards, the start of which was reported last year. In brief the Standards Committee can report that the work of revision has been proceeding rapidly and effectively and that in all the subject matter considered a very few points have been encountered in which there is great difficulty in reaching agreement.

The revision involves the separation of the Institute Standards, present and proposed, into a large number of pamphlets dealing with different classes of apparatus, there now being over 40 in the complete list. This involves careful work in the organization of the material so that the subdivisions shall be as useful as possible, to avoid overlapping of scope and to produce uniformity in treatment in the different groups of standards. This work has been carried on very ably by a Working Committee under the direction of Mr. Hobart, which cooperates with the other Working Committees and in most cases has prepared initial drafts for the use of the other committees.

The Standards Committee now has 22 Working Committees with a membership of about 200, not excluding duplications. These committees are working actively on 19 sections of the Institute Standards. Five more Working Committees are in the process of formation. One section of the standards on Industrial Control Apparatus has been approved as Institute Standards by the Committee and is waiting approval by the Directors. Four other sections have been accepted as proposed standards and are in process of publication.

The translation of the 1922 Standards into Spanish, which was undertaken a year ago under the direction of one of the Working Committees has been completed and it is understood that the Department of Commerce will print this translation in the immediate future.

The Institute is now sole sponsor for three projects under the A. E. S. C. procedure, joint sponsor with others for five other projects, and is represented in about twenty other sectional committees.

There has been a continuation of active cooperation with other organizations interested in electrical standardization, both in connection with the revision of the Institute rules and the other matters now before the Standards Committee. There have been conferences looking forward to the united action of these organizations in connection with the adoption as American Standards of many of the standards of the various cooperating organizations. The Board of Directors have instructed the Standards Committee that standards prepared by the Institute should be adopted as Institute standards before being placed under A. E. S. C. procedure, and it is expected that many of the revised sections of the Institute standards when so adopted will, together with similar material which has been adopted by the other organizations, form the basis for cooperation in the preparation of American Electrical Standards.

Closer relations have been brought about during the year with the U. S. National Committee of the International Electrotechnical Commission.

Arrangements have been made with the Meetings and Papers Committee for a session on Standards at the Annual Convention in June.

American Engineering Standards Committee.—The American Engineering Standards Committee is the national clearing house for industrial standardization—a federation of the principal national organizations and governmental departments that are active in such work. It serves as the official channel of cooperation in international standardization activities, and it also serves as a bureau of information on standardization activities both in this country and abroad.

Through its methods and procedure all organizations concerned participate in deciding whether a given piece of work shall be undertaken, in developing the standard, and in recommending its approval. In this way the results of the work of hundreds of bodies are being broadened and unified into a truly national system of standards.

There now exists the most widespread interest and activity in industrial standardization that there has ever been. The Great War and the reconstruction problems arising from it have given an enormous impetus to the movement.

The growth of the work of the American Engineering Standards Committee is indicative of the growth of the movement as a whole. The following statistical summary, giving the figures shown in the A. E. S. C. 1923 and 1924 Year Books, shows the advance which has been made in the work of the Committee:

	1923	1924
Member-Bodies—organizations or groups of organizations whose representatives form the A. E. S. C.	23	23
National organizations included in the Member-Bodies	33	34
Representatives forming the Main Committee	55	57
Standards approved by A. E. S. C.	29	53
Standards up for approval by A. E. S. C.	45	35
Projects having official status (already approved or on which work is under way)	121	152
Projects for which sponsorship has been accepted	76	113
Organizations acting as sponsors for projects	48	57
Trade, technical or governmental bodies cooperating through representatives on special or sectional committees	275	313
Individuals on sectional committees	917	1081

The sustaining-membership plan announced in last year's report has been sufficiently successful to permit considerable increased activities on the part of the American Engineering Standards Committee, one of these being the addition to the staff of an engineer-translator, making possible more satisfactory cooperative work with foreign standardizing bodies. An attempt is made to keep a complete file of foreign standards at the offices of the A. E. S. C., and information in regard to any of these may be obtained by communicating with the Secretary.

Close cooperative work has been maintained with the Federal Specifications Board, whereby the specifications which are being considered by the Board are reviewed by those groups cooperating in A. E. S. C. work which may be interested in the specifications.

During the year certain changes have been made in the procedure of the American Engineering Standards Committee, which permit of more freedom in the acceptance of specifications and the revision of specifications previously approved. This is resulting in the submission of an increased number of engineering specifications for adoption as "American Standards."

U. S. National Committee of I. E. C.—At the meeting of the Council of the International Electrotechnical Commission, held in Paris December 3rd last, Dr. C. O. Mailloux, who had been President of the Commission since 1919 retired, and was succeeded by Mr. Guido Semenza of Milan. Subsequently, in view of his distinguished services with the Commission, Dr. Mailloux was elected Honorary President of the Commission. An election was held also of the other general officers of the Commission. The Commission is represented in this country by the United States National Committee of the International Electrotechnical Commission.

The U. S. National Committee held its first meeting on March 12th. Dr. C. H. Sharp was elected President of the Committee, and immediately thereafter Dr. C. O. Mailloux, its former President, was elected Honorary President of the Committee.

The Institute of Radio Engineers was invited to become affiliated with the U. S. National Committee and appoint delegates to that Committee.

It was announced that meetings would be held in London on July 15th, 16th and 17th of the Advisory Committees on Rating of Electrical Machinery, on Nomenclature and on Graphical Symbols of the I. E. C., and the Executive Council was authorized to nominate delegates to these meetings.

U. S. National Committee International Commission on Illumination.—It was noted in the report of last year that at the plenary meeting of this Commission held in Paris in 1921, it was determined to hold the next plenary meeting of the Commission in the United States in 1924. Consequently, during the earlier part of the year the matter of holding such meeting in this country was the chief topic of discussion of the U. S. National Committee. The matter of the advisability of attempting to hold this meeting in the face of adverse European conditions was gone into very carefully, the advice of prominent English and European members of the Commission being obtained informally as to this point. It had been hoped that conditions would show a sufficient improvement so as to offer a reasonable prospect of carrying out the plan. However, political and economic developments were not of such a character as to justify this hope, and in order that the U. S. National Committee should not be put in the position of obstructing in any way the best interests of the Commission, a resolution was offered and carried at a meeting of the U. S. National Committee held on June 7th, 1923 waiving the right to hold the next plenary meeting in the United States, but expressing the hope that in case the 1924 meeting is not held in the United States the next plenary meeting will be held here.

The U. S. National Committee having thus, for the best interests of the I. C. I., waived its right to hold the meeting in this country, the officers of the I. C. I. determined to fix upon Geneva, Switzerland, as the place for the meeting. This meeting will be held on July 21st to 24th, next. The U. S. National Committee has appointed a committee to take care of the matter of American participation in this meeting. A suitable number of papers have been promised for this purpose and the attendance of a representative delegation from this country seems assured.

Committee on Safety Codes.—The Committee on Safety Codes is made up of representatives of the Institute assigned to cooperate with various standardizing committees in matters relating to different kinds of safety codes. In connection with the revision of the National Electrical Safety Code of the Bureau of Standards, the Institute is represented on the Sectional Committees covering the various subdivisions. Some progress has been made.

The Institute is represented on the Sectional Committee on Safety Codes for Elevators. This committee has partly completed its work.

The Institute is represented on the Sectional Committee for Safety Codes for Floor Openings and Railings. There has been little activity on this committee during the past year.

The Institute is represented on the Sectional Committee to consider electrical regulations in coal mines. The work of this Sectional Committee has been organized and allotted to various subcommittees and is progressing satisfactorily.

The Institute is represented on the Electrical Committee of the National Fire Protection Association. This committee has issued a regular biennial revision of the electrical code during the past year.

Technical Committees.—Reports of Technical Committees embracing an outline of the year's work

and a summary of progress in the industry will be presented at the Annual Convention and printed in the JOURNAL.

Membership.—The results of the Membership Committee's efforts this year are shown in the following table:

	Honorary Member	Fellow	Member	Associate	Total
Membership, April 30, 1923...	6	578	2,264	12,450	15,298
Additions:					
Transferred		20	79		
New Members Qualified		4	96	2,040	
Reinstated		4	9	53	
Deductions:					
Died		6	11	51	
Resigned		5	15	222	
Transferred			14	85	
Dropped		1	49	689	
Membership, April 30, 1924...	6	594	2,359	13,496	16,455

Net increase in Membership during the year 1,157

Deaths.—The following deaths have occured during the year.

Fellows: Robert F. Hayward, Henry St. Clair Putman, William M. Riggs, Charles P. Steinmetz, Arthur G. Webster, Charles Wirt.

Members: Frederick C. Bates, Louis Bell, John A. Britton, J. Stanford Brown, George A. Cellar, Berrywick S. Craig, Ralph E. Gilman, Wallace P. Hurley, Frank E. Kinsman, John Ely Moore, Herman J. Strobel.

Associates: Chester H. Arnold, E. W. Babcock, Otto C. Beck, Joseph A. Brennan, Arthur H. Burnett, Wilfred W. Chandler, Micheal F. D'Andre, Delwyn Dessar, John W. Ellard, William N. Fashbaugh, Frank E. Fielding, M. L. Gilmore, Frank R. Grady, John Grant, John A. Grimmons, George M. Haesler, Yagenda Hayashi, L. W. Hendricks, A. M. Hennefer, Henry J. Herman, John S. Holliday, William Hoopes, Edward J. Hunt, P. N. Jones, William E. Kampf, Mohachi Komatsu, Joseph A. Leahy, A. R. Ledoux, Earle S. Libby, Burton E. Lucas, Arthur Lund, Louis F. Matty, R. H. McKibben, John Mustard, Sam L. Naphtaly, L. L. Phillips, Herbert S. Pope, Louis L. Proctor, Yasuo Riko, Henry C. Russell, Karl E. Schrieber, C. P. Seidler, George A. Speer, Joshua W. Taylor, Chuzaburo Tsukamoto, Clinton H. Turner, Ralph A. Whiteman, Allan H. Whiting, Henry M. Whitney, Henry C. Wilson, Montraville Wood.

Total deaths, 68.

Board of Examiners.—The Board of Examiners during the year held eleven meetings, averaging about two hours and 45 minutes each. It considered and referred to the Board of Directors a total of 4036 applications for admission or transfer to the higher grades. This is very close to last year's figure.

APPLICATIONS FOR ADMISSION

Recommended for grade of Associate......	2137	
Not recommended........................	1	2138
Recommended for grade of Member.......	88	
Not recommended for admission to this grade................................	70	158
Recommended for grade of Fellow.........	2	
Not recommended for admission to this grade................................	5	7
Recommended for enrolment as Students..	1594	1594

APPLICATIONS FOR TRANSFER

Recommended for grade of Member.......	82	
Not recommended for transfer to this grade.	19	101
Recommended for grade of Fellow.........	24	
Not recommended for transfer to this grade.	4	28
Total number of applications considered....		4026

American Committee on Electrolysis.—The American Committee on Electrolysis has been practically inactive during the past year, pending the decision by the various organizations represented on the Committee as to the continuance of the work. Present indications are that the work of the Committee will receive the necessary financial support from these organizations, and that the active work will go forward during the present year.

Scholarships.—The governing bodies of Columbia University have placed at the disposal of the Institute two scholarships in electrical engineering in addition to the one previously granted. In consequence, the Institute is now authorized to award a scholarship each year so that there may be one man in each class holding a scholarship on the nomination of the Institute; these scholarships will continue until further notice. Each scholarship pays $350 toward the annual tuition, and reappointment for completion of course is conditioned upon the maintenance of good standing.

The first scholarship for the academic year 1923-24 was awarded by the Institute to Dudley P. South; this leaves the two other scholarships available for students who plan to graduate from the electrical engineering course in 1926 and 1927 respectively.

Institute Prizes.—At the meeting of the Board of Directors of the Institute of April 16, 1921, recommendations were approved establishing two Institute prizes to be awarded yearly to authors of worthy papers. The prize consists each of $100 in cash with suitable certificate.

"The Transmission Prize for 1922 was awarded R. J. C. Wood for his paper entitled '220-kv. Transmission system, Southern California Edison Company and Some 220-kv. Researches.' Honorable mention should be given H. B. Dwight for his paper entitled 'Electric Characteristics of Transmission Lines.'

"The First-Paper Prize for 1922 was awarded to C. H. Van Asperen for his paper entitled 'Mechanical Forces on Busbars Under Short-Circuit Conditions.' Honorable mention should be given to E. B. Shand for his paper entitled 'An Analytical Investigation of the Causes of Flashing of Synchronous Converters.' "

Edison Medal.—The Edison Medal for 1923 was awarded to John W. Lieb, New York, N. Y., "for the development and operation of electric central stations for illumination and power." The presentation ceremonies took place Monday evening, February 4th, 1924 at the Midwinter Convention, Philadelphia, Pa.

John Fritz Medal.—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical and Electrical Engineers, awarded the 20th medal to Dr. Ambrose Swasey in recognition of his achievements "as a designer and manufacturer of instruments and machines of precision, a builder of great telescopes, a benefactor of education and the founder of Engineering Foundation." The medal was presented at a gathering of engineers at the Engineering Societies Building, New York on the evening of April 23, 1924.

Kelvin Medal Award.—On December 14, 1923 the Committee of Award of the Kelvin Medal Trust named Dr. Elihu Thomson of Swampscott, Mass., as the recipient of the second triennial award. The Trust Fund represents the surplus obtained in connection with a call for subscriptions to erect a memorial window to Lord Kelvin in Westminster Abbey. The award is made by a committee composed of the Presidents of the principal representative British Engineering Institutions, as a mark of distinction to a person who has achieved eminence as an engineer or investigator in the kind of work applicable to the advancement of engineering with which Lord Kelvin was especially identified. The presentation of the medal will take place at the Kelvin Centenary Celebration, London, England on the afternoon of Thursday, July 10, 1924.

The Joseph Henry Bust.—In accordance with the custom of inviting civic, patriotic, scientific and other organizations and individuals to contribute bronze busts of those who have been elected to the Hall of Fame by the Senate of New York University, an invitation was received asking the Institute to act as sponsor in providing a bust of Joseph Henry. The necessary funds were raised by general subscription and by appropriation for the presentation of the bust and the unveiling ceremonies will take place on May 13, 1924

1922 Commission of Washington Award.—The Washington Award for 1922 was voted to Captain Robert W. Hunt and the presentation was made at the annual meeting of the Western Society of Engineers, held June 18, 1923. This 1922 award was made "For preeminent service in promoting the public welfare, for his pioneer work in the development of the steel industry in the United States and for a life devoted to the advancement of the engineering profession."

The award is made annually by a committee composed of nine representatives of the Western Society of Engineers and two each from the A. S. C. E., the A. I. M. E., the A. S. M. E. and the A. I. E. E. The award of the medal was established in 1917 by Past President J. W. Alvord of the Western Society "to be annually presented to an engineer whose work in some special instance, or whose services in general have been noteworthy for their merit in promoting the public good."

Employment Service.—The employment service which the Institute has maintained for many years is now conducted as a cooperative bureau in conjunction with a similar service maintained by the national societies of civil, mining and mechanical engineers under the title "Engineering Societies Employment Service."

The bureau was placed on a cooperative basis September 1, 1923 as the result of a report rendered in March 1923 by a joint committee of four major societies appointed to make a thorough investigation of all factors concerned in the maintenance and operation of an employment service; it having been generally recognized for some time that the scope of the service and its value to the individual member and employer was evidently falling far short of what might be possible under a more comprehensive plan of operation, were larger funds available.

With the committee's report as a basis the Secretaries of the A. I. E. E., A. S. M. E., A. S. C. E. and A. I. M. E., under whose supervision the service is conducted, drew up a plan for the maintenance of the bureau through the joint contributions of the societies and those individual members who are benefited, free service to be continued only to a limited extent principally by the publication from month to month without charge of announcements of available men in the respective journals of the societies concerned. An employment bulletin is issued weekly but only to those regularly registered as available. It is hoped that sufficient surplus funds may become available to permit the extension of the service to other cities, this plan to be continued from year to year until the bureau is on a truly national basis.

American Engineering Council.—During the past year American Engineering Council of the Federated American Engineering Societies has continued to function. The Annual Meeting was held in Washington

on January 11th and 12th, 1923, and was well attended. One of several Constitutional amendments endorsed by the Council at its Annual Meeting and which has since become effective eliminates from the name "Federated American Engineering Societies" so that the organization will be hereafter entitled "American Engineering Council."

One day of the annual session was set aside for considering Federal Government Reorganization by the establishment of a Department of Public Works, and a large number of engineering organizations, many of them not members of American Engineering Council, sent delegates.

During the year the Administrative Board held the following meetings:

January 10th	at Washington,
March 23-24	at Cincinnati,
June 6-7	at St. Paul,
Oct. 12-13	at Rochester.

The Institute has been represented on the Administrative Board, the Executive Committee and on most of the standing and special Committees and the representatives have been diligent in endeavoring to maintain and increase the prestige of the engineering profession through the work of the Council and its Committees, having always in mind the interests of our organization.

It is satisfying to be able to report that a very cordial cooperative attitude towards the Institute has been uniformly manifested by the delegates representing other organizations, and it is undoubtedly a fact that the frequent points of contact afforded by Council's activities have helped to strengthen the pleasant relationships between the Institute and such other organizations.

It is the belief of your representatives that an organization having the functions allocated to American Engineering Council is needed. The detail activities of American Engineering Council have been chronicled from month to month in the Institute JOURNAL.

World Power Conference.—The first World Power Conference will be held in London, June 30 to July 12, 1924. It is to be held at the British Empire Exhibition, Wembly, London, and is promoted by the Council of the British Electrical and Allied Manufacturer's Association, in cooperation with Technical and Scientific Institutions in Great Britain and other countries.

The Conference has been called for the purpose of discussing the technical and economic problems of power development, transmission and utilization and for promoting general interest in power development. It will consider how the industrial and scientific sources of power may be adjusted nationally and internationally.

The A. I. E. E. is officially cooperating in the World Power Conference and is represented on the organizing committee for American participation by three of its members. Several other members will present technical papers. The plan of the Program Committee was to explain the character and extent of American power development from both construction and operation standpoints, and give opportunity for setting forth conditions under which American capital has been able to undertake this development. The sections into which the program has been divided are as follows: Review of power resources; Water power and fuels; Steam and electric power; Industrial phases; Economic phases.

United Engineering Society.—This Society performs for the national societies of Civil, Mining, Mechanical and Electrical Engineers, certain specific acts which are governed by contracts; the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the national societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1924 JOURNAL.

Engineering Societies Library.—The library of the Institute is combined with the libraries of the national societies of Civil, Mining and Mechanical Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches for patent purposes, copying, preparing reference cards, etc. During the year arrangements have been made for a lending department.

An abstract of the annual report of the Engineering Societies Library covering the calendar year 1923 was published in the March 1924 JOURNAL.

Engineering Foundation.—Engineering Foundation is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

The Foundation has made appropriations for various research projects and has cooperated in others.

An abstract of the annual report for the year 1923 was published in the March 1924 JOURNAL.

Representatives.—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee and upon the Apparatus Makers and Users Committee, and the Board of Investigation and Coordination of the Society for the Promotion of Engineering Education. A complete list of representatives is published frequently in the JOURNAL.

Finance Committee.—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows:

Respectfully submitted for the Board of Directors.

F. L. HUTCHINSON, *Secretary.*

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

Pursuant to engagement, we have audited your books and accounts for the year ended April 30, 1924, and submit herewith our certificate and the following described exhibits and schedule:

Exhibit "A"—General Balance Sheet, April 30, 1924.

Schedule No. 1—Reserve Capital Fund—Securities.

Exhibit "B"—Summary of Income and Profit & Loss for the Year ended April 30, 1924.

Yours truly,

HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CERTIFICATE OF AUDIT

We have audited the books and accounts of the American Institute of Electrical Engineers for the year ended April 30, 1924, and

WE HEREBY CERTIFY that the accompanying General Balance Sheet properly exhibits the financial condition of the Institute at April 30, 1924, that the Summary of Income and Profit & Loss for the year ended that date is correct, and that the books of the Institute are in agreement therewith.

HASKINS & SELLS

NEW YORK,
May 12, 1924.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

EXHIBIT A.

GENERAL BALANCE SHEET, APRIL 30, 1924

ASSETS

REAL ESTATE:			
One-Fourth Interest in United Engineering Society's Land, Building, and Building Equipment, 25 to 33 West 39th Street (Depreciation carried on Books of United Engineering Society).			$491,642.36
EQUIPMENT:			
Library—Volumes and Fixtures		$40,477.27	
Works of Art, Paintings, etc		3,001.35	
Office Furniture and Fixtures	$15,949.72		
Less Reserve for Depreciation (including $3,000.00 funded)	11,121.13	4,828.59	
Total Equipment			48,307.21
WORKING ASSETS:			
"Transactions, etc"		$10,451.63	
Paper and Cover Paper		1,577.93	
Badges		2,486.46	
Total Working Assets			14,516.02
CURRENT ASSETS:			
Cash		$21,510.55	
Accounts Receivable:			
Members—For Dues		14,667.22	
Advertisers		2,640.90	
Miscellaneous		789.07	
Accrued Interest on Investments		323.55	
Accrued Interest on Bank Balances		206.48	
Total Current Assets			40,137.77
FUNDS:			
Reserve Capital Fund—Securities—Schedule No. 1.		$44,271.35	
Life Membership Fund:			
Cash	$1,638.67		
Chicago, Burlington & Quincy Railroad Company 4% Bonds, 1958, Par Value $5,000.00	4,868.75		
Accrued Interest	33.33	6,540.75	
International Electrical Congress of St. Louis—Library Fund:			
Cash	$494.03		
New York City 4½% Bonds, 1957, Par Value $2,000.00	2,210.43		
New York Telephone Company 4½% Bond, 1939, Par Value $1,000.00	878.75		
Accrued Interest	67.50	3,650.71	
Mailloux Fund:			
Cash	$5.17		
New York Telephone Company 4½% Bond, 1939, Par Value $1,000.00	1,000.00		
Accrued Interest	22.50	1,027.67	
Midwinter Convention Fund—Cash		149.56	
Depreciation of Furniture and Fixtures Fund—Cash		3,000.00	
Total Funds			58,640.04
Total			$653,243.40

LIABILITIES

CURRENT LIABILITIES:

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Reserve Capital Fund—Securities, April 30, 1924

Exhibit A.

Schedule No. 1.

	Par Value	Book Value
The Detroit Edison Company 1st and Refunding, 6% Series "B", Gold Bonds, due 1940	$5,000.00	$5,190.00
The New York Central Railroad Company Registered, 5%, Refunding and Improvement Mortgage Bonds, due 2013, Series "C"	6,000.00	5,742.50
Chicago, Burlington & Quincy Railroad Company 5%, 1st and Refunding Mortgage, Registered, Gold Bond, Series "A", due 1971	1,000.00	1,010.00
Great Northern Railroad Company 5½%, General Mortgage, Registered, Gold Bonds, Series "B", due 1952	6,000.00	5,827.50
Southern Railway Company 5%, 1st Consolidated Mortgage, Registered, Gold Bond, due 1994	1,000.00	980.00
City of Wilmington, Delaware, 4½% Bonds, due 1934	15,000.00	15,521.35
United States Third Liberty Loan 4¼% Bonds, due 1928	10,000.00	10,000.00
Total	$44,000.00	$44,271.35

Officers A. I. E. E. 1923-1924

PRESIDENT
(Term expires July 31, 1924)
HARRIS J. RYAN

JUNIOR PAST-PRESIDENTS

(Term expires July 31, 1924)
WILLIAM McCLELLAN

(Term expires July 31, 1925)
FRANK B. JEWETT

VICE-PRESIDENTS

(Terms expire July 31, 1924)
W. I. SLICHTER (District No. 3)
R. F. SCHUCHARDT (District No. 5)
H. T. PLUMB (District No. 9)
G. FACCIOLI (District No. 1)
H. W. EALES (District No. 7)

(Terms expire July 31, 1925)
J. E. MACDONALD (District No. 8)
HERBERT S. SANDS (District No. 6)
S.E.M. HENDERSON (District No.10)
H. E. BUSSEY (District No. 4)
WILLIAM F. JAMES (District No. 2)

MANAGERS

(Terms expire July 31, 1924)
HAROLD B. SMITH
JAMES F. LINCOLN
E. B. CRAFT

(Terms expire July 31, 1925)
R. B. WILLIAMSON
A. G. PIERCE
HARLAN A. PRATT

(Terms expire July 31, 1926)
H. M. HOBART
ERNEST LUNN
G. L. KNIGHT

(Terms expire July 31, 1927)
WILLIAM M. McCONAHEY
W. K. VANDERPOEL
H. P. CHARLESWORTH

TREASURER / **SECRETARY**
(Terms expire July 31, 1924)
GEORGE A. HAMILTON / F. L. HUTCHINSON

HONORARY SECRETARY
RALPH W. POPE

GENERAL COUNSEL
PARKER & AARON
30 Broad Street, New York.

PAST-PRESIDENTS—1884-1923

*Norvin Green, 1884-5-6.
*Franklin L. Pope, 1886-7.
*T. Commerford Martin, 1887-8.
Edward Weston, 1888-9.
Elihu Thomson, 1889-90.
*William A. Anthony, 1890-91.
*Alexander Graham Bell, 1891-2.
Frank Julian Sprague, 1892-3.
*Edwin J. Houston, 1893-4-5.
*Louis Duncan, 1895-6-7.
*Francis Bacon Crocker, 1897-8.
A. E. Kennelly, 1898-1900.
Carl Hering, 1900-1.
*Charles P. Steinmetz, 1901-2.
Charles F. Scott, 1902-3.
Bion J. Arnold, 1903-4.
John W. Lieb, 1904-5.
*Schuyler Skaats Wheeler, 1905-6.
*Samuel Sheldon, 1906-7.
*Henry G. Stott, 1907-8.
Louis A. Ferguson, 1908-9.
Lewis B. Stillwell, 1909-10.
Dugald C. Jackson, 1910-11.
Gano Dunn, 1911-12.
Ralph D. Mershon, 1912-13.
C. O. Mailloux, 1913-14.
Paul M. Lincoln, 1914-15.
John J. Carty, 1915-16.
H. W. Buck, 1916-17.
E. W. Rice, Jr., 1917-18.
Comfort A. Adams, 1918-19.
Calvert Townley, 1919-20.
A. W. Berresford, 1920-21.
William McClellan, 1921-22.
Frank B. Jewett, 1922-23.

*Deceased

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
Carroll M. Mauseau, Caixa Postal No. 571, Rio de Janeiro, Brazil, S. A.
Charles le Maistre, 28 Victoria St., London, S. W., England.
A. S. Garfield, 45 Bd. Beausejour, Paris 16 E, France.
H. P. Gibbs, Tata Sons Ltd., Navsari Building, Fort Bombay, India.
Guido Semenza, 39 Via Monte Napoleone, Milan, Italy.
Eiji Aoyagi, Kyoto Imperial University, Kyoto, Japan.
Lawrence Birks, Public Works Department, Wellington, New Zealand.
Axel F. Enstrom, 24a Grefturegatan, Stockholm, Sweden.
W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

A. I. E. E. Committees

GENERAL STANDING COMMITTEES

EXECUTIVE COMMITTEE

Harris J. Ryan, Chairman, Stanford University, Calif.
Frank B. Jewett, Vice-Chairman
E. B. Craft, G. L. Knight, William McClellan, George A. Hamilton, W. I. Slichter.

FINANCE COMMITTEE

G. L. Knight, Chairman, 360 Pearl Street, Brooklyn, N. Y.
W. I. Slichter, W. K. Vanderpoel.

MEETINGS AND PAPERS COMMITTEE

L. W. W. Morrow, Chairman, *Electrical World*, 10th Ave. & 36th St., New York, N. Y.
E. E. F. Creighton, E. B. Meyer, John Mills, J. E. Macdonald, D. W. Roper.
Chairman of Committee on Coordination of Institute Activities.
Chairmen of Technical Committees.
Chairmen of Sections.

PUBLICATION COMMITTEE

Donald McNicol, Chairman, 132 Union Road, Roselle Park, N. J.
F. L. Hutchinson, E. B. Meyer, L. W. W. Morrow, L. F. Morehouse.

COMMITTEE ON COORDINATION OF INSTITUTE ACTIVITIES

W. I. Slichter, Chairman, Columbia University, New York, N. Y.
F. L. Hutchinson, G. L. Knight, L. W. W. Morrow, Donald McNicol,

BOARD OF EXAMINERS

H. H. Norris, 211 Lorraine Avenue, Upper Montclair, N. J.
E. H. Everit, G. L. Knight, J. H. Morecroft, F. M. Farmer, F. V. Magalhaes, N. L. Pollard, Erich Hausmann, Donald McNicol,

SECTIONS COMMITTEE

A. W. Berresford, Chairman, 303 Hotel Astor, Milwaukee, Wis.
C. E. Magnusson, Vice-Chairman.
H. H. Henline, Herbert S. Sands, Harold B. Smith.
Chairmen of all Sections.

COMMITTEE ON STUDENT BRANCHES

C. E. Magnusson, Chairman, University of Washington, Seattle, Wash.
F. S. Dellenbaugh, Jr., C. Francis Harding, Harold B. Smith, Charles F. Scott,

MEMBERSHIP COMMITTEE

M. E. Skinner, Chairman, Duquesne Light Co., Pittsburgh, Pa.
C. E. Baker, C. E. Fleager, H. T. Plumb, E. E. Dorting, S. E. M. Henderson, J. F. Warwick, John M. Drabelle, G. A. Kositzky, J. L. Woodress, H. A. Lynette,
Chairmen of local membership committees.

HEADQUARTERS COMMITTEE

E. B. Craft, Chairman, 463 West Street, New York, N. Y.
F. L. Hutchinson, G. L. Knight.

LAW COMMITTEE

H. H. Barnes, Jr., Chairman, General Electric Co., 120 Broadway, New York, N. Y.
G. E. Folk, P. Junkersfeld, Charles A. Terry, R. F. Schuchardt,

PUBLIC POLICY COMMITTEE

H. W. Buck, Chairman, 49 Wall Street, New York, N. Y.
A. W. Berresford, F. B. Jewett, William McClellan, Gano Dunn, John W. Lieb, Calvert Townley.

COMMITTEE ON CODE OF PRINCIPLES OF PROFESSIONAL CONDUCT

John W. Lieb, Chairman, 124 E. 15th Street, New York, N. Y.
Comfort A. Adams, G. Faccioli, H. S. Wynkoop, A. H. Babcock, George F. Sever, C. E. Skinner.

SAFETY CODES COMMITTEE

H. B. Gear, Chairman, 72 West Adams St., Chicago, Ill.
H. H. Cochrane, M. G. Lloyd, R. W. E. Moore, E. E. F. Creighton, Ernest Lunn, H. R. Sargent, W. B. Hartshorne, Wills Maclachlan, H. S. Warren. L. C. Ilsley, Alexander Marks,

STANDARDS COMMITTEE

Executive Committee

H. S. Osborne, Chairman, A. T. & T. Co., 195 Broadway, New York City, N.Y.
H. E. Farrer, Secretary, 33 W. 39th St., New York, N. Y.
W. A. Del Mar, A. M. MacCutcheon, F. L. Rhodes, H. M. Hobart, J. Franklin Meyer, L. T. Robinson, G. L. Knight, F. D. Newbury, Clayton H. Sharp, Harold Pender, C. E. Skinner.

Ex-Officio

Chairmen of Working Committees of Standards Committee.
Chairmen of A. I. E. E. delegations on other standardizing bodies.

EDISON MEDAL COMMITTEE

Appointed by the President for term of five years

(Term expires July 31, 1924)
E. D. Adams, Chairman, H. H. Barnes, Jr., B. G. Lamme.
(Term expires July 31, 1925)
H. M. Byllesby, D. E. Drake, W. L. R. Emmet.
(Term expires July 31, 1926)
B. A. Behrend, John H. Finney, C. S. Ruffner.
(Term expires July 31, 1927)
Gano Dunn, F. A. Scheffler, W. R. Whitney.
(Term expires July 31, 1928)
C. C. Chesney, Robert A. Millikan, M. I. Pupin.

Elected by the Board of Directors from its own membership for term of two years.

(Term expires July 31, 1924)
E. B. Craft, G. Faccioli, William McClellan.
(Term expires July 31, 1925)
H. M. Hobart, Frank B. Jewett, W. K. Vanderpoel.

Ex-Officio

Harris J. Ryan, President, George A. Hamilton, Treasurer, F. L. Hutchinson, Secretary

SPECIAL COMMITTEES

COLUMBIA UNIVERSITY SCHOLARSHIP

Francis Blossom, Chairman, 52 William Street, New York, N. Y.
F. B. Jewett, W. I. Slichter.

AWARD OF INSTITUTE PRIZES

L. W. W. Morrow, Chairman, *Electrical World*, 10th Ave. & 36th Street, New York, N. Y.
F. G. Baum, Donald McNicol

TECHNICAL COMMITTEES

EDUCATIONAL

W. E. Wickenden, Chairman, Room 1607, 33 W. 39th Street, New York, N. Y.
W. C. Bauer, P. M. Lincoln, Harold B. Smith,
Edward Bennett, C. E. Magnusson, W. L. Upson,
C. R. Dooley, G. H. Pfeif, John B. Whitehead,
Charles S. Howe, H. W. Price, William R. Work.
Charles F. Scott,

ELECTRICAL MACHINERY

H. M. Hobart, Chairman, General Electric Co., Schenectady, N. Y.
B. L. Barns, W. J. Foster, H. P. Liversidge,
B. A. Behrend, V. A. Fynn, A. S. McAllister,
R. E. Brown, David Hall, F. D. Newbury,
James Burke, H. U. Hart, R. F. Schuchardt,
N. A. Carle, P. M. Lincoln, Philip Torchio,
G. Faccioli, R. B. Williamson.

ELECTROCHEMISTRY AND ELECTROMETALLURGY

J. L. Yardley, Chairman, Westinghouse E. & M. Co., East Pittsburgh, Pa.
Carl Hering, H. T. Plumb, G. W. Vinal,
J. A. Johnson, J. A. Seede, C. D. Woodward.

ELECTROPHYSICS

F. W. Peek, Jr., Chairman, General Electric Co., Pittsfield, Mass.
E. F. Burton, Charles Fortescue, Chester W. Rice,
L. W. Chubb, Roy S. Glasgow, F. B. Silsbee,
J. C. Clark, Robert A. Millikan, Harold B. Smith,
William Fondiller, J. H. Morecroft, J. B. Whitehead.

INDUSTRIAL AND DOMESTIC POWER

H. D. James, Chairman, Westinghouse E. & M. Co., East Pittsburgh, Pa.
P. H. Adams, S. F. Davies, H. W. Rogers,
H. E. Bussey, C. W. Drake, George Smith.
T. D. Montgomery,

INSTRUMENTS AND MEASUREMENTS

G. A. Sawin, Chairman, Westinghouse E. & M. Co., East Pittsburgh, Pa.
P. A. Borden, E. D. Doyle, F. V. Magalhaes,
H. B. Brooks, A. L. Ellis, Irving B. Smith,
G. L. Crosby, H. Brightwell Johnson, H. S. Vassar,
F. P. Cox, Paul MacGahan, Roy Wilkins.
William M. McConahey,

IRON AND STEEL INDUSTRY

F. B. Crosby, Chairman, Morgan Construction Co., 15 Belmont St., Worcester, Mass.
E. Gordon Fox, E. S. Jefferies, G. E. Stoltz,
Eugene Friedlaender, D. M. Petty, J. D. Wright.
A. G. Pierce,

LIGHTING AND ILLUMINATION

G. H. Stickney, Chairman, Edison Lamp Works, G. E. Co., Harrison, N. J.
J. M. Bryant, F. F. Fowle, P. S. Millar,
W. Devereux, G. C. Hall, Charles F. Scott,
H. W. Eales, C. A. B. Halvorson, Jr., B.E. Shackelford,
F. M. Feiker, H. H. Higbie, W. M. Skiff.
A. S. McAllister,

MARINE

G. A. Pierce, Chairman, Wm. Cramp & Sons S. & E. B. Co., Philadelphia, Pa.
L. C. Brooks, Secretary, Bethlehem Shipbuilding Corp., Quincy, Mass.
R. A. Beekman, H. Franklin Harvey, Jr., W. F. Meschenmoser,
J. F. Clinton, William Hetherington, Jr. I. H. Osborne
Maxwell W. Day, H. L. Hibbard, H. M. Southgate,
E. G. Gallagher, William F. James, W. E. Thau,
C. S. Gillette, M. A. Libbey, A. E. Waller.
C. S. McDowell,

MINES

F. L. Stone, Chairman, General Electric Co., Schenectady, N. Y.
R. T. Andrae, H. W. Eales, D. C. McKeehan,
C. N. Beebe, L. C. Ilsley, W. F. Schwedes,
M. C. Benedict, G. M. Kennedy, W. A. Thomas,
Graham Bright, R. L. Kingsland, C. D. Woodward.
A. B. Kiser,

POWER STATIONS

Nicholas Stahl, Chairman, Naragansett Electric Lighting Co., Turks Head Building, Providence, R. I.
H. A. Barre, C. F. Hirshfeld, I. E. Moultrop,
J. T. Barron, R. B. Howland, C. P. Osborne,
E. T. Brandon, J. P. Jollyman, A. L. Penniman, Jr.,
H. W. Eales, H. A. Kidder, F. A. Scheffler,
F. C. Hanker, W. H. Lawrence, R. F. Schuchardt,
John Harisberger, H. P. Liversidge, R. B. Williamson.
D. C. McClure,

PROTECTIVE DEVICES

H. R. Woodrow, Chairman, 360 Pearl Street, Brooklyn, N. Y.
G. H. Bragg, E. A. Hester, F. E. Ricketts,
P. H. Chase, F. L. Hunt, D. W. Roper,
L. B. Chubbuck, B. G. Jamieson, C. H. Sanderson,
W. S. Edsall, M. G. Lloyd, E. R. Stauffacher,
Clarence T. Evans, A. A. Meyer, E. C. Stone,
F. C. Hanker, W. H. Millan, A. H. Sweetnam,
S. E. M. Henderson, J. M. Oliver, John B. Taylor.
N. L. Pollard,

RESEARCH COMMITTEE

John B. Whitehead, Chairman, Johns Hopkins University, Baltimore, Md.
Edward Bennett, C. I. Hall, L. F. Morehouse,
E. H. Colpitts, L. A. Hawkins, Harold Pender,
E. E. F. Creighton, V. Karapetoff, G. W. Pierce,
F. S. Dellenbaugh, A. E. Kennelly, Clayton H. Sharp,
W. A. Del Mar, M. G. Lloyd, C. E. Skinner,
W. P. Dobson, R. W. Sorensen.

TELEGRAPHY AND TELEPHONY

O. B. Blackwell, Chairman, A. T. & T. Co., 195 Broadway, New York, N. Y.
F. L. Baer, D. H. Gage, Chester W. Rice,
H. P. Charlesworth, P. J. Howe, J. K. Roosevelt,
L. W. Chubb, F. H. Kroger, Edgar Russel,
E. H. Colpitts, N. M. Lash, H. A. Shepard,
R. N. Conwell, Ray H. Manson, I. J. Thorp,
C. E. Davies, G. W. McRae, F. A. Wolff,
H. W. Drake, R. D. Parker, C. A. Wright.
L. F. Fuller, F. A. Raymond,

TRACTION AND TRANSPORTATION

N. W. Storer, Chairman, Westinghouse E. & M. Co., East Pittsburgh, Pa.
George Gibbs, H. A. Johnson, W. S. Murray,
Dugald C. Jackson, W. B. Potter.

TRANSMISSION AND DISTRIBUTION

F. G. Baum, Chairman, Hobart Building, San Francisco, Calif.
R. W. Atkinson, L. M. Klauber, G. G. Post,
M. O. Bolser, C. H. Kraft, C. C. Robinson,
Wallace S. Clark, W. S. Lee, D. W. Roper,
W. H. Cole, W. M. McConahey, C. E. Schwenger,
R. N. Conwell, E. B. Meyer, Carroll H. Shaw,
W. A. Del Mar, G. J. Newton, Arthur Simon,
L . L. Elden, F. W. Peek, Jr., W. K. Vanderpoel,
F. M. Farmer, A. M. Perry, C. T. Wilkinson,
J. P. Jollyman, R. J. C. Wood.

A. I. E. E. Representatives

ON AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE COUNCIL

A. E. Kennelly, John B. Taylor.

ON AMERICAN BUREAU OF WELDING

H. M. Hobart.

ON AMERICAN COMMITTEE ON ELECTROLYSIS

B. J. Arnold, N. A. Carle, F. N. Waterman.

ON AMERICAN ENGINEERING COUNCIL

Comfort A. Adams, *Frank B. Jewett, Charles F. Scott,
C. G. Adsit, William McClellan, *C. E. Skinner,
H. W. Eales, *L. F. Morehouse, L. B. Stillwell,
*John H. Finney, E. W. Rice, Jr., Calvert Townley,
F. L. Hutchinson, R. B. Williamson.
*D. C. Jackson,

*Members of Administrative Board.

ON AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, H. S. Osborne, C. E. Skinner.
L. T. Robinson (Alternate)

ON APPARATUS MAKERS AND USERS COMMITTEE

C. E. Skinner.

ON BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

H. H. Barnes, Jr., Bancroft Gherardi, H. A. Lardner.

ON CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND COMMITTEE

Harris J. Ryan

ON ENGINEERING FOUNDATION BOARD

Frank B. Jewett, L. B. Stillwell.

ON JOHN FRITZ MEDAL BOARD OF AWARD

A. W. Berresford, William McClellan, Harris J. Ryan,
Frank B. Jewett.

ON JOINT CONFERENCE COMMITTEE OF FOUNDER SOCIETIES

The Presidents and Secretaries, *Ex Officio.*

ON LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, F. L. Hutchinson, W. I. Slichter.
E. B. Craft, Alfred W. Kiddle,

ON NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

The Chairman of the Institute's Committee on Safety Codes.

ON NATIONAL FIRE WASTE COUNCIL

John H. Finney, H. B. Gear.

ON NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

C. A. Adams, Bancroft Gherardi, A. E. Kennelly.
F. L. Hutchinson, *Ex Officio*

ON SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION BOARD OF INVESTIGATION AND COORDINATION

Gano Dunn, Frank B. Jewett.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

ON WASHINGTON AWARD, COMMISSION OF

John Price Jackson, Charles F. Scott.

ON WORLD'S CONGRESS OF ENGINEERS, PHILADELPHIA 1926. BOARD OF MANAGEMENT

Paul M. Lincoln, C. E. Skinner.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

Clayton H. Sharp, President, 556 E. 80th St., New York, N. Y.
[6]S. G. Rhodes, Secretary, 124 E. 15th St., New York, N. Y.

C. A. Adams,	H. W. Fisher,	F. D. Newbury,
P. G. Agnew,	[4]Com. C. S. Gillette,	H. S. Osborne,
[8]C. A. Bates,	[6]Gen. G. H. Harries,	L. T. Robinson,
George K. Burgess,	H. M. Hobart,	D. W. Roper,
[1]James Burke,	D. C. Jackson,	Harris J. Ryan,

Seattle	C. A. Lund	J. Hellenthal
Southern Virginia	Wm. C. Bell	Harold C. Leonard
Spokane	E. R. Hannibal	James S. McNair
Springfield, Mass.	J. M. Newton	J. Frank Murray
Syracuse	R. D. Whitney	Walter C. Pearce
Toledo	Gilbert Southern	Max Neuber
Toronto	C. E. Schwenger	D. B. Fleming
Urbana	E. B. Paine	Charles T. Knipp
Utah	C. R. Higson	Hiram W. Clark
Vancouver	F. W. MacNeill	A. Vilstrup
Washington, D. C.	L. M. Evans	A. F. E. Horn
Worcester	L. E. Pierce	Stuart M. Anson
Total 47		

LIST OF BRANCHES

Name and Location	Chairman	Secretary
Alabama Poly. Inst., Auburn, Ala.	R. C. Dickerson	L. R. Housel
Alabama, Univ. of, University, Ala.	C. S. Carlton	W. F. Graham
Arizona, Univ. of, Tucson, Ariz.	Roy Osborne	Edward Moyle
Arkansas, Univ. of, Fayetteville, Ark.	J. A. Cunningham	C. E. Bowman
Armour Inst. of Tech., Chicago, Ill.	D. E. Richardson	J. S. Farrell
Brooklyn Poly. Inst., Brooklyn, N. Y.	H. B. Hanstein	J. E. Loerch
Bucknell Univ., Lewisburg, Pa.	E. S. Hopler	A. L. Huffman
California Inst. of Tech., Pasadena	R. O. Elmore	M. L. Beeson
California, Univ. of, Berkeley, Calif.	S. W. Scarfe	F. E. Hurt
Carnegie Inst. of Tech., Pittsburgh, Pa.	W. J. Lyman	R. A. Garbett
Case School of Applied Science, Cleveland, O.	H. P. Davis	George Geyser

LIST OF BRANCHES (*Continued*)

Name and Location	Chairman	Secretary
Catholic Univ. of America, Washington, D. C.	C. G. Kirby	J. W. Dolan
Cincinnati, Univ. of, Cincinnati, O.	J. F. Morrissey	C. B. Hoffmann
Clarkson Coll. of Tech., Potsdam, N.Y.	L. L. Merrill	E. T. Augustine
Clemson Agri. College, Clemson College, S. C.	R. W. Pugh	O. A. Roberts
Colorado State Agri. Coll., Ft. Collins	Frank Ayres	Lyndall Hands
Colorado, Univ. of, Boulder, Colo.	M. B. Inman	C. V. Roberts
Cooper Union, New York	E. J. Kennedy	A. W. Carlson
Denver, Univ. of, Denver, Colo.	C. G. Diller	Ray Hoover
Drexel Institute, Philadelphia, Pa.	H. Shelley	D. L. Michelson
Florida, Univ. of, Gainesville, Fla.	J. R. Benton	Geo. Harrison
Georgia School of Tech., Atlanta, Ga.	R. A. Goodburn	J. A. Minor
Iowa State College, Ames, Iowa	A. Paone	R. E. Paxton
Iowa, Univ. of, Iowa City, Iowa	G. C. K. Johnson	C. A. Von Hoene
Kansas State College, Manhattan	V. O. Clements	W. K. Lockhart
Kansas, Univ. of, Lawrence, Kans.	H. A. Hudson	R. M. Ryan
Kentucky, Univ. of, Lexington, Ky.	K. R. Smith	J. D. Taggart
Lafayette College, Easton, Pa.	Wm. Welsh	J. B. Powell
Lehigh Univ., S. Bethlehem, Pa.	E. W. Baker	D. C. Luce
Lewis Institute, Chicago, Ill.	E. Millison	C. P. Meek
Maine, Univ. of, Orono, Me.	H. L. Kelley	H. E. Bragg
Marquette Univ., Milwaukee, Wis.	E. O. Triggs	N. W. Hoffman
Massachusetts Inst. of Tech., Cambridge, Mass.	G. P. Davis	F. J. Hecht, Jr.
Michigan Agri. Coll., East Lansing	S. N. Galbraith	V. O. Bernthal
Michigan, Univ. of, Ann Arbor, Mich.	K. Y. Tang	K. W. Richards
Milwaukee, Engg. School of, Milwaukee, Wis.	I. L. Illing	A. U. Stearns
Minnesota, Univ. of, Minneapolis	L. McLeland	Fred Kapple
Missouri, Univ. of, Columbia, Mo.	M. P. Weinbach	
Montana State Coll., Bozeman, Mont.	Jack Cowan	J. A. Thaler
Nebraska, Univ. of, Lincoln, Neb.	O. J. Ferguson	O. E. Edison
Nevada, Univ. of, Reno, Nev.	Robert Plaus	G. Fowble
North Carolina State College, Raleigh, N. C.	A. C. Bangs	J. C. Richert, Jr.
North Carolina, Univ. of, Chapel Hill	L. P. Brown	H.C.Klingenschmitt
North Dakota, Univ. of, University	S. J. Nogosek	T. E. Lee
Northeastern Univ., Boston, Mass.	L. F. Hubby	E. G. Crockett
Notre Dame, Univ. of, Notre Dame, Ind.	Frank Egan	K. Faiver
Ohio Northern Univ., Ada, Ohio	Arthur Upp	A. D. Beck
Ohio State Univ., Columbus, O.	L. S. C. Neeb	J. M. Comly
Oklahoma A. & M. Coll., Stillwater	F. C. Todd	R. W. Twidwell
Oklahoma, Univ. of, Norman, Okla.	R. B. Greene	M. F. Hill
Oregon Agri. Coll., Corvallis, Ore	M. P. Bailey	E. E. Bricker
Pennsylvania State College, State College, Pa.	H. O. Alexander	Leon Lentz, Jr.
Pennsylvania, Univ. of, Philadeplhia	G. V. Cresson	O. Ortlieb
Pittsburgh, Univ. of, Pittsburgh, Pa.	G. H. Campbell	F. Wills
Purdue Univ., Lafayette, Ind.	E. T. Obenchain	L. R. Bridge
Rensselaer Poly. Inst., Troy, N. Y.	F. M. Sebast	B. R. Chamberlain
Rhode Island State Coll. Kingston, R.I.	M. Chappell	C. S. North
Rose Poly. Inst., Terre Haute. Ind.	P. Wilkens	R. A. Reddie
Rutgers Coll., New Brunswick, N. J.	E. G. Riley	E. J. Butler
Southern California, Univ. of, Los Angeles, Calif.	H. A. McCarter	Chet Little
Stanford Univ., Stanford University, Calif.	M. L. Wiedmann	G. R. Stray
Swarthmore Coll., Swarthmore, Pa.	A. L. Williams	S. R. Keare
Syracuse Univ., Syracuse, N. Y.	E. J. Agnew	J. G. Hummel
Tennessee, Univ. of, Knoxville, Tenn.	E. Eubanks	W. T. Elliott
Texas A. & M. Coll., College Station	H. C. Hultgren	A. A. Ward
Texas, Univ. of, Austin, Tex.	G. C. Hengy	W. K. Sonnemann
Utah, Univ. of, Salt Lake City, Utah	I. J. Kaar	M. B. McCullough
Virginia Military Inst., Lexington	J. M. Yates	J. B. Lacy, Jr.
Virginia Poly. Inst., Blacksburg, Va.	F. L. McClung	E. M. Melton
Virginia, Univ. of, University, Va.	T. S. Martin, Jr.	J. W. McNair
Washington, State Coll. of, Pullman	J. Dunkin	J. T. Yasumura
Washington, Univ. of, St. Louis, Mo.	H. Spoehrer	C. M. Dunn
Washington, Univ. of, Seattle, Wash.	M. MacEwell	E. T. Naden
West Virginia Univ., Morgantown	O. A. Brown	James Copley
Wisconsin, Univ. of, Madison, Wis.	H. G. Holmes	K. E. Wooldridge
Yale Univ., New Haven, Conn.	W. C. Downing, Jr.	O. B. Skinner
Total 76		

SUBJECT INDEX

PAPERS, DISCUSSIONS AND REPORTS

Subject Classification

ACOUSTICS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS AFFAIRS

See also Professional, Standardization, Technical Committee Reports

BATTERIES

See Electrochemistry

CABLES

CENTRAL STATION SYSTEMS

See also Hydroelectric Power Stations

CIRCUIT BREAKERS AND SWITCHES

COMMUNICATION

See Telephone, Telegraph and Radio Phenomena

COMMUTATION

See Generators, Direct Current and Motors, Alternating and Direct Current

CONDENSERS

CONDUCTORS

See Electric Circuit Theory

CONTROL DEVICES

See also Industrial Applications of Power, Motors

CONVERSION METHODS AND EQUIPMENT

See also Substations

CORONA

See also Dielectric Phenomena

DIELECTRIC PHENOMENA

See also Corona

DISTRIBUTION

See also Substations, Transmission Lines

EDUCATION

ELECTRIC CIRCUIT THEORY

See also Induction, Power Factor, Transients, Wave Form

ELECTROCHEMISTRY

ELECTROPHYSICS

ELEVATORS

See Control Devices

FURNACES AND ELECTRIC HEATING

GENERATORS, ALTERNATING CURRENT

See also Losses and Efficiency, Regulation, Temperature in Apparatus, Wave Form

GENERATORS, DIRECT CURRENT

See also Losses and Efficiency, Regulation, Temperature in Apparatus

METALLURGICAL APPLICATIONS

MINING APPLICATIONS

MOTORS, ALTERNATING CURRENT

See also Control Devices, Industrial Applications of Power Losses and Efficiency Measurements, Transients

MOTORS, DIRECT CURRENT

See also Control Devices, Industrial Applications of Power, Losses and Efficiency Measurements, Transients

OUTDOOR INSTALLATIONS

See Substations

POWER STATIONS

See also Central Station Systems, Hydroelectric, Power Factor, Prime Movers

PROTECTIVE DEVICES

See also Grounded Neutral, Lightning, Reactors

RADIO PHENOMENA

REACTORS

See also Protective Devices

RESEARCH

ROLLING MILL DRIVE

STANDARDIZATION

STARTING CURRENTS

See Transients

SUBSTATIONS

SWITCHES

See Circuit Breakers
